The behavior of any physical system is determined in part by its symmetry properties. For the geodynamo this means the geometry of a spinning sphere and the symmetry properties of the equations of magnetohydrodynamics. Solutions have symmetry that is the same as, or lower than, the symmetry of the governing equations and boundary conditions. By "symmetry" here we mean a transformation T that takes the system into itself. Given one solution with lower symmetry, we can construct a second solution by applying the transformation T to it. Solutions with different symmetry can evolve independently and are said to be separable. If the governing equations are linear separable solutions are also linearly independent: they may be combined to form a more general solution. If the governing equations are nonlinear they may not be combined or coexist but they remain separable. The full geodynamo (q.v.) problem is nonlinear and separable solutions exist; fluid velocities and magnetic fields with the same symmetry are linearly independent solutions of the linear kinematic dynamo (q.v.) problem.

Symmetry considerations are important for both theory and observation. For example, solutions with high symmetry are easier to compute than those with lower symmetry and are often chosen for that reason. Time-dependent behavior of nonlinear systems (geomagnetic reversals for example) may be analyzed in terms of one separable solution becoming unstable to one with different symmetry ("symmetry breaking"). Observational applications include detection of symmetries in the geomagnetic field. The axial dipole field has very high symmetry but is not a separable solution of the geodynamo; it does, however, belong to a separable solution with a particular symmetry about the equator. Paleomagnetic data rarely have sufficient global coverage to allow a proper assessment of the spatial pattern of the geomagnetic field, but they can sometimes be used to discriminate between separable solutions with different symmetries.

The sphere is symmetric under any rotation about its centre while rotation is symmetric under any rotation about the spin axis. The symmetries of the spinning sphere are therefore any rotation about the spin axis and reflection in the equatorial plane (Figure G15). This conflict of spherical and cylindrical geometry lies at the heart of many of the properties of rotating convection and the geodynamo. The equations of *magnetohydrodynamics* (q,v.) are also invariant under rotation. They are invariant under change of sign of magnetic field B (but not other dependent variables) because the induction equation is linear in B and the magnetic force and ohmic heating are quadratic in B. They are also invariant under time translation.

**Figure G15** Reflection of a rotating sphere in a plane parallel to the equator. A', B' are the reflections of the points A, B. The reflected sphere turns in the same direction as the original sphere. A vector is equatorial-symmetric ( $E^{S}$ ) if its value at C' appears as a reflection as shown: it is  $E^{A}$  if it appears with a change of sign.

The group of symmetry operations is Abelian because of the infinite number of allowed rotations about the spin axis and time translations. The full set of symmetry operations is found by constructing the group table and using the closure property. The group table, including rotation of  $\pi$  about the spin axis but no higher rotations, is shown in Table G6. Note the additional symmetry operations *O*; these are combinations of reflection in the equatorial plane and rotation about the spin axis; they amount to reflection through the origin. Note also the subgroups formed by (I,i) and  $(I,i,E^S,E^A)$ . These are fundamental to some analyses of paleomagnetic data. Arbitrary time translation can be applied to any symmetry to produce steady solutions that are invariant under translation, drifting solutions that are steady in a corotating frame, more complicated time-periodic solutions that may vascillate or have reversing magnetic fields, and solutions that change continually and are sometimes loosely called "chaotic."

A word is needed about the behavior of vectors under reflection. A vector is usually defined by its transformation law under rotation. An axial or pseudovector (or tensor) changes sign on reflection whereas a polar or true vector (or tensor) does not. A true scalar is invariant under reflection, a pseudoscalar changes sign. Examples of true vectors are fluid velocity and electric current. Examples of axial vectors are angular velocity and magnetic field. The cross product changes sign under reflection (to see this consider the simple case of the cross product of two polar vectors); the curl also changes sign under reflection. Vectors v satisfying  $\nabla \cdot v = 0$  are often represented in terms of their toroidal and poloidal parts:

$$v = \nabla \times Tr + \nabla \times \nabla \times Pr;$$

if the toroidal part is a true vector the poloidal part will be a pseudovector and vice versa because of the extra curl involved. Helicity,  $v \cdot \nabla \times v$ , is a pseudoscalar because vorticity changes sign under reflection but velocity does not. Properties of true and pseudovectors are used to determine the symmetry of individual terms in the governing equations and to find separable solutions.

The symmetry of solutions is reflected in their spherical harmonic expansions. Potential fields with  $E^A$  symmetry involve only harmonics  $Y_1^m$  with l - m odd;  $E^S$  fields have l - m even. The symmetries are usually referred to as "dipole" and "quadrupole" families because of their leading terms  $Y_1^0$  (dipole) and  $Y_2^0$  (quadrupole). The terminology is somewhat unsatisfactory for two reasons: first, the equatorial dipole  $Y_1^1$  is a member of the quadrupole family, and second the internal, toroidal, field of each family has the opposite series to that of the external, poloidal, field. Fields with  $P_2^S$  symmetry have spherical harmonic series with m even,  $P_2^A$  have m odd. Solutions with higher symmetry have series containing m differing by larger integers, for example  $P_4^S$  has m multiples of 4.

The main use of symmetry properties in theoretical studies has so far been restricted to reducing the complexity of the solution in order to effect numerical solutions. For example, allowing only a "dipole family," or  $E^{S}$ , solution halves the number of spherical harmonics required to represent the solution (or, equivalently, the solution only need be found in one hemisphere);  $P_2^S$  halves it again. In practice solutions with high symmetry may be poor dynamos and be more difficult to compute, despite their apparent lack of spatial complexity, because they require strong driving and involve small-scale magnetic fields. The existence of a separable solution is no guarantee of maintaining a magnetic field: B may still decay to zero. Thus axial symmetry is an allowed symmetry but Cowling's theorem (q.v.) shows that no axisymmetric magnetic field can be sustained by dynamo action. Kinematic dynamos (q.v.) with axisymmetric fluid velocities have axisymmetric solutions that decay by Cowling's theorem, but solutions with lower symmetry, each proportional to  $expim\phi$ , can grow with time. They do not form separable solutions of the full, dynamical, dynamo problem because nonlinear terms in the equations couple the modes to include many values of m. Bullard and Gellman (1954) investigated an  $E^{S}P_{2}^{S}$  flow that also possessed a meridional plane of symmetry, again to reduce the computational effort required for the very small, early computer at their disposal. This last symmetry is not an allowed separable solution of the full dynamo problem. The lack of helicity imposed by this symmetry was later found to be the reason for the failure of the Bullard-Gellman dynamo (q.v.).

The future may see further studies of dynamo behavior making more use of symmetries. For example, reversals may be understood in terms of the "dipole"  $E^A$  solution becoming unstable to a "quadrupole"  $E^S$  or an oscillatory solution. It was once suggested that reversals

may involve only the observed poloidal field, the larger internal toroidal field retaining the same polarity, but this is unlikely because it violates the symmetry properties of the solution.

Symmetry properties have received more attention in observational studies, particularly with paleomagnetic data (see Geomagnetic field, asymmetries). The basic observation is that of an  $E^A$  field, the dipole, but equatorial symmetry appears to go beyond that of the dipole: the main concentrations of magnetic field on the core-mantle boundary form four lobes, two in the northern hemisphere and two in the southern hemisphere, on closely similar longitudes (see Plate 10c). This basic pattern is close to  $P_2^S$  symmetry, but a nonaxisymmetric pattern would only be of interest if it were long term. With homogeneous boundary conditions we would expect the solution to drift without reference to any longitude, averaging to axial symmetry. This has been assumed in many studies in the past; departures from axial symmetry would imply an effect of inhomogeneity on the boundary, such as variable heat flux from the core (see Core-mantle coupling, thermal). The lower mantle seismic velocities suggest a  $P_2^S$  pattern associated with subduction around the Pacific rim, which could favor  $P_2^S$  magnetic fields.

Further discussion of the theory is in Gubbins and Zhang (1993) and of the data analysis in Merrill *et al.* (1996).

# GEOMAGNETIC DEEP SOUNDING

Geomagnetic deep sounding (GDS) is the use of electromagnetic induction methods to determine the electrical conductivity within the Earth, working from observations of natural geomagnetic variations. It is differentiated from the *magnetotelluric method* (q.v.) in employing only the magnetic, and not the electric field. The term GDS is applied both to global and to regional studies. The aim of global investigations is to determine the variation of electrical conductivity with depth. That of regional studies is to map lateral differences in the conductivity of the crust and upper mantle. The book by Rokityansky (1982) covers all aspects of the subject. Weaver (1994) gives a detailed account of the theory.

# Sounding the earth using natural geomagnetic variations

A slowly varying magnetic field inside a uniform conductor (conductivity  $\sigma$  and relative magnetic permeability  $\mu$ ) satisfies the induction equation:

$$\nabla^2 \mathbf{B} = \mu \mu_0 \sigma \frac{\partial \mathbf{B}}{\partial t}$$

The time-varying field induces eddy currents in the conductor which flow so as to exclude the field from the deeper parts. The amplitude of a spatially uniform field of frequency  $\omega$  falls to 1/e of its surface value at the "skin-depth":

$$z_0 = \sqrt{2/\omega\mu\mu_0\sigma}.$$

This expression provides a rough guide to the "sounding depth" which might be expected of a particular frequency. However, the geometry of the external source also restricts the depth or volume sampled by the field. When induction effects are negligible, a field with spatial wavelength  $\lambda$  falls to 1/e of its surface value at depth  $\lambda/2\pi$ . The basis of the sounding method is to measure the Earth response at a range of frequencies and/or source wavelengths. If the response of a one-dimensional earth is known precisely either at all frequencies or all spatial scales, the radial variation of conductivity is uniquely defined.

## The geomagnetic variation spectrum

The frequency range of the externally generated electromagnetic spectrum (Figure G16) is extremely wide. The longest periods available are associated with the solar cycle (11 or 22 years), and penetrate into the lower mantle. Unfortunately, they are difficult to separate from the purely internal variations with periods longer than 3 years generated by the secular behavior of the dynamo. Much of the spectrum between 2 years and 2 days period comes from fluctuations in the total energy of particles in the radiation belts, which drift in the geomagnetic field, creating the *ring current* (q.v.). Because the current is located between 3 and 5 Earth radii, the field it creates at the Earth is relatively uniform, and its spatial structure can be represented by a small number of zonal spherical harmonics (q.v.), of which the first (n = 1) is much the most important. Variations with this structure include the semiannual line, the quasiperiodic harmonics at 27, 13.5, 9 days, etc., driven by the Sun's rotation and the persistence both of solar sources and sector structure in the solar wind, and the continuum. The annual variation, however, has a distinct spatial structure that is antisymmetric about the equator, suggesting a seasonal driving force.

The daily variation and its harmonics are created by dynamo action in the ionosphere, where thermal and gravitational tides move plasma through the magnetic field. Their spatial structure can be adequately

represented by spherical harmonics up to degree n = 4. The continuum from a few days to a few minutes period originates in the current systems produced by geomagnetic storms. Their spatial structure is complex, and in the auroral regions is localized as electrojets in the ionosphere, and field-aligned currents connecting with the outer magnetosphere. Micropulsations are vibrations of geomagnetic field lines, while Schumann resonances are oscillations of the Earth-ionosphere waveguide excited by large-scale thunderstorm activity.

## GDS—the global problem

Only magnetic observatories provide the record lengths required for global sounding to depths of hundreds of kilometers. Because of their poor distribution and insufficient numbers, only the smoother fields are defined adequately. Temporary arrays of magnetometers are deployed to map the more complex fields, and, in the absence of conductivity anomalies, the field gradients can be used for local soundings.

The determination of the vertical variation of conductivity is conveniently divided into two steps. The first is the measurement of the response or *transfer function* (*q.v.*) which links the input—the external part of the magnetic field—to the output—the internal part created by the induced currents. The second is the inversion of the response for the conductivity—discovering what can be inferred about  $\sigma(r)$  from the response and its associated errors.

#### Definition and determination of the response function

In global GDS, *spherical harmonic functions* (q.v.) are commonly used to define the spatial structure of the field. The response  $Q_n^m(\omega)$  is the ratio of the internal and external parts of the field at frequency  $\omega$  for a spherical harmonic component of degree *n* and order *m*. An alternative is the *C* response:

$$C = \frac{B_r}{\partial \mathbf{B}_r / \partial r}$$

The radial gradient of the vertical field is replaced by the horizontal gradients of the horizontal components using the condition div B = 0. For plane earth geometry, and a smooth external field,

$$C = \frac{B_z}{\partial \mathbf{B}_x / \partial x + \partial B_y / \partial y}$$

The *C* response has been favored in recent investigations because of its intercomparability between global and local studies, and physical significance as a penetration scale (its dimension is length).

The magnetic observatory network is inadequate for determining all but the largest scale spatial structures. Instead of a full spherical harmonic analysis, a simple spherical harmonic model is usually adopted, based on what is known of the source. For periods between 2 years and 2 days, a single zonal harmonic has been used, with the advantage that the response can be computed from vertical (*Z*) and horizontal (*H*) component records at a single observatory. The total potential of internal (*g*<sub>i</sub>) and external (*g*<sub>e</sub>) sources for a spherical harmonic degree n = 1 and order m = 0, is

$$\Omega = \frac{a}{\mu_0} \left\{ g_i \frac{a^2}{r^2} + g_e \frac{r}{a} \right\} \cos \theta$$

The corresponding components of the magnetic induction are

$$Z = -B_r(r = a) = \{-2g_i + g_e\}\cos\theta$$
$$H = -B_\theta(r = a) = -\{g_i + g_e\}\sin\theta$$

The ratio of the vertical and horizontal components of the field, multiplied by  $\tan \theta$ , is itself a response  $(W_1^0)$ , which can be computed from the component records by standard response estimation techniques:

$$W_1^0 = \frac{Z}{H} \tan \theta = \frac{\{1 - 2Q_1^0\}}{-\{1 + Q_1^0\}}$$

The major factors limiting the precision of response estimates are the inadequacy of the source model and the influence of lateral variations in conductivity. Attempts to incorporate these effects into response determination and modeling are hampered by the limitations of the observatory network.

#### Determination of the conductivity

The second step is the transformation of the electromagnetic response data into a conductivity model. In the *forward modeling approach* (q.v.), a conductivity distribution is selected either on the basis of independent geophysical constraints, or for mathematical convenience. Its response is computed and compared with the observations, and the model parameters adjusted until a satisfactory fit is achieved. In the *inverse modeling method* (q.v.), parameters which define the structure are determined directly from the data. In practice, the two approaches are more alike than at first appears. The class of structure, which is to be the target of an inversion must be selected, and preferences about the smoothness of models incorporated. A preliminary exploration of simple models, for which the relationship between data and structure is well understood, is always worthwhile.

Consider a model in which a perfectly conducting "core," radius r = Ra, is surrounded by an insulating shell. The  $Q_1^0$  response (to excitation by ring current-generated fields) can be interpreted using the spherical harmonic model to downward continue the field. The radial component of the field in *any* source-free region is:

$$B_r = -\left\{g_i \frac{-2a^3}{r^3} + g_e\right\} \cos\theta,$$

and it must be zero at the surface of the perfect conductor. If  $B_r = 0$  at r = Ra,

$$Q_1^0 = g_i/g_e = R^3/2$$

At 27 days period, the value of  $Q_1^0$  is 0.3, which implies R = 0.84, corresponding to a depth of 1000 km. This is a strong indication that the conductivity rises steeply in the upper mantle.

# The global electromagnetic response and global conductivity distribution

The earliest determinations of the global response are summarized by Chapman and Bartels (1940). Schuster, Chapman, Price, and Lahiri used the daily variation and time-domain analyses of magnetic storms. Conductivity models were restricted to those with analytical solutions-a uniform core surrounded by a uniform insulator, and a power law increase. With the arrival of the digital computer, Fourier transform-based spectral analysis methods were introduced (Currie, 1966). The response could be determined at a continuous range of frequencies, and it was possible to calculate the theoretical response of arbitrary models (Banks, 1969). Recognition of the problems posed by source complexity and lateral variations in conductivity led to more robust response estimation and regionalization of the models (see Constable, 1993). Weidelt and Parker (see Parker, 1983) clarified the inverse problem and demonstrated that the best-fitting model for any set of data was a set of thin conducting sheets. They also showed how to construct more realistic models, which would, however, fit the

**Figure G17** Representative electrical conductivity models. LP, Lahiri and Price model d; B, Banks; C, Constable; O, Olsen.

data less well. Constable applied their techniques to collated response data. Olsen (1998, 1999) further refined both the response and models for the European area.

There was early recognition of a steep rise in conductivity in the 400–800 km depth range to a value of  $2 \text{ Sm}^{-1}$  (Figure G17). Later work has made only minor differences. The major factors inhibiting improvement are the inadequacy of the source model and the influence of lateral variations in conductivity. Attempts to incorporate these effects into response determination and modeling (Schultz and Zhang, 1994) are hampered by the nature of the observatory network. *Satellite observations* may be one route to future progress.

## GDS—mapping lateral variations in conductivity

#### Conductivity anomalies and their response

Outside the auroral zones, the externally generated part of the timevarying magnetic field is uniform over hundreds of kilometers. If the electrical conductivity were similarly uniform, the induced currents would double the horizontal component of the external magnetic field but cancel the vertical component. Such a conductivity structure, and the fields associated with it, are referred to as "normal." What additional "anomalous" fields are created when a region of different conductivity—a conductivity "anomaly"—is embedded within the normal structure?

The anomaly's response depends on how its characteristic size (*L*) relates to the length scale of the normal field, and with a uniform field what matters is its skin-depth  $z_0$ , which increases with period. When  $z_0 \ll L$  (at high frequencies), the characteristics of the induced currents are controlled by the local structure. When  $z_0 \gg L$  (at low frequencies), they are determined by the host body. The pattern of the "normal" induced currents is modified by electric charges set up on the boundaries of the anomaly. A dipolar current system is created which enhances (a conductive anomaly) or opposes (a resistive anomaly) the normal current flow, but which is in phase with it.

Considered as an input/output problem, the input is the normal, spatially uniform horizontal field; the output is the anomalous magnetic field. This is either the entire measured vertical component (since the normal vertical field is zero), or the difference between the local and normal horizontal fields. The output is the sum of the response to two independent inputs—orthogonal directions of the normal horizontal field:

$$B_{z}(\omega) = Z_{zx}(\omega)B_{x}^{n}(\omega) + Z_{zy}(\omega)B_{y}^{n}(\omega),$$

where  $B_z$  is the vertical field at frequency  $\omega$  at a site influenced by the anomaly, and  $B_x^n$ ,  $B_y^n$  the north and east components at a normal site.

In practice, recordings at a single site are often used, and the vertical field related to the horizontal field  $(B_x, B_y)$  at the same site:

$$B_z(\omega) = T_{zx}(\omega)B_x(\omega) + T_{zy}(\omega)B_y(\omega).$$

Z and T are complex quantities, reflecting the phase shifts between the anomalous currents and the normal fields.

## Magnetic variation mapping experiments

An ideal magnetic variation (MV) mapping experiment requires a large array of simultaneously recording magnetometers, spaced sufficiently closely as to avoid aliasing the structure, with at least one instrument at a normal site. Between 1965 and 1985, arrays of up to 50 magnetometers were constructed and deployed (Gough, 1989). They provided valuable initial information on the conductivity structure of the crust and upper mantle in North America, East and Southern Africa, Australia, India, and Europe. However, their limitations were soon clear. Even relatively low frequencies were affected by structures in the upper crust, so spacings less than 10 km were required, limiting the coverage. The analog recording method limited the frequency response and volume of data which could be interpreted. In particular, sampling at 0.1 to 1 Hz for a few weeks restricted the response to the range for which scattering by crustal anomalies was the dominant process. Later experiments with broader-band digital recording were restricted to a small number of instruments, and were forced to revert to the transfer function techniques described above.

The first task in interpretation is to determine the spatial pattern of conductivity without actually modeling the response. With small numbers of irregularly distributed magnetometers, a useful technique is to plot *induction arrows* (q.v.). For the T response, the vector is plotted with lengths in the north and east directions proportional to  $T_{zx}$  and  $T_{zv}$ , respectively. Near two-dimensional bodies, the arrows point toward or away from the structure. Arrows are harder to interpret when the structure is three-dimensional. Once the responses at a network of sites have been determined, the defining equations can be used to predict the spatial pattern of the vertical fields for a selected horizontal field-the "hypothetical event." However, the T response includes the effect of local anomalous horizontal fields, so the predicted vertical field anomalies do not correspond to induction by a uniform horizontal field. Banks (1986) devised a method of determining the Z transfer functions from the spatial variation of T, together with the constraint that the field derives from a potential that satisfies the Laplace equation. Egbert (2002) reviews methods of organizing and displaying MV array data. These include the further step of inverting the MV data for a map of the conductance in a thin sheet. The final step is to apply forward and inverse modeling techniques (q.v.) to combined MV and MT responses. The latter provide the vital constraints on absolute conductivity values.

#### General remarks

GDS was the most popular natural source electromagnetic method between 1950 and 1980. The magnetotelluric method was viewed with some suspicion because of the limitations of technology (difficulties in measuring electric fields, the need for high capacity data storage facilities, infield processing to evaluate data quality, etc.—all this came along after 1980 with microprocessor technology), lack of understanding of the effects of very local distortion on the electric field, and inability to compute the electromagnetic fields associated with twoand three-dimensional structures. But it had the huge advantage that measurements at a single site had the potential to define both the vertical and horizontal structure. With the advent of more powerful computing facilities, MT took over from GDS, which was then somewhat ignored. Now there is a realization that measuring and analyzing both electric and magnetic fields adds enormously to the information that can be derived.

# **GEOMAGNETIC DIPOLE FIELD**

A long thin bar magnet gives a magnetic field, the lines of force of which (in the usual sign convention) leave the magnet near its north magnetic pole, and reenter near its south magnetic pole. If we think of the magnet being physically reduced in size, but keeping the same magnetic moment (see below), then in the limit of infinitesimal size we have, what we call, a dipole field.

Near the Earth, its magnetic field resembles that of a magnetic dipole situated at the geocenter; formally, if we represent the field as a series of spherical harmonics (see *Harmonics, spherical*), then the field given by the n = 1, dipole, terms dominates. (Note that these are the fields of *fictitious* dipoles; the real source is electric currents

distributed throughout the core.) For many purposes it is adequate to approximate the geomagnetic field as that of a dipole; however, there are several possible definitions of such an approximating dipole.

When averaged over thousands of years, the field is very nearly that of a central axial dipole; i.e., the dipole is at the center of the Earth, and directed along the geographical axis, the spin axis. (This alignment is almost certainly due to the very strong influence the Earth's rotation has on the motions in the liquid core which produce the electric currents—see *Geodynamo*.) At present, the dipole points from north to south (in the sense that the north pole of the fictitious magnet is nearer the south geographic pole), but the direction has reversed many times during geological time (see *Geomagnetic polarity reversals, observations*). This axial dipole corresponds to the coefficient  $g_1^0$  in a spherical harmonic analysis.

Physically, an axial dipole field is produced by a suitable axially symmetric distribution of electric currents, and its magnitude (or strength), called the dipole moment, is given in units of  $Am^2$  (current multiplied by "area turns"); at present its value is about  $8 \times 10^{22} A m^2$ , a value probably rather larger than its average over the last  $10^9$  y (see *Dipole moment variations*). For the geomagnetic axial dipole, the north-to-south horizontal magnetic field on the equator at radius *r* is given by

 $B = (\mu_0/4\pi r^3)$  (Dipole moment).

The spherical harmonic Gauss coefficient  $g_1^0$  gives this value for the Earth's surface, r = a, and at present it is about -30000 nT; the negative sign is there because the field is actually directed south-to-north.

But while on average the dipole is axial, at any one time the bestfitting dipole is usually inclined to the spin axis, by an angle of about  $10^{\circ}$ . A general central dipole can be resolved into three orthogonal components: one along the spin axis (corresponding to the Gauss coefficient  $g_1^0$ ), plus two in the equatorial plane—one  $(g_1^1)$  in the direction of zero longitude (the Greenwich meridian), and the other  $(h_1^1)$  in the direction of 90° longitude. The total dipole is called the inclined dipole, and its axis is called the geomagnetic axis; for phenomena (such as the ionosphere) which are controlled by the geometry of the geomagnetic field, it is often convenient to work in a coordinate system which is based on this geomagnetic axis, rather than on the geographic axis.

While this dipole field dominates, the remaining *nondipole field* (q.v.) is still significant. This nondipole field corresponds to all the n > 1 terms in a spherical harmonic analysis, and at the Earth's surface is typically about 25% that of the dipole field. (At the core-mantle boundary the nondipole field is larger than the dipole field, as its smaller scale fields increase downward more rapidly than the large-scale dipole field.) (See *Harmonics, spherical* and *Geomagnetic spectrum, spatial.*)

Several other planets of the solar system, and many other astronomical bodies, have dipole-like magnetic fields. For a given body, and at a given time, the magnitude and orientation of the dipole are unique. In fact the magnitude and direction of the vector dipole moment are invariant; whatever coordinate system we choose to measure from, we will always get the same dipole moment, i.e., magnitude and direction in space.

The (central) inclined dipole is a reasonable approximation to the observed field. However, if we move the position of this inclined dipole away from the center this introduces three more parameters, so it is possible to get a slightly better fit to the observed field; the displacement reduces the magnitude of what we have called the nondipole field. Conventionally, such a fit is not made to the whole of the nondipole field, but only to the n = 2, quadrupole, part of it; while keeping the moment and direction of the inclined dipole constant, the dipole is moved away from the geocenter in such a direction, and by such an amount, as to minimize (in a least-squares sense) the quadrupole field as seen from the displaced origin. Such a displaced dipole is called the eccentric dipole. It should be noted that (like the

other dipoles) it is a simply a convenient mathematical fiction, but using it can be a useful arithmetic simplification in, for example, the study of the deflection of cosmic rays. At present the displacement is about 550 km, toward Japan; the displacement is increasing with time, because the dipole field is reducing in magnitude compared with the quadrupole field.

Various authors have suggested other definitions for the "best-fit" dipole (see Lowes, 1994), but those discussed above are the ones currently used.

# GEOMAGNETIC EXCURSION

Records of the Earth's magnetic field have shown that on occasions it has reversed its (see geomagnetic polarity reversals). Intervals during which the field is predominantly of the same polarity (>1 Ma) have been called chrons. Occasionally within a chron, the magnetic field reverses its polarity for a short time (<0.1 Ma)-these have been called subchrons. The last major change in the Earth's magnetic field occurred ~0.78 Ma ago, when it changed from a predominantly reversed regime (the Matuyama Chron) to its present predominantly normal regime (the Brunhes Chron). A number of cases have also been found when the magnetic field has departed for an even shorter time from its usual nearaxial configuration, without establishing, and perhaps not even instantaneously approaching, a reversed direction. Such events have been called excursions (see Figure G18). They have been arbitrarily defined as cases where the colatitude,  $\theta$ , of the virtual geomagnetic pole is greater than 45°. This definition distinguishes excursions from the geomagnetic secular variation (q.v.) when  $\theta$  is less than 45°.

Excursions have been observed in lava flows of various ages in different parts of the world and from deep-sea and lake sediments. A controversial question is whether excursions are worldwide events. This is difficult to decide since the duration of an excursion is short and so accurate dating is essential. It has been achieved for some excursions (e.g., the Laschamp  $\sim$ 45 ka), but in many cases it is still unresolved. The difficulty is further compounded by another controversial issue—does the secular variation, which varies across the world, also reverse its polarity during a reversal.

Measurement of the intensity of the magnetic field at the Earth's surface gives the total field which includes the *nondipole field*, *ND* (q.v.). Unfortunately it is not possible to estimate the contribution of the ND field to the observed value. Excursions are accompanied by a reduction in the strength of the field, perhaps to as much as a tenth of its value. It has been suggested that in such cases, the ND field could dominate over a large portion of the globe, so that local reversals of the field could occur.

In some cases it has been observed that one or more excursions have occurred prior to a major polarity change. Quidelleur *et al.* (2002) found an excursion in lava flows about 40 ka before the Mayuyama/Brunhes transition that correlated with minima observed

**Figure G18** Inclination versus age profile for the paleomagnetically valid section at Hole 480 from 5 to 62 ka (5–49 m subbottom). in the intensity of the field in high-resolution deep-sea records before this transition. The number of subchrons and excursions found in the Brunhes and Matuyama Chrons has increased in the last 4 years (Figure G19). Lund *et al.* (1998) reported 14 such events in the Brunhes Chron. Merrill and McFadden (1994) questioned such a large number of polarity changes, since it would imply that the reversed polarity state was substantially less stable than the normal state during the Brunhes Chron, whereas the dynamo equations show that the two polarities must be statistically the same.

Singer *et al.* (1999) later identified new short-lived polarity events between 1.18 and 0.78 Ma and suggested that during this period of the Matuyama reversed chron there were at least 7, and perhaps more than 11, attempts by the geodynamo to reverse, implying that the geodynamo was equally unstable in this part of the Matuyama Chron as it was in the Brunhes Chron. This was confirmed by Channell *et al.* (2002) who reported four subchrons and seven excursions in the Matuyama Chron.

The large number of subchrons and excursions in the Brunhes and Matuyama Chrons raises a number of unanswered questions on the stability of the Earth's magnetic field. One problem is the lack of reversals observed over geologic time—the oldest known reversal occurred  $\sim$ 3500 Ma ago. There is fair coverage for the last 1 Ma, but comparatively few records older than  $\sim$ 2 Ma. Thus, any conclusions reached about the behavior of the field during the last 2 Ma may not be true for earlier times. Another problem is dating—we cannot give accurate ages for events that last only a few thousand years or less. Possible explanations for excursions are that they are simply the

**Figure G19** Geomagnetic instability timescale (GITS) for the Brunhes Chron (proposed events which require further verification are labeled with italic letters). Black corresponds to normal polarity and white to reverse polarity. (After Knudsen *et al.*, 2003.)

expression of large amplitude changes in the secular variation, that they are aborted attempts to reverse, or that they are the result of chaotic behavior in the nonlinear system of equations that govern the magnetic field.

An interesting further question is what is the distinction, if any, between excursions and reversals. A possible explanation for this has been given by Gubbins (1999) who suggested that the Earth's inner core (IC) could stabilize the magnetic field. The IC is solid and changes in the field can only take place by electrical diffusion. On the other hand, changes in the field in the outer core (OC) can take place much faster since they result from convection in the OC which is fluid. Gubbins proposed that excursions arise when a field reversal takes place in the OC, but not in the IC. A full reversal only occurs when the field reversal in the OC persists long enough for the field in the IC to change polarity as well. If Gubbins' explanation is correct, then excursions would be global. It is also consistent with the approximate ratio of excursions to reversals observed in the Brunhes and Matuyama Chrons.

Geomagnetic Polarity Reversals Geomagnetic Secular Variation Nondipole Field

# **GEOMAGNETIC FIELD, ASYMMETRIES**

The geomagnetic field is produced by dynamo action within the molten iron in the outer core. This is a dynamic process intimately linked to cooling of the core and the rapid spin of the Earth. The very nature of the generative process means that the field is never static but constantly changing, a change referred to as secular variation. Hence, at any given time, there will be asymmetries in the detail of the field. Furthermore, in 1934, Cowling showed that a steady poloidal magnetic field (the part of the Earth's field that we see is a poloidal field) with an axis of symmetry cannot be maintained by motion symmetrical about that axis. This means that at any given time, the magnetic field cannot be symmetric about the rotation axis unless the field is decaying.

The situation is quite different when the field at each point is averaged over a sufficiently long period of time that the statistical variations of the process are averaged out. The resulting field is known as the time-average field and, given a symmetric Earth with symmetric properties, we would expect this time-average field also to be symmetric. Indeed, a fundamental assumption used in paleomagnetic studies is that the time-average field is that of a geocentric axial dipole. Although an asymmetry in the Earth would not necessarily lead to an asymmetry in the magnetic field, we expect that any asymmetry in the time-average geomagnetic field would be a consequence of an asymmetry in the Earth. Hence, asymmetries in the time-average geomagnetic field or in the time-average secular variation are of interest because of the potential to provide information about asymmetries deep within the Earth. Some aspects of the dynamo process are sensitive to boundary conditions and so any asymmetry is likely to be a consequence of asymmetry in the boundary conditions on the core. Hence, the lowermost 150-200 km of the lower mantle, commonly referred to as the D" layer, probably has the greatest potential to influence dynamo behavior and produce asymmetries. This is a thermal chemical boundary layer that exhibits lateral variation in its structure and composition; analyses of the time-average magnetic field, of the polarity chronology, of magnetic field reversal paths, and of secular variation have all been used to examine the impact of these lateral variations on the magnetic field.

# How much time is required to obtain a time-average field?

The magnetic field of internal origin varies on timescales from less than a day to more than  $10^8$  years. Variations with characteristic times less than a year are screened out by the semiconducting mantle; the very long characteristic times are associated with changes in the rate of magnetic reversals. Most dynamo theorists are of the view that the characteristic times of dynamo processes are less than  $10^6$  years, and so the changes in the rate of magnetic reversals are usually attributed to changes in boundary conditions of the outer core.

It is well recognized that under ideal conditions an interval of at least 10<sup>4</sup> years is needed to obtain a reasonable estimate of the timeaverage field. This reflects the characteristic times of geodynamo processes and shows that our record of direct observations is woefully short to provide a reasonable estimate of the time-average field. Furthermore, because the magnetic field occasionally experiences excursions with duration around 10<sup>4</sup> years, much longer times (more like  $1 \times 10^6 - 5 \times 10^6$  y) are typically required to obtain a proper time-average field. Consequently it is necessary to appeal to paleomagnetic observations in order to estimate the time-average field. This then brings with it the problems of inadequate and inaccurate recording by the rocks and nonuniform distributions in space and time of the observations. Errors in plate (continent) reconstruction associated with global tectonics can interfere with magnetic field reconstruction when time intervals of order 10<sup>7</sup> y or longer are used and there is potential for the boundary conditions to have changed on these longer time frames. Hence, it is difficult to determine the best time interval to use to estimate the time-average field. Although paleomagnetists involved in tectonic studies often use shorter time spans, most investigators examining the time-average magnetic field properties use a time span around  $5 \times 10^6$  y.

The issue is then further complicated by the fact that, on occasion, the geomagnetic field reverses its polarity, the two states being referred to as normal (the present state) and reverse polarity. In the past few million years the average reversal rate has been around 4 to 5 reversals per million years and so the field may well have changed polarity several times during an appropriate averaging interval. If fields of opposite polarity are simply averaged then the result is likely to be close to zero and quite unrepresentative of the actual field. In order to avoid this, the normal and reverse polarity results are either treated separately or combined by reversing the sign of the reverse polarity data. We do not know enough about reverse polarity fields to know if it is actually correct to combine them in this way with normal polarity fields. For example, if only the dipole component changes sign during a reversal then simply reversing the sign of the reverse polarity data will invert all of the nondipole field when in fact that should not be done. This is unlikely to produce a false asymmetry in the analysis but there is a minor possibility that it could incorrectly average out a real asymmetry.

## Secular variation asymmetry

In the early 1930s, it was noted that the historical rates of secular variation in the Pacific region were anomalously low. In the 1970s, extensive paleomagnetic investigations of Brunhes-age lava flows from around the world including, especially, data from the Hawaiian Islands, showed that the local dispersion of paleodirections of the magnetic field were anomalously low for Hawaii. This was interpreted as being strong evidence for subdued secular variation in the central Pacific for the past 0.7 Ma, indicating that this was a feature of the time-average field and not just the historical field. The evidence seemed reasonably robust because Hawaii was the most extensively sampled region at that time. Several mechanisms have been suggested, generally invoking lateral or radial inhomogeneity in D'' that suppresses the generation, beneath the Pacific, of nondipole fluctuations. This was interpreted as meaning that the observed variations came from the dipole field, leading to this region being referred to as the *Pacific dipole window* or the Pacific nondipole low.

The claimed low from paleomagnetic evidence has not been sustained by subsequent analyses using much larger data sets. Its origin seems to reflect inadequate time-averaging that occurred because basalt flows in Hawaii typically erupt in clusters. Examination in the 1990s of historical data found an intense focus of the nondipole field in the north Pacific in the 17th century, suggesting that the mere absence of nondipole field and its secular variation in the Pacific is only a recent and therefore transient phenomenon. Nevertheless, Constable and Johnson (1999) proposed there still is evidence for some longitudinal asymmetry in the paleomagnetically estimated secular variation. If these results are confirmed by more data and subsequent analyses, it would indicate an asymmetry that is evidenced in the secular variation data but not in the mean field data.

## **Polarity asymmetries**

Over the years, there have been studies that have concluded that the normal and reverse polarity fields differ in respects other than a simple change of sign. The questions to be addressed are: is there a bias toward one or other of the polarities; do the two polarity states have the same stability; and is the intensity of the field the same for the two polarity states?

The equations governing the geodynamo are complex and nonlinear, making it extraordinarily difficult to obtain a solution. However, the equations are even in **H**, the magnetic field. That is, the equations are insensitive to the sign of **H**, and so if **H** is a solution then so also is  $-\mathbf{H}$ . Hence it is to be expected that the two polarities would have the same statistical properties and any asymmetry would have to be a consequence of some boundary condition.

## Polarity bias

Over the years an enormous amount of effort has been put in to determine a reliable chronology for reversals as far back as possible. Such a chronology is now quite well determined for the past 170 Ma from analyses of marine magnetic anomalies. As the reversal timescale developed it became clear that the character of the reversal pattern has changed markedly with time. The most obvious change occurred about 118 Ma ago, when the field apparently locked in to a normal polarity state and remained that way for the next 35 Ma, after which reversals again occurred. Similarly, during the late Paleozoic the field was locked in to a single polarity. This phenomenon of long intervals of time with a single polarity (known as superchrons) has been interpreted as the field exhibiting a clear preference for one polarity state over the other and has been referred to as *polarity bias*. It is interesting to note that during the late Paleozoic this apparent bias was for reverse polarity but during the Cretaceous it was for normal polarity, suggesting that the (interpreted) bias has been a function of time. This perceived polarity bias was attributed to boundary conditions imposed by the D" layer. Improved data and a better understanding of the reversal process suggest a more simple interpretation. The process producing reversals was evolving in such a way that the reversal rate gradually decreased from about 165 Ma until at about 118 Ma the rate became zero. At that stage, the field was locked in to whatever polarity it had at the time. Some time later the evolution of the process changed and at about 83 Ma reversals again started occurring, the rate gradually increasing from then until the present. Hence, superchrons represent a time when the reversal process ceased rather than representing a time of preference for one polarity state over the other. As such, they do not represent an asymmetry.

## Relative stabilities of the two polarity states

Excluding superchrons, when the reversal process was in abeyance, the intervals of time between reversals may be modeled as a gamma distribution. This distribution depends on two parameters: the rate at which the reversals occur; and a parameter k that describes the shape of the distribution. If the gamma parameter, k, equals 1 then the process is the simple Poisson process and the occurrence of an event (reversal) has no impact on the probability of a future event; the process has no memory. For k > 1 the probability of a future reversal drops to zero as soon as a reversal occurs and then gradually recovers to its undisturbed value. Thus, the process has a memory of the previous event and this memory temporarily depresses the probability of occurrence of future events. Hence, the parameter k can be interpreted in terms of the stability of the field (against a further reversal) immediately after a reversal. Early studies suggested that k is different for the two polarities, indicating that the relative stabilities of the polarity states are different. A concern with these early studies was that the sense of this asymmetry was sensitive to minor details in the polarity chronology. A major problem is that it is easy to miss a short interval in the polarity record, and this has major consequences for interpretation. Consider the situation if a short reverse interval is missed. The three-interval polarity segment normal-reverse-normal appears as a single-interval-normal polarity segment: the three original intervals have been incorrectly concatenated into a single interval. It is simple to show that if three intervals are drawn at random from a Poisson distribution (k = 1) and concatenated into a single interval, then the result is the same as drawing a random interval from a gamma distribution with k = 3. Hence, when short intervals are missed it erroneously increases the estimated value of k, and this was not appreciated in the early studies. With this in mind, and with improved data, it is now apparent that the data are consistent with the two polarities having the same value of k. Indeed, for the reversal process, k is close to 1 and so the process is nearly Poisson, if not actually Poisson.

## Intensity of the field

Reliable determination of the paleointensity of the geomagnetic field is notoriously difficult. Consequently, conclusions based on paleointensities are generally less robust than those based on paleodirections or on the reversal chronology. Nevertheless, paleointensities are an important source of information. During the 1980s several studies indicated that there were minor but statistically significant differences in the distributions of paleointensity for the normal and reverse polarity fields. However, none of these observations was robust and each suffered from structural problems such as dependence on one or two extreme values or poor spatial distribution of observations. Further work has not supported these apparent differences and there now seems no reason to reject the simple view that the two polarity states have a common time-average paleointensity.

## Structure of the normal and reverse polarity fields

By far the most common way to analyze the geomagnetic field is through the use of spherical harmonics. The lower-degree harmonics are probably best known by the terms dipole (degree 2), quadrupole (degree 3), and octupole (degree 4). Zonal harmonics are harmonics that are symmetrical about the spin axis and dominate the structure of the time-average field. In the late 1970s and into the 1980s, analyses of data from the past 5 Ma indicated that the structure of the timeaverage reverse polarity field has been discernibly different from that of the time-average normal polarity field. Specifically, it appeared that the time-average reverse polarity field had a proportionately larger quadrupole and octupole content than the time-average normal polarity field. However, there were (and remain) significant problems with the data. The data came primarily from lava flows on continents and islands and from deep-sea sedimentary cores, which generally provided only values of the paleomagnetic inclination. The spatial distribution of the data is poor, particularly in the southern hemisphere, and the data are poorly distributed in time. Also, rock magnetic and other effects can produce spurious estimates of odd-degree harmonics, particularly the octupole term. Later work has shown that these early conclusions were not robust and were mainly due to data artifacts.

#### Polarity transition asymmetry

Our understanding of the structure of the field during transition from one polarity to the other is, at best, rudimentary. Despite the fact that the field at the Earth's surface is unlikely to be dominantly dipolar during a transition, it is standard practice to use the field direction to calculate the position on the Earth's surface where the pole would be if the field were dipolar. This is referred to as a virtual geomagnetic pole, or VGP. In the absence of a dominant dipolar field structure it would be expected that, for a single reversal transition, the VGP transition path would be quite different for observations taken from different locations. Of particular interest here is the fact that in the absence of a persistent asymmetry in the Earth, there should be no consistency in the VGP transition paths from one reversal transition to another.

Several investigators have noted the existence of apparently preferred VGP polarity transition paths, both within individual transitions and persisting across several different transitions. Indeed, there is also some suggestion of similar preferential paths in VGP movement as a consequence of normal secular variation. There are also proponents for periods of VGP stasis during transitions with preferred positions for the clustering of VGPs. Appeals have been made to the existence of persistent regions of relatively high electrical conductivity in D", anomalous regions of heat flux through D", or topography at the core-mantle boundary to influence the dynamo behavior and produce these preferred paths. Conversely, there are investigators who feel the interpretation of preferred paths is a consequence of grossly inadequate data. This is currently one of the more controversial topics in paleomagnetism.

#### Structure of the time-average field

Over the years, several attempts have been made to determine the structure of the time-average field by undertaking spherical harmonic analyses of paleomagnetic data for the past 5 Ma. Of particular interest here is the question of whether any nonzonal harmonic terms are genuinely present in the time-average field. Most of the modelers who have undertaken these investigations do claim the presence of nonzonal terms, but the agreement between different models is poor and this suggests that the conclusions are as yet not robust. As already discussed, there is no reliable evidence for polarity asymmetry and so a comparison of normal and reverse polarity results can be used to assess errors in the estimation of individual harmonic terms. Such a comparison suggests that the actual errors exceed the formal errors assigned by modelers.

Once again there are questions regarding reliability of the data. The data are not well distributed either in space or in time, and it is difficult to detect small rotations in the rocks providing the data. Consequently, our knowledge about the structure of the time-average field remains inconclusive and there is inadequate robust evidence to identify any specific asymmetries.

#### Field structure from direct observations

Spherical harmonic models have been created using data from magnetic observatories, satellites, and (corrected) ancient mariner logs. There are now models based on these data that extend from approximately 400 years ago to the present. While this time span is well short of that required to obtain a valid time-average magnetic field, some of the results combined with theory have stimulated research on possible long-term magnetic field asymmetry.

In particular, Jeremy Bloxham and David Gubbins found four lobes (in two pairs) in the structure of the field that are placed approximately

symmetrically on either side of the equator at  $60^\circ$  latitude and at 120°W and 120°E longitude. Most of the nondipole field drifts westward, but these flux lobes appear to have been fixed for the time interval investigated. A third north-south pair of lobes is required to produce symmetry, and the speculation is that such a third pair has been disrupted by fluid flow near the surface of the outer core. Bloxham and Gubbins hypothesized that the stationary lobes reflect convection rolls found much earlier in weak-field dynamo models by Fritz Busse. ("Weak-field" means that the magnetic field has a negligible effect on fluid motions in the core. Most theory today involves strong-field models.) However, dynamo models indicate that the convection rolls should drift westward or eastward depending on the details of the model. Thus, it was posited that there are thermal anomalies that pin the flux lobes to certain locations in the lowermost mantle. If true, this would lead to long-term asymmetry in the time-average magnetic field. Gubbins and Bloxham also emphasize that the data show a persistent low secular variation in the Pacific hemisphere and, as already discussed, this would also lead to a manifestation of asymmetry in the secular variation data.

#### Conclusion

Dynamo theory is notoriously complex and even with the computing power available today a working model, based on parameters that actually match those in the Earth, remains elusive. Hence, it is not currently possible to predict that the particular asymmetry in the Earth will manifest as a particular asymmetry in the geomagnetic field. Thus, although there are several mechanisms that it is speculated might lead to geomagnetic asymmetry, such as anisotropy in the inner core, asymmetry in any initial field, thermal-electric and battery effects originating in the mantle, or thermal and chemical heterogeneities in D", there is no robust evidence that this would actually occur. Certainly, it is not currently possible to invert from an observed asymmetry in the geomagnetic field to the underlying cause of that asymmetry. However, dynamo models do indicate that thermal structure at the base of a mantle does influence the structure of the field generated by the geodynamo.

The case for or against time-average asymmetry in the magnetic field and/or its secular variation remains inconclusive. The case against asymmetry is simple to state: all evidence put forth to advocate asymmetry contains errors, inadequacies, or debatable assumptions. The case for asymmetry is more subtle. Proponents recognize the problems, but point to a variety of data types that each weakly suggest a common location for an asymmetry of some form in the lowermost mantle. For example, the stationary flux lobes evidenced in the direct observations, claimed biases of VGP polarity transition data, and some secular variation data, have all been used to argue for anomalous mantle near the eastern margin of the Pacific hemisphere. This is also a region that appears to exhibit different seismic properties. Although a scientific cliché, we conclude that more data and analyses are required.

## Introduction

Geomagnetic variations take place over a wide range of timescales. The longer-term variations, typically those occurring over decades to millennia, are predominantly the result of dynamo action in the Earth's core (see *Geodynamo*). However, geomagnetic variations on timescales of seconds to many years also occur due to dynamic processes in the ionosphere (see *Ionosphere*), magnetosphere (see *Magnetosphere of the Earth*), and heliosphere (see *Magnetic field of Sun*). These changes are ultimately tied to variations associated with the solar activity cycle. To a lesser extent geomagnetic variations are also caused by changes in the solar ultraviolet emission that controls the ionization of the Earth's ionosphere (see *Periodic external fields*). However, the largest geomagnetic variations are due to sporadic solar activity in the form of solar coronal mass ejections (CMEs) and the number of CMEs varies with the phase of the solar cycle.

In a CME, the rapid reconfiguration, through magnetic reconnection processes, of the fields in and above solar sunspot regions results in the release of magnetic flux and plasma into the solar wind. Traveling toward Earth, these plasma "bubbles" can interact with the Earth's magnetic field, depositing particles and energy into the magnetosphere, and driving geomagnetic storms (see *Storms and substorms, magnetic*).

Solar activity, and hence geomagnetic storm frequency, varies on a cycle of between about 9 and 14 years (see *Dynamo, solar*). A large-scale dipolar solar magnetic field exists during times of sunspot minimum. This dipolar field progressively diminishes through solar (sunspot) maximum, becoming reestablished with the opposite polarity around the time of the next cycle minimum. Sunspots, flares, and associated CMEs are the means by which the large-scale field is changed and magnetic flux is expelled into the solar wind (see *Magnetic field of Sun*).

The fact that the geomagnetic field does respond to solar conditions can be useful, for example, in investigating Earth structure using magnetotellurics (see *Magnetotellurics*), but it also creates a hazard. This geomagnetic hazard is a risk to technology, rather than to health (for recent reviews see, e.g., Lanzerotti, 2001; Pirjola *et al.*, 2005). Astronauts are certainly at risk from bursts of ionizing solar energetic particle radiation that follow solar flares (Turner, 2001). Astronaut protection involves appropriate spacecraft shielding and positioning relative to the Sun. However, at the Earth's surface, the atmosphere acts as a protective layer equivalent to several meters of concrete. Only in the polar regions and at airline altitudes anywhere may solar radiation storms be a health issue, and major airline operators and aviation authorities are considering the risks (Getley, 2004). In terms of hazard to health, modeling and predicting the changing morphology of the geomagnetic field is important in determining where charged particles may enter into the lower atmosphere (see *Main field modeling*; *Geomagnetic secular variation*).

# Conducting networks and geomagnetically induced currents

A time-varying magnetic field external to the Earth induces a secondary magnetic field, internal to the Earth, as a consequence of Faraday's law. Associated with time variations in the induced field is an electric field, which is measurable at the surface of the Earth. The surface electric field causes electrical currents, known as geomagnetically induced currents (GIC), to flow in any conducting structure, for example, a power grid grounded in the Earth. This electric field, measured in V  $m^{-1}$ , acts as a voltage source across networks, with the different grounding points at different electrical potentials.

Examples of conducting networks are electrical power transmission grids, oil and gas pipelines, undersea communication cables, telephone and telegraph networks, and railways. GIC are often described as being quasi-direct current (DC), although the variation frequency of GIC is governed by the time variation of the electric field. For GIC to be a hazard to technology, the current has to be of a magnitude and frequency that makes the equipment susceptible to either immediate or cumulative damage. The size of the GIC in any network is partly governed by the electrical resistance of the network, relative to the resistance of the underlying Earth. The largest external magnetic field and magnetospheric current variations occur during geomagnetic storms and it is then that the largest GIC occur. Significant variation periods are typically from seconds to about an hour, so the induction process involves the upper mantle and lithosphere (see Magnetotellurics; Geomagnetic deep sounding). Since the largest magnetic field variations are observed at higher magnetic latitudes, GIC have been regularly measured in Canadian, Finnish, and Scandinavian power grids and pipelines since the 1970s. GIC of tens to hundreds of Amps have been recorded. However, GIC and effects have also been recorded in countries at midlatitudes during major storms. There may even be a risk to low latitude nations during a storm sudden commencement (see Storms and substorms, magnetic) because of the high, short-period, rate of change of the field that occurs everywhere on the dayside of the Earth.

GIC have been known since the mid-1800s when it was noted that telegraph systems could run without power during geomagnetic storms, described at the time as operating by means of the "celestial battery" (Boteler *et al.*, 1998). However, technological change and the growth of conducting networks have made the significance of GIC greater and more pervasive in modern society. We therefore describe the GIC hazard in detail in two of the best-studied networks, power grids and pipelines. The technical considerations for undersea cables, telephone and telegraph networks, and railways are similar. However, fewer problems are known, or have been reported in the open literature, about these systems. This suggests that the hazard is less, or that there are reliable methods for equipment protection.

Modern electrical transmission systems consist of generating plant interconnected by electrical circuits that operate at fixed transmission voltages controlled at transformer substations. The grid voltages employed are largely dependent on the path length between these substations and 200–700 kV system voltages are common. There is a trend toward higher voltages and lower line resistances to reduce transmission losses over longer and longer path lengths. However, low line resistances produce a situation favorable to the flow of GIC. Power transformers have a magnetic circuit that is disrupted by the quasi-DC GIC: the field produced by the GIC offsets the operating point of the magnetic circuit and the transformer may go into half-cycle saturation. This produces a harmonic-rich AC waveform, localized heating, and leads to high reactive power demands, inefficient power transmission and possible misoperation of protective measures. Balancing the network in such situations requires significant additional reactive power capacity (Erinmez *et al.*, 2002). The magnitude of GIC that will cause significant problems to transformers varies with transformer type. Modern industry practice is to specify GIC tolerance levels on new transformer purchases.

On 13 March 1989 a severe geomagnetic storm caused the collapse of the Hydro-Quebec power grid in a matter of seconds as equipment protection relays tripped in a cascading sequence of events (Bolduc, 2002). Six million people were left without power for 9 hours, with significant economic loss. Since 1989 power companies in North America, the UK, Northern Europe, and elsewhere have invested time and effort in evaluating the GIC risk and in developing mitigation strategies. GIC risk can, to some extent, be reduced by capacitor blocking systems, maintenance schedule changes, additional on-demand generating capacity, and, ultimately, shedding of load. However, these options are expensive and sometimes impractical. The continued growth of high voltage power networks, for example, in North America and in mainland Europe, is leading to a higher risk. This is partly due to the increase in the interconnectedness at higher voltages; connections to grids in the auroral zone, and commercial considerations that see grids run closer to capacity than was the case historically.

To understand the flow of GIC in power grids and therefore to advise on GIC risk, analysis of the quasi-DC properties of the grid is necessary. This must be coupled with a geophysical model of the Earth that provides the driving surface electric field, determined by combining time-varying ionospheric source fields and a conductivity model of the Earth. Such analyses have been performed for North America, the UK, and in Northern Europe. However, the complexity of power grids, the source ionospheric current systems, and the 3D ground conductivity makes an accurate analysis difficult. By being able to analyze, postevent, major storms, and their consequences we can build a picture of the weak spots in a given transmission system and even run hypothetical event scenarios. An example of a postevent grid analysis for Central Scotland and Northern England during the peak of the 30 October 2003 magnetic storm is shown in Figure G20 (Thomson et al., 2005). At this time the measured GIC was 42 A, a significant, though in this case, manageable level and comparable with the model results.

Grid management is also aided by space weather forecasts of major geomagnetic storms. This allows for mitigation strategies to be implemented. Solar observations provide a 1–3 day warning of an Earthbound CME, depending on CME speed. Following this, detection of the solar wind shock that precedes the CME in the solar wind, by spacecraft at the Lagrangian L1 point, gives a definite 20–60 min warning of a geomagnetic storm (again depending on local solar wind speed). However, the magnitude and accurate time of arrival of a CME prior to shock detection is unknown, although there is much research and model development within the space weather community. Given the demands on managing power grids more accurate information would have high value.

Major pipeline networks exist at all latitudes and many systems are on a continental scale. Pipeline networks are constructed from steel to contain high-pressure liquid or gas and are covered with special coatings to resist corrosion. Weathering and other damage to the pipeline coating can result in the steel being exposed to moist air or to the ground, causing localized corrosion problems. Cathodic protection rectifiers are used to maintain pipelines at a negative potential with respect to the ground. This minimizes corrosion without allowing any chemical decomposition of the pipe coating and the operating potential is determined from the electrochemical properties of the soil and Earth in the vicinity of the pipeline. The GIC hazard to pipelines is that GIC cause swings in the pipe-to-soil potential, increasing the rate of corrosion during major geomagnetic storms (Gummow, 2002).

**Figure G20** Estimated GIC in a network model of the Central Scotland and Northern England high voltage power grid, at the peak of the 30 October 2003, storm at 21:20 UT. Circle shading denotes GIC flowing to/from earth (dark/light) at transformers in the grid and the arrows denote the instantaneous *E* and *B* fields at Eskdalemuir magnetic observatory. The *E*-field is calculated from a radially varying Earth conductivity model using measured Eskdalemuir geomagnetic variations at this time. GIC amplitudes are proportional to spot size, with 40 A shown for scale. White spots show the locations of permanent GIC measurement sites in the grid.

GIC risk is not, therefore, a risk of catastrophic failure, rather the reduced service lifetime of the pipeline, or parts of it.

Pipeline networks are modeled in a similar manner to power grids, for example, through distributed source transmission line models that provide the pipe-to-soil potential at any point along the pipe (Boteler, 1997). These models need to take into account complicated pipeline topologies that include bends as well as electrical insulators, or flanges, that electrically isolate different sections of the network. From a detailed knowledge of the pipeline response to GIC, pipeline engineers can understand the behavior of the cathodic protection system even during a geomagnetic storm, when pipeline surveying and maintenance may often be suspended.

# Satellite operation, navigation, and radio communication

The ionosphere plays a significant role in very low frequency (VLF) through to high-frequency (HF) radio communication, and in navigation systems such as Loran-C and Omega (Lanzerotti, 2001; Schunk, 2001). Ionospheric conductivity is partly affected by geomagnetic storms but more significantly by solar ultraviolet and x-ray control of the ionospheric D, E, and F layers (see *Ionosphere*). Solar flares cause signal-phase anomalies and amplitude variations to occur (fades and enhancements) and conditions can persist for minutes to hours. Solar flares and CMEs are also important as sources of solar energetic particles, affecting radio communications at high latitudes. Disturbed conditions can persist for days to weeks in the Polar Regions during periods of high particle flux into the polar caps. Ultrahigh-frequency (UHF) radio signals are central to the Global Positioning System (GPS) that utilizes satellites in Earth orbit for precise ground position determination. UHF waves pass largely unattenuated through the

ionosphere but the system accuracy is sensitive to variations in the total electron content (TEC) in the path between ground and satellite. The TEC determines the signal propagation delay. TEC variations occur during geomagnetic storms and these particularly degrade the accuracy of single-frequency GPS equipment. Geomagnetic storms also produce ionospheric irregularities and scintillations that occur both on the dayside and nightside of the Earth.

In practical terms, radio navigational and communication systems and operators adjust to the prevailing conditions, although accurate forewarning of solar and geomagnetic activity may be useful for planning purposes.

Low Earth orbit satellites and space stations (up to around 1000 km altitude) experience increased air drag during geomagnetic storms. Enhanced ionospheric currents deposit heat in the atmosphere. This causes the atmosphere to expand outward and, at a given altitude, atmospheric density increases. This leads to heightened drag forces, slowing of satellite velocities, and lowering of orbit altitudes. The cumulative effect of geomagnetic storms is therefore to reduce the operational lifetime of satellites, particularly those in low initial orbits, where air density is higher. High-altitude atmospheric density models often parameterize geomagnetic heating effects by geomagnetic activity indices (e.g., Roble, 2001). By predicting geomagnetic indices, on day-to-day and solar cycle timescales, more efficient use can be made of satellite fuel supplies, with judicious orbit reboosts used to extend mission lifetimes. More sophisticated models of the upper atmosphere are being developed, involving near real-time calibration data from many orbiting satellites, as well as a better understanding and modeling of the physics of the atmosphere and its response to solar and geomagnetic forcing.

Satellites also suffer increased surface and internal electrical charging from ionized particles during geomagnetic storms. This can result in system malfunctions as electronic components experience physical damage and logic errors. Satellite manufactures take the solar cycle varying radiation environment into account when designing components, using statistical models of radiation dosages over component lifetimes. Modeling of the geomagnetic field morphology and predicting changes in the field (see *Main field modeling*; *Geomagnetic secular variation*) help to map the radiation environment of the Earth and the response of satellites to that environment. In operation, satellites can be temporarily powered down or placed in an appropriate "safe mode" following warnings of solar and geomagnetic activity.

## Geophysical exploration and geomagnetic variations

Aeromagnetic surveys are affected by geomagnetic storm variations (see *Crustal magnetic field*; *Magnetic anomalies for geology and resources*; *Aeromagnetic surveying*). These cause data interpretation problems where external field amplitudes are similar to those of the crustal field in the survey area. Accurate geomagnetic storm warnings, including an assessment of the magnitude and duration of the storm, would allow for an economic use of survey equipment.

For economic and other reasons, oil and gas exploration often involves the directional drilling of well paths many kilometers from a single wellhead in both the horizontal and vertical directions. Target reservoirs may only be a few tens to hundreds of meters across and accurate surveying by gyroscopic methods is expensive since it can involve the cessation of drilling for a number of hours. An alternative is to use magnetic referencing while drilling (Clark and Clarke, 2001). Near real-time magnetic data are used to correct the drilling direction and nearby magnetic observatories prove vital. There is no drilling "down-time" during a magnetic storm and storm forecasts are not normally seen as being important.

## Summary and outlook

The geomagnetic hazard to technology results from the strengthening of magnetospheric and ionospheric current systems by the solar wind and by CMEs. These electrical current enhancements cause rapid and high amplitude magnetic variations during geomagnetic storms. Processes internal to the magnetosphere also drive variations, particularly after CME-driven activity. A common theme that emerges from a study of geomagnetic hazards is a need for accurate geomagnetic storm forecasting, in terms of onset time and duration, maximum amplitude, and variation periods. The close connection of geomagnetic hazard with solar activity and space weather is also clear. Some practical applications of geomagnetic variations require only monitoring data, but other applications (will) clearly benefit from a thorough physical understanding of the Sun-Earth magnetic interaction and, in particular, accurate prediction of geomagnetic variations.

# **GEOMAGNETIC JERKS**

## Observations

Geomagnetic jerks are abrupt changes in the second-time derivative, or secular acceleration, of the magnetic field that arises from sources inside the Earth. They delineate intervals of oppositely signed, nearconstant secular acceleration. The first observed geomagnetic jerk was that around 1969 (Courtillot et al., 1978), and since the late 19th century when direct and continuous measurements of the Earth's magnetic field have been made at a number of observatories around the world, geomagnetic jerks have also been observed to occur around 1925, 1978, 1991, and 1999 and possibly also around 1901 and 1913 (e.g., Malin and Hodder, 1982; Courtillot and Le Mouël, 1984; Macmillan, 1996; Alexandrescu et al., 1996; Mandea et al., 2000). These jerks are most readily observed in the first-time derivative of the east component at European observatories (Figure G21). Understanding their origin is important, not only because they result from interesting dynamical processes in the core and may help determine the conductivity of the mantle, but also for improving time-dependent models of the geomagnetic field (q.v.) and for the strictly practical purpose of forecasting its future behavior, for example, as used in navigation.

# Analysis of jerks

Many studies have been undertaken to assess jerk characteristics, such as origin, times of occurrence, and spatial patterns. At observatories the measured magnetic field is the vector sum of fields arising from three primary sources, namely the main field generated in the Earth's core, the crustal field from local rocks, and a combined disturbance field from electrical currents flowing in the upper atmosphere and magnetosphere, which also induce electrical currents in the sea and the ground. As the long-period variations of the disturbance field associated with the 11-year solar cycle are in the same frequency band as variations arising from sources inside the Earth, the separation of the sources is an important part of any analysis of geomagnetic jerks. Spherical harmonic analysis applied to monthly or yearly mean geomagnetic observatory data has shown that jerks are internal in origin and, where sufficient data exist, are global phenomena (e.g., Malin and Hodder, 1982, McLeod, 1985).

Various analysis techniques have been applied to jerks to investigate specific aspects of their temporal and spatial characteristics. Methods such as optimal piecewise regression analysis and wavelet analysis have established the exact dates of occurrence at different observatories without any *a priori* assumptions. Using wavelets, the 1969 and 1978 jerks have been shown to have different arrival times at the Earth's surface, with the northern hemisphere leading the southern hemisphere by about 2 years (Alexandrescu *et al.*, 1996).

## Implications for studies of the Earth's deep interior

The shortest variations in the Earth's internal field that can be seen at the Earth's surface are determined by the rate of change of the magnetic field at the core-mantle boundary (CMB) and by the electrical conductivity of the mantle through which the magnetic signal from the core must pass. From analyses of surface data we know that the duration of individual jerks, as indicated by the width of impulses in the third-time derivative, is no more than about 2 years. However, it

**Figure G21** Geomagnetic jerks as seen in the secular variation of the east component of the Earth's magnetic field observed at European observatories. Time of jerks are shown by arrows.

is difficult to make any estimate of the rate of change of the magnetic field at the CMB, or the electrical conductivity of the mantle, from geomagnetic field observations at the Earth's surface. As in most geophysical problems, assumptions have to be made or constraints have to be applied using information from other data sources. In the case of geomagnetic jerks one useful independent dataset is length of day (LOD) observations. Correlation of the occurrences of jerks with marked changes in the deficit LOD (the former appearing to lead the latter by a few years) indicates some form of coupling between the core and the mantle. It has recently been shown that inflexion in the time derivative of splines fitted to filtered LOD data from 1960 onwards coincide remarkably well with geomagnetic jerks, including the late arrivals reported for the southern hemisphere (Holme and de Viron, 2005).

Jerks are most likely to result from dynamic processes inside the Earth that produce changes in the magnetic field near the top of the fluid core. These include the changes caused by advection and shear within the flow. Diffusion is not likely to be an important factor because of the short timescales involved. Core flows can be estimated directly from observatory secular variation data or indirectly from spherical harmonic models of secular variation. Again, assumptions have to be made or constraints applied so that a unique solution is found. One common assumption applied when determining core flows from magnetic data over time intervals of a few decades is the frozenflux hypothesis with tangentially geostrophic time-varying flows. With this assumption the fine detail of the secular variation, including jerks, can be well fitted (Jackson, 1997) but the models offer little physical explanation of the flows in terms of core processes. Another assumption that also gives good fits to data is steady flow in a core reference frame that is allowed to rotate about the Earth's rotation axis with respect to the mantle (Holme and Whaler, 2001). This, not surprisingly, provides results which are consistent with LOD data.

A time-dependent flow model that comprises only torsional oscillations, recovers jerks very well while not producing spurious jerks where none are observed (Bloxham *et al.*, 2002). This suggests that the origin of jerks is related to the action of torsional oscillations on the local magnetic field at the CMB. If this is correct, then the torsional oscillations provide a physical representation for the origin of jerks, for they are not only a part of the mathematical representation of core flows but, more importantly, are an actual component of flow predicted to occur in the geodynamo. They also provide the angular momentum changes required to explain the LOD changes. However, the specific details of jerk generation in the core are still to be resolved, in particular the mechanism driving torsional oscillations.

# **GEOMAGNETIC POLARITY REVERSALS**

## Early records of reversals

Natural magnetization of rocks opposed to that of the present day field was observed by David and Brunhes about one century ago. Brunhes concluded that "at a certain moment of the Miocene epoch in the neighborhood of Saint-Flour the north pole was directed upward: it was the south pole which was the closest to central France" (see Laj et al., 2002). Then, Matuyama observed in 1929 other reverse polarities in the magnetic directions of lava flows from Japan and Manchuria. However, early studies did not provide definite evidence that the geomagnetic field had reversed its polarity, in particular because self-reversal in some rocks can produce thermoremanent magnetization antiparallel to the geomagnetic field at cooling time. Existence of polarity reversals was definitely established when K-Ar dating demonstrated that all lavas from the same age have a similar polarity, whatever their geographical position at the Earth surface. First Geomagnetic Polarity Timescales (GTPS) were constructed in the 1960s (Cox, 1969). Then, discovery of marine magnetic anomalies (Figure G22) confirmed seafloor spreading (Vine and Matthews, 1963), and the GTPS was extended to older times (Vine, 1966; Heirtzler et al., 1968; Lowrie and Kent, 1981). Since then, succession of polarity intervals has been extensively studied and used to construct magnetostratigraphic timescales linking biostratigraphies, isotope stratigraphies, and absolute ages (see Opdyke and Channell, 1996, for a review).

## **Reversal frequency**

The geomagnetic polarity timescale constructed from seafloor magnetic anomalies (Figure G23) revealed that polarity reversals were common in Earth's history. Their occurrence, however, is not constant through time. Reversal frequency has increased during the past 85 Ma, since the long Cretaceous interval of normal polarity. Before this superchron, reversal frequency decreased since the Late Jurassic.

Changes in reversal frequency occur with time constant of tens of millions of years or more, of the same order of magnitude of those involved in mantle overturning. It was therefore suggested that reversal frequency is linked to the structure of the mantle, an idea that was reinforced by 3D computations of the geodynamo (Glatzmaier *et al.*, 1999). The question of the existence of a 15 Ma periodicity in reversal frequency (Mazaud *et al.*, 1983) has been largely debated (see Jacobs, 1994).

**Figure G23** Geomagnetic polarity timescale with magnetic anomaly numbers for the past 160 Ma. (Figure from Merrill *et al.*, 1996).

# Geometry and dynamics of the transitional field

Polarity transitions occur so quickly on a geological timescale that it is difficult to find rocks that have preserved in detail variations of the transitional field. Also, sediment and lava may sometimes provide different views of the phenomenon. Lava flows acquire magnetic memory during their cooling, and provide instantaneous pictures of the Earth magnetic field. Polarity transitions are recorded only if eruptions occurred at the time of the transition, and if no alteration or secondary heating affected the recording rocks. Lava may provide absolute paleointensities, by using Thellier, Shaw, or Thellier and Coe determination methods. In contrast, sediments provide continuous records of geomagnetic field changes, but acquisition process may smooth out fastest field changes. Only relative changes of past geomagnetic intensity are obtained, and only with sediment exhibiting limited downcore variations in magnetic mineralogy and magnetic particle grain size.

Despite difficulties to obtain paleomagnetic records of polarity transitions, several characteristics have emerged in the last few decades. The geomagnetic intensity decreases a few thousands of years before directional changes. Then, the magnetic vector exhibit directional changes while intensity remains low. When the direction reaches opposite polarity, the geomagnetic intensity rises to normal values. The total process takes place in few thousand years, and may vary for different reversals. It was also suggested that the geomagnetic field intensity progressively decreases during periods of stable polarity and recovers high values immediately after a transition (Valet and Meynadier, 1993).

## The standing field hypothesis and the flooding models

The geometry and the dynamics of the geomagnetic field during polarity transitions have been subject to large debate. Hillhouse and Cox (1976) suggested that if the usual nondipole drift (secular variation) was unchanged during a polarity reversal, which is theoretically envisaged (Le Mouël, 1984), then one should observe large longitudinal swings in reversal records. Their absence in the first records obtained from sediments led these authors to suggest the standing field hypothesis, in which an invariant component dominates the transitional field when the axial dipole component has vanished. The standing field hypothesis, however, was not confirmed. A classical tool used for investigating the morphology of the transitional field is the virtual geomagnetic pole (VGP), defined as the pole of the dipolar field that gives the observed direction of magnetization at studied site. If VGPs obtained at several sites for a given instant in time coincide, then the field has a dipolar structure. If different VGPs are obtained at different sites, then the field was not dipolar (the word "virtual" indicates that VGPs can be calculated for any field, not necessarily dipolar).

322

Sedimentary records also indicated different VGP paths for the same transition studied at different sites at the Earth's surface, with transitional VGPs moving progressively along longitudinal great circles. This led Hoffman and Fuller (1978) to develop flooding models, in which reversals originate in a localized region of the core and then progressively propagate into other regions.

## Stop and go behavior

Higher resolution records were obtained from lava and sedimentary series. They suggested some repetition over successive reversals (Valet and Laj, 1984), and also stop-and-go behavior, with alternating phases of rapid change and stationarity during transitions. This is seen in the Miocene reversal record obtained at Steens Mountain, Oregon (Figure G24) (Prévot *et al.*, 1985), and also in Miocene sedimentary records from Northwest Greece (Laj *et al.*, 1988).

## The two preferred bands

An intriguing point was issued by Laj and colleagues (1991), examining the longitudinal distribution of the VGP paths of sedimentary records of reversals over the past 10 Ma. They found that VGP paths tend to follow paths located into two preferred bands, over Americas and eastern Asia. These two preferred bands coincide with regions of fast seismic wave propagation in the lower mantle, in the downward continuation of subducted slabs in the mantle (Figure G25). These two bands also coincide with the main patches of radial magnetic flux at the core-mantle boundary in the present-day field and the historical field (Bloxham and Gubbins, 1985), and in paleofield reconstructions (Constable, 1992; Gubbins and Kelly, 1993). Thus, Laj and colleagues (1991) argued that the persistence of these two preferred bands over time of the order of magnitude of mantle convection was experimental evidence that the geodynamo was constrained by temperature patterns at the core-mantle boundary, as suggested by present day

and historical magnetic observations. The existence of the two preferred bands was and is still debated, in particular because they were not seen in the volcanic compilation of Prévot and Camps (1993). However, another analysis of volcanic databases suggests that the two bands also exist in compilations of volcanic reversals records (Love, 1998). Influence of variable conditions at the core-mantle boundary is suggested in 3D computations of the geodynamo (Glatzmaier *et al.*, 1999).

## Toward a consistent picture of polarity reversals?

Progressively, a consistent picture emerges from high-resolution sediment and lava records. In 1992, Hoffman observed long-lived transitional states of the geomagnetic field, with VGPs of volcanic reversal records clustering in the two preferred bands (Figure G26).

More recently, several high-resolution sedimentary records were obtained that exhibited complex field behavior, with VGP loops and clusters reminiscent of volcanic records. Some clusters, but not all, lie in the two preferred bands (Figure G27). Transitional precursors are sometimes observed.

### Conclusion

The situation is still complex, because different reversals may document different behavior and the question of the two preferred longitudinal bands is still open. The relation between polarity reversals and excursions is under investigation. Geomagnetic excursions are seen as aborted reversals in which the field may reverse in the liquid outer core, which has timescales of 500 years or less, but not in the solid inner core, where field must change by diffusion with a timescale of  $\approx 3$  ka. This disparity of dynamical timescales between the inner and outer core is consistent with the presence of several excursions between full reversals (Gubbins, 1999). Overall, the mechanisms that trigger reversals and excursions have to be better understood. Whether or not the present-day axial dipole field decrease corresponds to a reversal or excursion onset, or to a field fluctuation during stable polarity, is not yet known.

Combination of supercomputer 3D simulations (see for instance Glatzmaier and Olson, 2005, for a review) and new high-resolution records from both sediments and lava flows should lead to a better understanding of the mechanisms involved in field generation and GEOMAGNETIC POLARITY REVERSALS, OBSERVATIONS

# GEOMAGNETIC POLARITY REVERSALS, OBSERVATIONS

Earth's magnetic field exhibits the remarkable property of undergoing a 180° change in directions at geologically frequent, but irregular, intervals. As a result, a compass needle that had been pointing to one geographic pole (such as North), would point to the opposite geographic pole. Why the field reverses polarity remains a mystery and solving this mystery is important for understanding the processes in Earth's fluid outer core responsible for generating the geomagnetic field.

The best record of how frequently the geomagnetic field reverses polarity comes from marine magnetic anomalies (Cande and Kent, 1995). Neither the marine anomaly record nor long stratigraphic sequences of polarity history, often record field directions that fall in between the two stable polarity directions. Given the seafloor spreading and sedimentation rates, this indicates that polarity reversals are rapid events,

324

at least on geological timescales. For example the marine magnetic anomaly record limits the time for a reversal to occur to less than 20 ka.

The first step in attempting to solve the mystery of why Earth's magnetic field reverses is to determine what happens as the field reverses. Paleomagnetic records of polarity transitions are the only source of information about how the geomagnetic field behaves during a reversal. Because polarity reversals are very short events, polarity transition records are difficult to obtain. Not only is it necessary to find a paleomagnetic recorder that provides great enough time resolution to catch the field in the act of reversing, but also it is necessary for that recorder to provide a high fidelity recording of the field, even when the field was weak.

Two very different types of paleomagnetic recorders have repeatedly yielded polarity transition records. Volcanic sequences created by rapid extrusion periods that coincide with a polarity reversal, record the changing field as successive lava flows cool and become permanently magnetized in the transitional field. Sequences of sedimentary rocks or unconsolidated sediments have also proven useful in transition studies. If sedimentation rates are rapid and continuous enough, a record of a polarity transition may result as layers of sediment become magnetized as they accumulate during the reversal.

These two types of paleomagnetic recorders document transitional fields in fundamentally different ways. Most importantly, the way each type of recorder becomes magnetized is very different, and these differences must be considered carefully when interpreting each type of record. A second important difference is the two kinds of recorders provide different types of temporal information about reversing fields.

The processes by which lavas become magnetized are well founded in the theory of thermoremanent magnetization (TRM). This theory explains how grains of magnetic minerals become permanently magnetized as they cool through their magnetic blocking temperatures in the presence of an external field. Because the cooling times for typical lava flows are rapid, it may be assumed that the lava flows provide a spot reading in time of the magnetic field direction and intensity at the time of cooling. TRM acquisition theory also provides a basis for obtaining measures of the strength or intensity of the field, known as absolute paleointensities.

On the other hand, the processes by which sediments become magnetized are less well understood. Although it is clear that many types of sediments can record the geomagnetic field accurately, as evidenced by recording the full polarity directions predicted for their site location, it is not clear how these magnetizations are acquired. A number of studies indicate that a postdepositional remanent magnetization process that locks-in the magnetization at some depth beneath the seafloor magnetizes marine sediments. Of particular interest in polarity transition studies is not so much the depth offset of remanence acquisition, but rather over what depth range the acquisition process occurs simultaneously. If the remanence becomes fixed over a relatively thick depth interval, the sediment in that layer will average out the changes in the field that occur. The resulting magnetization therefore would be an integration of the field during that time, and would provide an average of those changes in the field. As the thickness of sediment over which the remanence becomes blocked in becomes thinner, the magnetization approaches more of a spot reading of the changing field. Unfortunately, the remanence lock-in thicknesses in sediments are not known, and this presents an important difficulty in interpreting sediment records of polarity transitions.

Unlike the theory of TRM, theories of how sediments become magnetized do not provide a basis for determining absolute field intensities. But, if conditions are favorable, it is possible to obtain records of relative changes in field strength (Tauxe, 1993). In other words, sediments are capable of providing information on the increasing or decreasing field strength, but as of yet, it is not possible to calibrate those relative changes to absolute magnitudes of field strength.

In addition to the different ways these two types of recorders become magnetized, there is also a fundamental difference in the temporal resolution provided by each type of recorder. On the timescales over which polarity reversals occur, it is not possible to determine the rates at which lavas are extruded from a volcano, or how much time has elapsed between successive lava flows. This means, that while lavas may provide high fidelity recordings of the field, the timing of the sequence of magnetizations of the flows is unknown. Recent advances in radiometric dating techniques using  ${}^{40}\text{Ar}{}^{39}\text{Ar}$  and K/Ar methods (Singer and Pringle, 1996) are approaching the precision needed to provide bounding limits on the durations of the youngest reversals but cannot yet provide information of timing with reversals.

Sediment records on the other hand, generally provide a much more continuous recording of the field. Correlation of  $\partial^{18}$ O records with the Marine Isotopic Stages can provide high-resolution age control through a reversal. Such records provide important information regarding the age, timing, and duration of polarity transitions.

Paleomagnetic studies of polarity transitions result in a sequence of magnetizations that were acquired as a reversal occurred. These results are generally presented as magnetization declination, inclination, and intensity or virtual geomagnetic pole (VGP) latitude as a function of stratigraphic position (either as positions in a sequence of sediments or lava flows). In order to compare records from different geographic locations it is necessary to take into account the fact that even during intervals of full polarity, different field directions are expected at different sites. For full polarity intervals, paleomagnetists do this by using the Geocentric Axial Dipole hypothesis to calculate the equivalent geomagnetic pole for the given magnetization directions (where the site results would place Earth's magnetic north pole). If the magnetization is thought to represent a spot reading (nearly instantaneous) of the field in time, the pole is called a VGP.

Polarity transition data are often presented as VGP positions as a function of stratigraphic position (Figure G28). This method of viewing the data is a convenient way to show the polarity reversal by illustrating how the apparent north magnetic pole (VGP), calculated from the observed directions at a site, moves from one high latitude position to the other.

An additional way of presenting a transition record is to plot the path of the VGP on a world map as it moved from one geographic pole to the other (Figure G29). This method makes it possible to compare records from distant sites and to test the hypothesis that the transitional field was dipolar.

**Figure G28** A record of the Lower Jaramillo polarity transition (Gee *et al.*, 1991) plotted as virtual geomagnetic pole position versus stratigraphic position. The full polarity intervals exhibit VGPs, which cluster close to the geographic poles. The dotted intervals represent a measure of the scatter of the VGPs about the full polarity average direction. The progression of VGP positions from one geographic pole to the other defines the polarity transition (shown by dashed interval). In this case, the transitional interval is defined as the zone in which the VGPs fall a statistically significantly distance from the geographic poles.

**Figure G29** The Matuyama-Brunhes polarity transition obtained from North Atlantic deep-sea sediments (Channell and Lehman, 1997) shown as the path the VGP positions track along as the field gradually changes from reverse polarity (VGPs near the south geographic pole) to normal polarity (VGPs near the north geographic pole).

If the transitional fields were not dipolar, then it is not strictly appropriate to calculate VGPs from the transitional magnetizations, because this calculation assumes a dipolar field. But then some other method is needed for comparing records from distant sites. One method that has been proposed is to plot the changing directions on an equal-area stereographic projection; a method commonly used by paleomagnetists. However, before plotting the directions, the vectors are rotated so that the plot is constructed looking down the full polarity direction (Hoffman, 1984). This method provides a way of comparing the directional behavior observed from different locations without invoking the assumption of dipolar field geometries. This method, however does not illustrate absolute or relative paleointensities.

Although the details of transitional field behavior remain uncertain, the number of paleomagnetic records of polarity transitions now available makes it possible to address the major features of reversals with greater certainty. It is generally agreed that during a reversal, the strength of the geomagnetic field drops to low levels, close to that of the strength of the present-day nondipole field (Merrill and McFadden, 1999). This represents about an 80% drop in intensity. Both volcanic and sedimentary transition records record intensity lows.

The timing of the directional change relative to the intensity change is not tightly constrained; however, the majority of sediment records and many volcanic records show that the directional change occurs while the field is weak. In other words, the directional change begins after the field has weakened and finishes before the field strength increases to full polarity values.

Simple geometrical models of reversals generally suggest that the directional change occurs at slightly different times during the low intensity depending on the site location. For example, the directional change may occur earlier at low latitudes than at high latitudes. Unfortunately, the records available to date do not have enough time control to rigorously test for this result.

The time it takes for a reversal to occur provides a major constraint on the geodynamo process. The reversal durations obtained from the available sediment records indicate that the time it takes for the directional change to occur is  $\approx 7 \pm 1$  ka. The intensity change takes longer, perhaps up to 11 ka. These duration estimates are less than estimates of the free-decay time of the geodynamo (20 ka), indicating that reversals do not result from a passive decay of the field (Clement, 2004).

The reversal durations are also dependent on site latitude, with the directional change occurring faster at low latitude than at high latitude (Clement, 2004). Again, this observation is expected based on simple geometrical models of reversals and provides constraints on three-dimensional numerical simulations of the dynamo. While the features described above are generally agreed upon, there remain several controversial interpretations of transitional field behavior, most of which involve interpreting the transitional field geometries (based on the directional data).

Some of the earliest comparisons of records of the most recent reversal showed that VGP paths from widely separated sites do not coincide (Hillhouse and Cox, 1976). This means that the field geometry was not dipolar, but was more complex. In other words, the reversal did not occur by a simple rotation of a dipole from one geographic pole to the other. This interpretation has held for the majority of reversals for which multiple records are available.

Based on this result, it has traditionally been held that the simplest hypothesis is that, because the field is weak during a reversal, the field geometry would likely be very complex: much like that of the presentday, time-varying, nondipole field. This interpretation is supported by dynamo theory and what is known about the properties of the core. This hypothesis predicts that there should be no systematic variation in intermediate polarity field directions observed at distant sites.

Perhaps the most controversial issue regarding polarity transitions is that several polarity reversals do, in fact, exhibit systematic variations in directions. For the most recent and several older reversals, it has been shown that the distribution of transitional VGPs from multiple sites fall into two, nearly antipodal, preferred longitudinal bands, one passing through the Americas and the other through eastern Asia (Clement, 1991; Laj *et al.*, 1991). The observation that multiple records of the same reversal exhibit VGPs in both longitudinal bands means that the transitional fields were not dipolar, but instead, some other, relatively simple transitional field geometry gave rise to the VGP distribution.

Because there is no known intrinsic property of Earth's outer core or the geodynamo that should give rise to this distribution of VGPs or the recurrence of the pattern in multiple reversals, it has been suggested that lateral variations in the lowermost mantle affect the dynamo and influence the geometry of the transitional fields. However, this interpretation remains controversial because the grouping of longitudinal bands of transitional VGPs comes primarily from sediment records, and because the geographic distribution of available transition records is not wide enough to rigorously demonstrate the grouping.

Some volcanic transition records have been obtained that exhibit clusters of VGPs that fall within one or the other of the preferred longitudinal bands, suggesting that this distribution may not be an artifact of the remanence acquisition process in sediments (Love and Mazaud, 1997). Because clusters of VGPs from multiple lava flows occur, it has been suggested that the transitional field may get temporarily locked into a geometry that produces these VGPs (Hoffman, 1992). If so, this could explain the longitudinal grouping of VGPs from the sediment records by assuming that the sediment records have averaged the dominant field geometry over the reversal. This process would produce a great circle VGP path over the cluster of VGPs from the lava records.

An additional controversy centers over the observation of recurring VGP positions that occur within individual transition records. Several records, some volcanic and some sedimentary, exhibit VGP paths remarkable in that the VGPs return to a position that had occurred previously during the reversal. This observation suggests that the reversal process possesses a memory, at least over the timescales of a single reversal. A few lava records have also been interpreted as exhibiting VGPs that return to similar positions during different reversals, suggesting a memory in the dynamo process that exists over much longer timescales. In both cases, lateral variations in the lowermost mantle are the likeliest candidate for providing such a memory (Hoffman, 1991).

This interpretation has been questioned by suggesting that the recurrent VGP positions may be an artifact of the remanence acquisition processes. If such an artifact is present or a magnetic overprint was acquired at a later age, it is possible that the observed sequence of transitional directions does not correspond to the actual temporal sequence that occurred during the reversal. So far, however, only one example

**Figure G30** A record of a polarity reversal recorded in lava flows at Steens Mountain, Oregon (Mankinen *et al.*, 1985; Prevot *et al.*, 1985). The changes in magnetization through the reversal are shown here plotted as declination, inclination, and paleointensity in stratigraphic sequence of similar magnetization vectors. The data are plotted versus vector group number because it is assumed that successive flows exhibiting the same magnetizations were extruded rapidly and represent multiple records of the same field and do not necessarily represent times when the field was not changing.

has been found for a remagnetization of intermediate directions in a sediment record of an excursion (Coe and Liddicoat, 1994).

Yet another controversy regards how fast the magnetic field can change during a reversal. The reversal recorded by lava flows at Steens Mountain, Oregon provides evidence that the transitional field may change as fast as degrees per day (Coe and Prevot, 1989; Coe *et al.*, 1995). This rate is extremely fast and in fact is thought to be too fast (Figure G30). This is because the electrical conductivity of Earth's mantle filters field changes produced by the dynamo and should limit just how fast the dynamo-produced field can change at Earth's surface.

The evidence for the rapid changes comes from magnetizations recorded within a single lava flow. The magnetizations differ with position in the flow. Using cooling rate estimates for the flow, the rate at which the field was changing can be estimated. Despite an intensive effort, no evidence has been found to suggest that the different magnetizations result from differences in the magnetic minerals that record the field.

These controversies will likely be resolved as additional polarity transition records are obtained from a greater geographic distribution and as records of older reversals are obtained. These records will help solve the mystery of what happens during a polarity reversal, and that knowledge will in turn help us understand what it is about Earth that gives rise to this fascinating feature of our magnetic field.

# GEOMAGNETIC POLARITY TIMESCALES

#### Marine magnetic anomaly record

It is well established that Earth's magnetic field has alternated frequently but irregularly between two opposing polarity states for at least most of the Phanerozoic. Older rocks of Proterozoic age that display both polarity states are also known, but whether they correspond to reversals of a dipole field is less firmly established. The time interval during which geomagnetic polarity remains constant is called a polarity chron; long episodes of continuous reversal behavior are called superchrons. The polarity equivalent to the present state is referred to as "normal" and the opposite state as "reversed."

The history of geomagnetic polarity is derived from two sources: the interpretation of lineated marine magnetic anomalies, and magnetic polarity stratigraphy in continuous sedimentary sequences and radiometrically dated igneous rocks. Since the Late Jurassic, when the current phase of seafloor spreading began, these records support and confirm each other. The geomagnetic polarity timescale (GPTS) is most reliable for this time. It is divided into two sequences of alternating polarity, the younger covering the Late Cretaceous and Cenozoic, and the older corresponding to Early Cretaceous and Late Jurassic time. The reversal sequences are referred to as the C-sequence and M-sequence, respectively. They are separated in the oceanic record by the Cretaceous Quiet Zone in which lineated magnetic anomalies are absent. It appears that Earth's magnetic field did not reverse polarity during this time interval, which is referred to as the Cretaceous normal polarity superchron (CNPS). Prior to the Late Jurassic only the polarity record preserved in rocks is available. Knowledge of older geomagnetic polarity history is patchy and, despite some excellent magnetostratigraphic results, largely unconfirmed.

# Construction and identification of a polarity chron sequence

Although the pioneering studies of geomagnetic polarity were carried out on radiometrically dated lavas, the marine magnetic anomaly record provides the most extensive, detailed and continuous record of reversal history and forms the basis of all GPTS covering the last 160 Ma of the Earth history. The appearance of lineated large amplitude, long wavelength marine magnetic anomalies (Figure G31) depends on the latitude and direction of the corresponding measurement profile. The first step in constructing a GPTS thus consists of interpreting the anomalies as a block model of alternating magnetization of the oceanic crust responsible for the anomalies. The polarity pattern is used to correlate coeval segments of different profiles and to obtain an optimized model that minimizes local variations in spreading rate on any given profile. The ensuing composite block model constitutes a polarity sequence in which the distances between the block boundaries are proportional to the relative lengths of the polarity chrons. No consideration is usually given to the finite duration of a polarity transition, which is thought to last about 4-6 ka (Clement and Kent, 1984). This time is included in the lengths of polarity chrons, which are measured between the midpoints of polarity transitions. This simplification is generally acceptable but it may be problematic for accurately describing short polarity chrons for which the transitional time may be an appreciable fraction of the duration of the chron.

The anomalies are identified by numbering them in increasing order away from the spreading axis. In the C-sequence the positive magnetic anomalies, corresponding to normal polarity, are numbered and preceded by the letter "C," as anomalies C18, C29, etc. The M-sequence oceanic crust in the North Pacific Ocean was magnetized south of the equator but plate motion has brought it into the northern hemisphere. The positive anomalies, identified by the letter "M" as anomalies M0, M13, etc., correspond to reversely magnetized crust. To reconcile the two numbering schemes, adjacent normally and reversely polarity chrons are paired, so that the younger member has normal polarity. Thus marine magnetic anomaly C15 is associated with polarity chrons C15n and C15r.

To obtain an optimized global model of polarity, which then becomes the polarity sequence for a GPTS, block models for different spreading centers must be compared, stretched, and squeezed differentially. The matching of block models may be visual or more sophisticated. To form an optimized record of the C-sequence of polarity Cande and Kent (1992a) used nine rotation poles to stack polarity records on contemporaneous profiles and determine relative widths of crustal blocks for the modeled reversal sequence. Before a timescale can be generated, the optimized polarity sequence must be dated. Biostratigraphic stage boundaries or other dated levels are correlated by magnetostratigraphy to the polarity

sequence. Intervening reversal boundaries between the calibration levels are dated by linear interpolation and older boundaries by extrapolation. The largest sources of error in this dating are the "absolute" ages associated with the tie-levels. The relative lengths of the polarity chrons, derived from a crustal block model that assumes constant spreading rate, are known more accurately.

#### Cenozoic and Late Cretaceous GPTS

The pioneering efforts to determine a GPTS were carried out on marine magnetic anomalies at actively spreading oceanic ridge systems. Heirtzler et al. (1968), hereafter referred to as HDHPL68, derived a GPTS from the present time to the Late Cretaceous by matching profiles in different oceans to a reference profile in the South Atlantic, which was judged to be the most likely to have a constant spreading rate. The spreading rate at the South Atlantic Ridge was estimated by correlating distances to young reversals with radiometrically dated reversals from lava sequences. By assuming this spreading rate to be constant, the distance of a polarity reversal from the ridge could be converted to age. However, it was later found that the magnetic anomalies composing anomaly C14 in HDHPL68 were not reproducible in other oceans and thus did not correspond to polarity intervals; moreover, the HDHPL68 timescale did not cover the full range of older anomalies following the Cretaceous Quiet Interval. Improved, extended, and modified, the HDHPL68 timescale served as the basis for several subsequent versions of the GPTS for this time interval (Figure G32). Magnetostratigraphic correlation of the Cretaceous-Tertiary boundary to the upper part of chron C29r in a continental exposure of marine limestones (Alvarez et al., 1977) provided a way of associating age with the older end of the reversal sequence and resulted in improved calibration of the C-sequence GPTS. The magnetostratigraphy also confirmed that the C-sequence began at C33r, as termination of the CNPS. Together with more detailed analysis of the oceanic record, this led to a more complete and accurate GPTS (LaBrecque et al., 1977), hereafter LKC77.

The number of stage boundaries now tied to the polarity record led Lowrie and Alvarez (1981) to propose a modification of the GPTS. They assumed the polarity sequence in LKC77 and best estimates of the "absolute" ages for 11 tie-levels that correlated the stratigraphic and marine magnetic polarity records. Disregarding the effects on seafloor spreading rates they stretched and squeezed the polarity record between the tie-points and obtained a new GPTS. The ensuing timescale resulted in a history of seafloor spreading characterized by sudden large changes in spreading rate. To avoid this, Harland *et al.* (1982) modified the ages of tie-points and obtained a GPTS that gave a smoother seafloor spreading record. One of the most important uses of a GPTS is now recognized to be the ability to attach numeric ages to faunal appearances and extinctions. Berggren *et al.* (1985) and Harland *et al.* (1990) produced GPTS versions in which the biostratigraphy was well tied to the magnetic polarity record, which was derived from that of LKC77.

Cande and Kent (1992a) carried out a detailed reevaluation of the C-sequence marine magnetic anomalies and improved the definitions of the corresponding oceanic block models, resulting in adjustments of the relative lengths of polarity chrons. They associated ages with the improved polarity sequence by fitting a cubic spline curve to nine dated correlation points. In so doing they used a nonstandard age for the Cretaceous-Tertiary boundary. An updated version of their timescale (Cande and Kent, 1995), hereafter referred to as CK95, is the current reference GPTS for the Late Cretaceous and Cenozoic. An archive of Cenozoic-Late Cretaceous timescales has been assembled by Mead (1996).

## The Cretaceous normal polarity superchron

The C-sequence and M-sequence polarity chrons are separated by the CNPS. Using the nomenclature for labeling chrons, this might be called C34n or M0n, but it is customary to designate it separately from the adjacent sequences. In the marine magnetic anomaly record the CNPS corresponds to regions of oceanic crust referred to as the Cretaceous Quiet Zone, in which magnetic anomalies, although present, are not lineated. It is believed to represent an interval of time, from about 121 to 83 Ma ago, in which the geomagnetic field had a consistent normal polarity. Despite magnetostratigraphic and deep-tow investigations to find polarity reversals within this 38 Ma interval, there is no incontrovertible evidence of them. The absence of polarity changes

The authors of individual C-sequence models are as follows: HDHPL68, Heirtzler *et al.* (1968); LKC77, LaBreque *et al.* (1977); LA81, Lowrie and Alvarez (1981); GTS82, Harland *et al.* (1982); BKFV85, Berggren *et al.* (1985); GTS89, Harland *et al.* (1990); CK95, Cande and Kent (1995).

in the CNPS may imply a special behavior of the geodynamo. A few very long polarity chrons, lasting several million years each, are found adjacent to the CNPS.

#### Early Cretaceous and Late Jurassic GPTS

The oldest regions of oceanic crust characterized by lineated magnetic anomalies were formed during the Late Jurassic. The Phoenix, Japanese, and Hawaiian lineations are found in the Western Pacific, and the Keathley lineations in the western North Atlantic. Larson and Pitman (1972) identified and correlated these sets of anomalies, numbering them from M1 to M22 in order of increasing age. They realized that the three sets of Pacific lineations were inverted with respect to the Keathley sequence. The North Pacific oceanic crust had been magnetized south of the magnetic equator, so that positive anomalies are now found over reversely magnetized crust. Larson and Hilde (1975) refined the reversal record for the Hawaiian lineations, resolving additional anomalies, adding a younger anomaly M0, and extending the older anomaly record to M25 (Figure G31). They dated their timescale (LH75) by estimating the age of magnetic basement at drillholes of the Deep Sea Drilling Project from the paleontological ages of the oldest calcareous fossils found in the holes. The magnetic reversal block model was derived for the Hawaiian lineations, but the ages were determined for sites on other lineation sets and correlated by the magnetic polarity pattern to the Hawaiian set.

The LH75 polarity sequence has formed the basis for subsequent modifications and improvements to the M-sequence GPTS (Figure G33). Later versions (Kent and Gradstein, 1985; Harland *et al.*, 1990) are somewhat better dated, but still rely on bottom ages in groups of drillholes near the ends of the sequence. A new Hawaiian block model with an optimized approximation to a constant spreading rate was derived by Channell *et al.* (1995) after critical comparison of block models for the Hawaiian,

**Figure G33** Evolution of the geomagnetic polarity timescale for the Early Cretaceous and Late Jurassic. The authors of individual M-sequence models are as follows: LH75, Larson and Hilde (1975); KG85, Kent and Gradstein (1985); GTS89, Harland *et al.* (1990); CENT94, Channell *et al.* (1995).

Japanese, Phoenix, and Keathley lineations. This model (CENT94), covering magnetic polarity chrons CM0r to CM29r, is probably the optimum current GPTS for the M-sequence anomalies.

Oceanic crust older than chron CM25r was thought to be free of lineated magnetic anomalies and was labeled the Jurassic Quiet Zone by analogy to the Cretaceous equivalent. However, magnetic lineations with low amplitude were subsequently identified in the youngest part of this Quiet Zone, extending the polarity sequence to CM29r (Cande *et al.*, 1978). These weaker old anomalies are related to oceanic crust whose magnetization decreases with increasing age. Even older anomalies, with short wavelengths and low amplitudes, have been detected within the Jurassic Quiet Zone, both from aeromagnetic profiles (Handschumacher *et al.*, 1988) and from deep-towed magnetometer surveys (Sager *et al.*, 1998). Their origin is as yet uncertain. They may have been formed during an episode of high reversal

frequency, in which case they would extend the M-sequence from CM29r to CM41r. This would imply that the Jurassic Quiet Zone is different in origin from the Cretaceous Quiet Zone, in which no reversals are thought to have occurred. However, the polarity pattern corresponding to these anomalies has not been established definitively and the reversal sequence has not been confirmed independently by magnetostratigraphy. It is possible that the anomalies may be due to fluctuations of paleomagnetic field intensity, as suggested to explain low amplitude, short wavelength anomalies in the Cenozoic (Cande and Kent, 1992b).

## Early Jurassic and Triassic GPTS

The record of geomagnetic polarity prior to the onset of seafloor spreading is much less well known. In the absence of a marine

**Figure G34** Construction of a GPTS for the Late Triassic based on overlapping magnetostratigraphies from drillholes in the Newark Basin, USA (after Kent *et al.*, 1995). The GPTS is that of Kent and Olsen (1999), calibrated by astrochronological dating of the magnetozones.

magnetic anomaly record, the GPTS must be pieced together from magnetostratigraphic results. This is a large undertaking. Changes of sedimentation rate within a given depositional basin or from one basin to another can strongly modify the "fingerprint" pattern of reversals that is essential for correlation. Investigations in marine limestones of Middle and Early Jurassic age have identified magnetozones, but these have only rarely been confirmed by other magnetostratigraphic results.

Kent *et al.* (1995) determined detailed magnetostratigraphies in overlapping drillholes through continental redbeds of Late Triassic age in the Newark basin. They matched the individual records stratigraphically to produce a composite geomagnetic polarity record (Figure G34). The sediments displayed lithological variations related to cyclical changes in Earth's orbital parameters, of which the 400 ka fluctuation of orbital eccentricity was prominent. Kent and Olsen (1999) used this Milankovitch cycle to convert the polarity sequence to a GPTS (Figure G34), assuming an "absolute" age of 202 Ma for the Jurassic-Triassic boundary. The Newark section currently serves as the standard of reference for the history of geomagnetic polarity in the Late Triassic.

# **GEOMAGNETIC PULSATIONS**

Geomagnetic pulsations or mircopulsations are ultralow frequency (ULF) plasma waves in the Earth's magnetosphere. These waves have frequencies in the range 1 mHz to greater than 10 Hz and appear as more or less regular oscillations in records of the geomagnetic field (see Figure G35). Geomagnetic oscillations, or ULF pulsations as they are also called, can also be identified in electric field measurements in the ionosphere as well as observations of the electromagnetic field of the magnetosphere as made onboard spacecraft.

The lower frequency pulsations have wavelengths comparable to typical scale lengths of the entire magnetosphere. They may also be interpreted as eigenoscillations of or standing waves in the magnetospheric systems. The higher frequency waves are usually identifiable as proton ion-cyclotron waves in the magnetospheric plasma. The amplitudes of the lower frequency pulsations can reach several tens up to hundreds of nanotesla in the auroral zone region while the higher frequency waves reach amplitudes of the order of a few nanotesla.

The first observation of a geomagnetic pulsation was published in 1861 by the Scottish scientist Balfour Stewart who identified quasisinusoidal variations of the geomagnetic field in records of the Kew observatory after the great magnetic storm that occurred in 1859. The International Geophysical Year (1958–1959) with its large

number of coordinated geomagnetic field observations made available a multitude of studies on ULF pulsations, stimulated the interest in this type of geomagnetic field variation and created an active area of research.

The classification scheme (Table G7) of the International Association of Geomagnetism and Aeronomy (IAGA) distinguishes seven different types of geomagnetic pulsations based on their oscillation period and appearance in magnetograms as almost continuous and more irregular pulsations. The two classes, continuous pulsations (Pc) and irregular pulsations (Pi), are usually divided into subclasses. A more detailed overview of this morphological classification was given by Jacobs (1970). Though this classification is still widely in use it is somewhat outdated as the increased understanding of the physical nature and properties of geomagnetic pulsations allows a more indepth classification based on physical processes and generating mechanisms. The long-period pulsations are at present interpreted as magnetohydrodynamic waves while the short-period pulsations are related to ion-cyclotron waves propagating in the magnetosphere. As for many magnetospheric phenomena the solar wind provides the energy for geomagnetic pulsations, partly directly, partly indirectly.

A direct energy source is plasma waves generated in the solar wind and penetrating the magnetopause. A major source of these waves are plasma instabilities in the upstream region of the near-Earth solar wind where, for example, protons reflected at the magnetospheric bow shock constitute an unstable particle distribution, generating a variety of upstream waves. These waves are convected downstream toward the magnetopause and couple through it into the magnetosphere. Detailed investigations, however, indicate that the transmission of hydromagnetic waves through the magnetopause is a rather inefficient process. Only a small percentage of the energy of the upstream solar wind waves couples to oscillations of the magnetosphere.

A more efficient, solar wind-driven process is the impulsive excitation of plasma waves by sudden impulses from the solar wind. The magnetosphere constitutes a kind of body capable of eigenoscillations. It can be excited much like a bell. The British scientist Jim Dungey in 1954 was the first to analyze such eigenoscillations in more detail. Assuming that the magnetospheric magnetic field is of dipole nature only, he studied the magnetohydrodynamic equations of such a dipole-magnetosphere filled with an ionized gas of spatially depending mass density. The boundaries of this magnetosphere are the magnetopause and the ionosphere, where the geomagnetic field lines are anchored much as strings of a violin are anchored between the pegs and the tailpiece.

He derived the so-called Dungey equations, a set of partial differential equations describing the coupling between toroidal oscillations of the fluid velocity field and the toroidal (poloidal) component of the electric (magnetic) field oscillations in this dipole-magnetosphere. If the excitation of the dipole-magnetosphere is axisymmetric, then the toroidal components of these two fields are decoupled. This in turn

**Table G7** The IAGA classification of geomagnetic pulsations

implies that individual field line shells are oscillating independent from each other, much as different violin strings oscillate independently. The oscillation period depends on Alfvén wave velocity along the considered field line. Therefore geomagnetic pulsations can also be used as a diagnostic tool for magnetospheric physics.

This is very much in accord with the observational finding that the periods of geomagnetic pulsations in the Pc4–5 range decrease with decreasing geomagnetic latitude. At lower latitudes the length of field lines anchored between the northern and southern ionosphere is much shorter than at higher latitudes, which causes a smaller oscillation period at low-latitudes. Geomagnetic oscillations can thus be viewed at as standing field line oscillations with fundamental and higher harmonic waves being generated (Figure G36).

Besides an impulsive excitation of geomagnetic pulsations the socalled Kelvin-Helmholtz instability can drive magnetospheric magnetohydrodynamic waves. At the interface between the solar wind plasma and the magnetosphere plasma, the so-called magnetopause, strong shear flows exists. The solar wind plasma has to flow around the magnetosphere along the magnetopause. Much as atmospheric wind flow over a water surface can cause water waves the velocity shear at the magnetopause destabilizes this boundary and causes surface waves which are coupled into the magnetosphere. The energy for these waves is drained out of the solar wind flow and maximum instability of the magnetopause is expected at the flanks of the magnetosphere, which is in the dawn and dusk hours. Furthermore, the unstable waves should propagate tailward that is they propagate east at dusk and west at dawn. This is indeed observed in ground and satellite observations of geomagnetic pulsations.

As the plasma density distribution is not uniform wave propagation in the magnetosphere may lead to a very interesting physical effect, field line resonance or resonant mode coupling. A Kelvin-Helmholtz instability generated wave is a compressional magnetohydrodynamic wave, which couples to a transverse oscillation, an Alfvén wave, at a region in the magnetosphere where the surface wave's period equals the local eigenperiod of the toroidal field oscillation or Alfvén wave. At this resonance point the oscillation magnitude maximizes and the wave phase changes by 180° when crossing the resonant field line in the radial direction. The physics of this resonant mode coupling between a surface wave and a local eigenmodes is actually a tunneling process (Southwood and Hughes, 1983).

Internal to the magnetosphere a variety of wave sources exist. Most important is the ring current region with its energetic protons. Proton distributions are usually nonthermal and tend to thermalize via interaction with electromagnetic waves. These waves in turn can be generated by plasma instabilities such as the so-called bounce-resonance or drift-mirror instabilities (Samson, 1991; Walker, 2004).

The ring current region is also the source region of many of the Pc1-Pc2 geomagnetic pulsations. During the expansive phase of magnetospheric substorms large numbers of energetic ions are injected from the magnetotail into the inner magnetosphere where they drift westward to create the substorm-enhanced ring current. These energetic particle populations are highly unstable against the ion-cyclotron instability and cause the generation of short-period geomagnetic pulsations (Kangas *et al.*, 1998).

Once geomagnetic pulsations have been generated in the magnetosphere their energy must be dissipated somewhere. Most of this dissipation occurs in the ionosphere where the pulsation-associated electric fields cause current flow, which in turn leads to significant Joule heating of the ionosphere. Local kinetic temperature increases of several thousand Kelvin have been observed. Part of the wave energy is also used to accelerate magnetospheric particles. Such high-energy particles may subsequently hit the atmosphere where they can cause aurora.

Much as the terrestrial magnetosphere also magnetospheres of other planets, in particular those of Mercury, Jupiter, and Saturn exhibit magnetic field oscillations comparable to geomagnetic pulsations

**Figure G36** Schematic representation of standing geomagnetic field line oscillations. The perturbed field line is the dashed-dotted line. The electric field always has a node in the ionosphere as large electrical conductivity there shortcuts all electric potential differences.

(Glassmeier *et al.*, 1999). Magnetic pulsations of these magnetospheric systems have different properties than those at Earth due to, for example, different spatial scales of the oscillating system.

## Introduction

It is now well recognized that the geomagnetic field is produced by dynamo action within the molten iron in the outer core. This is a dynamic process intimately linked to cooling of the core and the rapid spin of the Earth. The equations governing the geodynamo, which have to be solved jointly to obtain a full model of the process, are Maxwell's equations, Ohm's law, the Navier-Stokes' equation, the continuity equation, Poisson's equation, the generalized heat equation, and the equation of state for the material in the outer core. This is a complex, nonlinear set of equations, making it extraordinarily difficult to obtain a full solution. However, the equations are even in H, the magnetic field. That is, the equations are insensitive to the sign of H, and so if H is a solution then so also is -H. We know from present-day observations that the geomagnetic field can exist in a relatively stable state in which the field at the Earth's surface is approximately that of a dipole with its axis almost parallel to the Earth's spin axis. Consequently we should expect that there is a similar relatively stable solution, with the same statistical properties as the field we observe today, that simply has the opposite polarity, that is, the north and south poles are swapped. Hence, if there is a mechanism for the field to move from one solution to the other, we should expect to see reversals of the geomagnetic field. The solar magnetic dynamo reverses regularly with a full period of about 22 years (see Magnetic field of Sun), so we know that reversal is possible in other self-sustaining dynamos. This then leaves open the question of how we can tell whether the field has reversed polarity in geological time, well before humans started to observe the field and its behavior.

By at least the late 18th century it was recognized that deviation of magnetic compasses could occur because of nearby strongly magnetized rocks. The first observations that the magnetization in certain rocks was actually parallel to the Earth's magnetic field were made independently by Delesse and Melloni. Folgerhaiter extended their work but also studied the magnetization of bricks and pottery. He argued that when a brick or pot was fired in the kiln then the remanent magnetization it acquired on cooling provided a record of the direction of the Earth's magnetic field. With the wisdom of hindsight it is fairly obvious that this would be the case. Volcanic rocks are heated well above the Curie point so the magnetization is free to align with the external magnetic field and becomes locked in as the rock cools. This is known as a *thermoremanent magnetization* (TRM) (q.v.) and, in extrusive volcanics, provides a record of the direction of the magnetic field at that locality at a specific point in time.

There are several processes by which a rock will lock in a fossil record of the ancient (or paleo) magnetic field. The fossil magnetism naturally present is termed the natural remanent magnetization (NRM) (q.v.) and its existence provides us with an opportunity to discover the direction of the geomagnetic field over geological time. David in 1904 and Brunhes in 1906 reported the first discovery of NRM that was roughly opposite in direction to that of the present field and this led to the speculation that the Earth's magnetic field had reversed its polarity in the past. At that time it was not recognized that the field was generated by a self-sustaining dynamo in the outer core, so the possibility of reversal was more exciting than it may seem from our perspective today. In 1926, Mercanton pointed out that if the Earth's field had in fact reversed itself in the past then reversely magnetized rocks should be found in all parts of the world. He demonstrated that this was indeed the case for Quaternary-aged rocks around the world. The speculation gained further support when Matuyama in 1929 observed reversely magnetized lava flows from the past 1 or 2 Ma in Japan and Manchuria. However, doubts about the validity of the field reversal hypothesis surfaced during the 1950s after Néel presented theory that showed it was possible for samples to acquire a magnetization antiparallel to the external field during cooling, a process referred to as self-reversal. Shortly thereafter Nagata and Uyeda found the first laboratory-reproducible self-reversing rock, the Haruna dacite. Subsequently, it was recognized that self-reversal is relatively rare and by the early 1960s it was accepted that the Earth's magnetic field has indeed reversed and that the phenomenon of field reversal has occurred many times. An excellent history of this subject was given by Glen (1982).

A critical component in our understanding of reversals was development in the early 1960s of the K-Ar dating method, which made it possible to date young volcanic rocks with reasonable precision. Consequently, it was possible to undertake systematic studies attempting to define the geomagnetic polarity timescale (GPTS) using joint magnetic polarity and K-Ar age determinations on young lavas. As data rapidly became available, it was established that rocks of the same age had the same polarity of magnetization, helping to confirm that the observed reversals of magnetization were indeed due to reversals of the geomagnetic field itself. A few of the earliest compilations, covering the years 1959–1966, of the GPTS for the past 4 Ma are shown in Figure G37. Not surprisingly, when the field has the polarity that we observe today, it is referred to as normal polarity, and the opposite polarity is referred to as reverse polarity.

As already noted, the solar magnetic field has a periodic reversal, and the first timescale put forward by Cox *et al.* (1963) appeared to be consistent with geomagnetic reversals having a periodicity of about 1 Ma intervals. However, as new data appeared it rapidly became apparent that there was no simple periodicity; some of the observed polarity intervals were nearly a million years in length and some were as short as 0.1 Ma. Furthermore, there did not appear to be any regular pattern to these different lengths. This led to the suggestion that there is a random component to the reversal process and, therefore, to interest in the statistical structure of the geomagnetic reversal sequence.

It is extremely difficult to solve the geodynamo problem, that is, to determine just how the geodynamo operates. Determination and understanding of the statistical structure of the geomagnetic reversal sequence provides insight into the long-term dynamic process and in so doing can provide powerful constraints on geodynamo models. For example, the observation that the solar dynamo reverses with a clear periodicity but the geodynamo reversal process appears random, is probably a reflection of the different boundary conditions on the two dynamos.

When examining a time sequence such as the GPTS it is crucial that the observed events be ordered correctly. This, together with other difficulties, has led to severe problems with the land-based polarity sequence. As one goes further back in time, the absolute error in dating a rock soon becomes larger than the length of the shorter polarity intervals. Because the land-based information comes from combined observations of magnetic polarity from rocks in widely spaced localities worldwide and not from a single continuous sequence, the ordering relies on the accuracy of the K-Ar dates. Hence, the ordering of events is effectively indeterminate for events closer together than the dating error. Consequently the length of the reliable land-based polarity timescale has been too short for reliable estimation of the statistical structure of the GPTS. Recently however, Kent and coworkers (e.g., Kent and Olson, 1999) have shown the potential for GPTS extension in thick, complete continental sedimentary sections.

The most useful data source for development of the GPTS has been marine magnetic anomalies, and the reversal chronology is now quite well determined for the past 165 Ma. The absolute error in the age assigned to individual reversals will still often be greater than the length of the shorter intervals, but the continuous nature of the data source means that the ordering of events will be correct. Furthermore, because of the way ages are assigned in the marine magnetic anomaly timescales, the lengths of the intervals between reversals will typically be about right.

Naturally though, there are difficulties and problems with the marine magnetic anomaly timescales. As we go further back in time the record is more degraded, so the timescale from 120 Ma back to about 165 Ma is less reliable than that from the present back to 80 Ma. Furthermore, because of subduction of the seafloor, any record prior to about 170 Ma has been destroyed.

A major problem with marine magnetic anomalies is that it is fairly difficult to identify all of the very short intervals, particularly if a short interval appears between two relatively long intervals of the opposite polarity. This had led to significant problems in interpreting the GPTS.

Despite the problems in the marine magnetic anomaly timescales, these provide us with our best GPTS and so analyses of the statistical structure of the geomagnetic reversal sequence have typically been performed on these timescales.

## **Relevant probability distributions**

It has been established that individual reversals take only a few thousand years to complete, which is a short time relative to the average interval between reversals. Thus it is a reasonable approximation to assume that the reversals themselves are instantaneous relative to the time constants of interest. It has already been noted that there appears to be a random component in the reversal process, and so it is sensible to look for a probabilistic description. Consider an interval of time  $\Delta x$ short enough that the probability of having two reversals in  $\Delta x$  is negligible, but with probability of  $\lambda \Delta x$  of having a single reversal in  $\Delta x$ . This is then a Poisson process, and it is a simple matter to show that the probability density p(x) of interval lengths x between reversals is given by

$$p(x)dx = \lambda e^{-\lambda x} dx, \qquad (Eq. 1)$$

where  $\lambda$  is the rate of the process and  $\mu = 1/\lambda$  is the mean interval length.

It is possible to test if the observed distribution of interval lengths is compatible with the Poisson distribution. Initially it was concluded that there was indeed compatibility but after further testing it was suggested that there were too few short intervals in the observed record. Naidu (1971) showed that a gamma distribution provided a good fit to the then observed intervals of the Cenozoic timescale and Phillips (1977) confirmed this in an extensive study of geomagnetic reversal sequences. For a gamma process the probability density p(x) of interval lengths x is given by

$$p(x)dx = \frac{1}{\Gamma(k)} (k\Lambda)^k x^{(k-1)} e^{-k\Lambda x} dx$$
$$= \frac{1}{\Gamma(k)} \lambda^k x^{(k-1)} e^{-\lambda x} dx; \quad \lambda = k\Lambda$$
(Eq. 2)

where the mean interval length is now given by  $\mu = 1/\Lambda = k/\lambda$ .  $\Gamma(k)$  is the gamma function of *k*, given by

$$\Gamma(k) = \int_0^\infty z^{k-1} \mathrm{e}^{-z} \mathrm{d}z \tag{Eq. 3}$$

If k is an integer, then this is just the factorial function of k-1, i.e.,  $\Gamma(k) = (k-1)!$ .

From Eqs. (1) and (2) it is apparent that the gamma process leads to a family of distributions depending on the value of k, and that the Poisson process is simply the special case of a gamma process with k = 1. Figure G38 shows appropriately scaled probability densities for this family of distributions. It is immediately apparent that a gamma process with k > 1 has far fewer very short intervals than a Poisson process.

Statistical tools for analyzing the reversal sequence in terms of a renewal process are given by McFadden (1984a) and McFadden and Merrill (1986, 1993).

## Implications of a gamma or Poisson process

Consider the general probability of a reversal occurring at an interval  $\Delta x$ . Let x be the interval of time since the most recent reversal (i.e., no reversals have occurred in the interval 0 to x), and let  $f(x)\Delta x$  be the probability that a reversal will then occur in the interval x to  $(x + \Delta x)$ . Hence the function f(x) describes how the instantaneous probability for the occurrence of another reversal varies with the time since the last reversal and is given by

$$f(x) = \frac{p(x)}{1 - \int_0^x p(t) dt}$$
 (Eq. 4)

Figure G39 shows  $f(x)/\lambda$  plotted as a function of  $(x\lambda)$ . For a Poisson process the occurrence of a reversal has no impact on the probability of a future reversal. That is, the system has no memory. For k > 1, the probability for a future reversal drops to 0 as soon as a reversal

**Figure G38** Probability densities of gamma distributions plotted against the interval length scaled to the mean length. The k = 1 curve represents a Poisson distribution, which has a relatively large number of shorter intervals compared with the other distributions.

occurs and then gradually rebuilds to its undisturbed value. That is, the system has a memory of the previous reversal and this memory causes inhibition of future events by depressing their probability of occurrence.

## Is the process gamma or Poisson?

As noted above, there may be too few very short intervals in the observed timescale for a Poisson process, but a gamma distribution provides a good fit. Thus it may initially appear as a clear case in favor of a general gamma process, and indeed this was felt to be so for some time. Analysis of early timescales showed that k was quite different for the normal and reverse polarity sequences: at times it was about 4 for the normal polarity sequence while it was close to unity for the reverse polarity sequence. This suggested a substantial asymmetry between normal and reverse polarity, which was surprising when theoretical considerations strongly implied that there should be no asymmetry (see above and *Geomagnetic field, asymmetries*).

However, McFadden (1984a) showed that these estimates of k were not robust and that the actual reversal process is much more likely to be nearly Poisson. Obtaining a reliable GPTS from the marine magnetic anomaly record is not a trivial matter: the major problems relate to accurate dating of the individual events and reliable recognition of the shorter intervals. A small error in the dating of an individual reversal has small consequences. By contrast, there are significant consequences when a short polarity interval is actually missed. When a short interval is not identified it is, in effect, combined with the preceding and succeeding intervals of the opposite polarity. This means that the short interval is missed from its own polarity sequence thereby tending to increase the apparent value of k for that polarity sequence. At the same time, it incorrectly produces a long interval of the opposite polarity that is the sum of the interval preceding the missed short interval, the short interval itself, and the succeeding interval.

McFadden (1984a) has shown that if *n* intervals from a gamma process with index *k* are joined together then the resulting interval appears to have been drawn from a gamma process with index *nk*. Therefore, if the process is Poisson and a short interval is missed, the resulting long interval of the opposite polarity appears to be an observation drawn from a gamma process with k = 3. Hence the parameter *k* can be a fairly sensitive indicator of polarity intervals that have been missed.

McFadden and Merrill (1984) concluded that k for the observed sequence was about 1.25 for the period from about 80 Ma to the

**Figure G40** Estimated reversal rate  $\lambda$  for the past 160 Ma. Constructed from the timescales of Kent and Gradstein (1986) and Cande and Kent (1995), following the methods of McFadden (1984a). From Merrill *et al.* (1996).

present. This suggested that several short intervals had not been identified in the GPTS. McFadden and Merrill (1993) discussed the possible alternative that the reversal process is actually gamma and showed that this would imply that following a reversal the probability for another reversal would be depressed for about 50 ka.

The observed sequence is statistically similar to a sequence that would be obtained by taking a Poisson process with the appropriate rate  $\lambda$  and filtering the sequence so that any interval less than 30 ka in duration is incorporated into the surrounding intervals of opposite polarity. This is consistent with the conclusion of Parker (1997) that the maximum resolution of the GPTS from marine magnetic anomalies is about 36 ka.

Overall it is probably safe to conclude that the reversal process is either Poisson or nearly Poisson, that there is no asymmetry between the normal and reverse sequences, and that the polarity sequence can be considered as a single sequence without regard to the actual polarity of the individual intervals.

## Nonstationarity in the reversal process

Recently the reversal rate has been about 4.5 Ma–1, around 40 Ma it was about 2 Ma–1, and from about 83 Ma back to about 119 Ma there were no reversals, the field having normal polarity. Clearly the rate at which the reversal process occurs has not been constant through time. This is of central geophysical interest because the existence of nonstationarity implies a change in the properties of the origin of the process, typically in the boundary conditions.

Estimates of the reversal rate  $\lambda$ , using the reversal chronology of Cande and Kent (1995) for the interval 0 to 118Ma and that of Kent and Gradstein (1986) for the interval 118–160 Ma, are shown in Figure G40. These estimates have been obtained using a sliding window containing 50 polarity intervals. The Cretaceous Superchron, an interval of about 36 Ma from about 118 to 82 Ma when the polarity was normal and there were no reversals, is very obvious in the sequence and requires explanation.

The characteristic time of these changes is the same as that associated with changes in boundary conditions imposed by the mantle on the outer core (e.g., Jones, 1977; McFadden and Merrill, 1984, 1993, 1995, 1997; Courtillot and Besse, 1987). Suggestions that spatial variations in the core-mantle boundary conditions can affect the reversal rate are now supported by some dynamo theory (e.g., Glatzmaier *et al.*, 1999). The variation in  $\lambda$  shown in Figure G40 led to the interpretation first articulated by McFadden and Merrill (1984), that changes in the core-mantle boundary conditions gradually slowed the reversal process until eventually the process ceased, creating the superchron without any reversals. Gradually the boundary conditions became more favorable for reversals until eventually the reversal process restarted and gradually sped up to its current rate.

Gallet and Hulot (1997), using the same timescales, proposed an alternative nonstationarity. They suggested that the reversal rate had been essentially constant from about 158 to 130 Ma and from about 25 Ma to the present, with an intermediate nonstationary segment including the Cretateous Superchron. However, McFadden and Merrill (2000) developed a statistical test that showed that the data demanded the trends identified in Figure G40. Subsequently, using the methodology developed by McFadden and Merrill (2000), Hulot and Gallet (2003) analyzed the Gradstein et al. (1994) and Channell et al. (1995) timescales. These timescales update the pre-superchron information. Hulot and Gallet (2003) concluded that these newer timescales show no long-term trend in reversal rate leading into the superchron. Indeed, they suggest that the only precursor to the superchron was perhaps a single unusually long interval (CM1n) just before the superchron. If this is confirmed by future timescales then the interpretation of the causes of the superchron will naturally change.

There is some fine structure observable in Figure G40, and the question arises as to whether this structure is meaningful. Several authors (Mazaud *et al.*, 1983; Negi and Tiwari, 1983; Raup, 1985; Stothers, 1986; Marzocchi and Mulargia, 1990; Mazaud and Laj, 1991; Rampino and Caldeira, 1993) have suggested either a 15- or a 30 Ma periodicity in the reversal chronology record. Hulot and Gallet (2003) have recently suggested a 20 Ma periodicity. Clearly the perceived periodicity is not robust. McFadden (1984b) showed that similar apparent periodicities are produced when using fixed-length sliding windows to analyze a Poisson process with a linear trend in the reversal rate, but that such periodicities are not observed when using sliding windows with a fixed number of intervals (McFadden and Merrill, 1984). Lutz (1985), Stigler (1987), McFadden (1987), and Lutz and Watson (1988) all showed that the perceived periodicities are more likely an artifact of the methods of analysis than real geophysical phenomena.

It is now widely accepted that the Earth's magnetic field is generated by electric currents in the iron-rich liquid outer core. A dynamo process converts the energy associated with fluid convection within the Earth's core into magnetic energy. At the surface of the Earth, the field varies on timescales that range over more than 18 orders of magnitude, from less than a millisecond to more than 100 Ma. The most dramatic field variations are reversals. Almost exactly one century ago, Bernard Brunhes (1903, 1905) and his colleague David measured the magnetization of a lava flow, which was magnetized in the opposite direction to the present field. After investigating several possibilities, they convinced themselves that this resulted from a magnetic field with its magnetic north pole close to the south geographic pole. In other words the field would have been flipped in the opposite configuration to the present field with its south magnetic pole (in contrast to the current belief the pole referred as the north magnetic pole is actually a south pole which attracts the northern edge of the magnet) close to the north geographic pole. It took about 50 years before the existence of the geomagnetic reversals was established. Between 1925 and 1935 the discovery of new reversely magnetized rocks from different continents convinced the Japanese Matuyama (1926, 1929) and the French scientist Mercanton (1931) of their existence. However Louis Néel (1955) and his colleagues reported that reversely magnetized rocks could result from specific arrangements of the atoms lattices and the Japanese Uyeda (1958) observed this mechanism in a dacite from Mount Haruna. Further work demonstrated that this process was actually associated with specific chemical configurations and thus very rarely met in natural rocks. In the meantime, dating using new radiometric techniques indicated that rocks of the same age had the same polarity. Hence, it was obvious that the presence of reversed magnetization was a worldwide phenomenon, not caused by self-reversing processes. The discovery of the geomagnetic reversals allowed also understanding why the basaltic seafloor magnetization was organized in alternances of positive and negative giant anomalies parallel to the ridge axis. This pattern actually reflects the succession of the two polarities of the geomagnetic field, which were initially recorded at the ridge axis and then pushed away by the spreading seafloor.

## Geomagnetic polarity timescale and the duration of reversals

The first reversals were dated using the ages derived from land sequences. This yielded the construction of the first geomagnetic polarity timescale (GPTS), which covered the past 5 Ma (Cox *et al.*, 1963). Using the ages of these individual reversals, it was then possible to interpolate or to extrapolate on the basis of the width of the marine magnetic anomalies, which led to extend the timescale over the past 160 Ma (Figure G41). Beyond this period, we are faced to the absence of magnetic anomalies. During the past 20 years much activity has been devoted at studying long sequences of exposed sediments or lava flows in order to build up the polarity timescale for the older periods.

The succession of polarity intervals during the past 160 Ma shows the existence of periods of high reversal frequency, which alternate with periods of low frequency. The mean reversal frequency is of the order of 1 reversal per million years and the maximum value does not seem to exceed 6 reversals per million years. During the period extending from 118 to 83 Ma, the field remained in a virtually uninterrupted normal state. These 35 Ma in the upper Cretaceous are known as the "Cretaceous normal superchron (CNS)" (between 120 and 83 Ma). Before the Kiaman reversed superchron stretches undisturbed for 50 Ma from the late Carboniferous to the middle Permian (between 310 and 260 Ma). The period between these two superchrons looks very much like the magnetic record that has followed the CNS. A third superchron, although apparently shorter in duration (20 ka), has been proposed from magnetostratigraphic studies (Pavlov and Gallet, 1998). Thus, in the present state of knowledge superchrons can be seen as a constant characteristic of the polarity timescale. It was frequently claimed that the slow decrease of reversal frequency before the Cretaceous superchron (McFadden and Merrill, 1995) would led to the superchron, thus resulting from a long-term influence of the mantle dynamics on core convection. Recent analysis (Hulot and Gallet, 2003) has shown that no long-term behavior over the 40 Ma preceding the Cretaceous superchron can be seen in the reversal rate that could be invoked as announcing its occurrence 120 Ma ago.

Superchrons might correspond to times when the process responsible for geomagnetic reversals passed below a certain critical threshold, and reversals could start again when that threshold was exceeded again. Other analyses suggest that the superchrons indicate the existence of a nonreversing state of the geodynamo in contrast to its reversing state. Alternatively, changes between the two processes may depend on factors directly connected to the boundary conditions, such as the distribution of heterogeneities within the "D" layer (just above the core-mantle boundary) that affect the flow pattern within the core and therefore may not be related to the intrinsic time constants of the geodynamo.

340

The time span between two successive reversals appears to be random. Many statistical analyses were aimed at detecting periodicities or recurrent features, which would be hidden behind the succession of reversals. The succession of polarity intervals is closely approximated by a Poissonian distribution or at least by a gamma process if one assumes that short events have been missed in the reversal sequence. One can always consider that subsequent refinement of the reversal sequence can change this view. A critical aspect is the presence of field excursions which large deviations from the geocentric axial dipole during periods of very-low-field intensity. Excursions and reversals share common characteristics, which suggest that they could be treated as manifestations of similar processes within the core. In fact many authors proposed that excursions must be seen as aborted reversals whereas others regard them as intrinsic secular variation in presence of a weak dipolar field. In the first case, they should be treated at the same level as reversals in the statistics, which would provide a very different picture of the field. A critical point to answer these problems would be to determine whether excursions existed during the superchrons.

#### Dating reversals and estimating their duration

The age of the successive reversals is critical for analyzing their succession. As described earlier most reversals were dated by extrapolating the ages of the recent reversals after combining the spreading rates. Very significant progress was accomplished during the past 20 years with the discovery that carbonated sediments revealed the succession of the orbital cyclicities of the Earth (23 ka). The ages of the Pliocene and Pleistocene reversals were refined by using this independent method (Shackleton et al., 1990; Tauxe et al., 1992, 1996; Channel and Kleiven, 2000) which relies on correlating climate proxies (such as oxygen isotope ratios, susceptibility or density variations ... or simply counting the astronomical cycles recorded in continuous sedimentary sequences) with calculated variations of the Earth's orbit. Using seafloor spreading rates for five plate pairs, Wilson (1993) has shown that the errors in the astronomical calibration are not greater than 0.02 Ma (which corresponds to a precessional cycle of the Earth's orbit) and also that spreading rate can remain constant for several million years.

A critical question that comes to mind is how long it takes for the field to reverse from one polarity to the other. Before dealing with this aspect, it is important to determine when a reversal starts and when it ends. There are many observations showing successions of large oscillations (Hartl and Tauxe, 1996; Dormy et al., 2000) preceding or following polarity changes, and it is not clear whether or not they should be incorporated in the reversal process. Such oscillations can be linked to enhanced secular variation in presence of low dipole field. Alternatively, they can be considered as successive attempts by the field to reverse. Important also is the definition of a transitional direction, which must exceed the normal range of secular variation (i.e., the range of the field variations during periods of polarity). Limits on the virtual geomagnetic pole (VGP) latitudes have been mostly used since it is rare that VGPs reach latitudes lower than 60°, although a strict definition should be restrained to positions lower than 45° (episodes of large secular variation can occasionally reach these latitudes).

The sharp transition between magnetic anomalies of opposite polarities, the very narrow thickness of the intervals recording sedimentary columns as well as the small number of lava flows with directions being unambiguously identified as "intermediate" between the two polarities were rapidly convincing and strong evidences that reversals are short phenomena on a geological timescale. The data recorded from the best continuous and documented sedimentary sequences indicate that the jump between the two polarities is shorter than one precessional cycle (23 ka). If we refer to radiometric dating (e.g., K-Ar or Ar-Ar techniques) of lava flows, the problem is delicate because of the sporadic succession of the flows characterized by pulses of eruptions occurring over a short period and long intervals without any magmatic event. A direct consequence is that sequences of lavas provide only very partial records of one or several phases of the reversal but not the entire process. Finally and even more critical is the fact that uncertainties on the ages cannot be ruled out as this is clearly illustrated by the large number of studies performed on the last reversal (Brunhes-Matuyama). The compilation of K-Ar and/or Ar-Ar dating (Quidelleur et al., 2003) for 23 volcanic records indicates an age of  $789\pm8$  ka (total error). The tuning of the  $\delta^{18}O$  records from sedimentary sequences to orbital forcing models gives an age of 779  $\pm$  2 ka (Tauxe et al., 1996). Recently, Singer et al. (2005) mentioned that the astronomical determination is close to the age of the lavas from Maui (Hawaii) (776  $\pm$  2 ka), and therefore that the other volcanic records are related to the onset of the transitional process. Consequently they deduce that a field reversal would require a significant period. One can oppose that there is no reason to consider that the onset of the reversal was initiated at the same time everywhere but above all if we consider the total uncertainties on the ages, there is no significant difference. Actually this uncertainty leaves doubts as to the possibility of constraining the duration of the transition with precision. There is also no reason to consider that all reversals have the same duration. Most studies converge to estimates between 5 and 10 ka but durations as short as 1 ka or as long as 20-30 ka have been proposed also. Clement (2004) recently analyzed the four most recent reversals recorded in sediments with various deposition rates and found a mean average duration of 7 ka for the directional changes (Figure G42). An interesting characteristic is that the mean duration seems to vary with latitude, as expected from simple geometrical models in which the nondipole fields are allowed to persist while the axial dipole decays through zero and then builds in the opposite direction.

## The reversing field

#### Recorded by sediments

There has been a great deal of speculations concerning the processes governing field reversals. In order to decipher the mechanisms it was important to focus on the morphology of the field during the transition from one polarity state to the other. The first major step was to determine whether this "transitional" field would keep its dipolar dominant character. To achieve this goal, the paleomagnetists took advantage of

**Figure G42** (a) Geographical distribution of Matuyama-Brunhes transitional VGPs derived from a selection of sedimentary records of the last reversal (from Clement, 1991). (b) Longitudinal distribution of transitional VGPs plotted as the number of transitional VGPs in a sliding 30° wide longitude window. Note the presence of two peaks over the American and Asian continents.

the concept of the VGP, which defines the position of the pole assuming that the field is dominantly dipolar. The idea was very simple. If the field remained dipolar, then any vector at the surface of the Earth would point toward the same pole following the rotation of the dipole with its north (south) pole passing to the (south), while in the opposite situation the poles would be different at any site. Using the first records from sediments, it was rapidly shown that the field was not dipolar during reversals (Dagley and Lawley, 1974; Hillhouse and Cox, 1976). In the meantime the first records of paleointensity established that the field intensity was systematically very low during the transitions. This decrease in dipole intensity is necessary before directions depart significantly from dipolar ones (Mary and Courtillot, 1993) and therefore consistent with the concept of a nondipolar field. The nature of this nondipolar field is one of the major questions to elucidate.

Two objectives were pursued in order to provide some answers to this question-the first one relied on the acquisition of multiple records of the same transition. It was proposed that because the Earth's rotation keeps a major role in field regeneration the transitions would be dominated by axisymmetrical components (quadropolar or octupolar). This suggestion could be tested at least at the first order by referring again to the useful concept of the VGPs. Indeed to satisfy the axial symmetry, the VGPs always follow the great circle passing through the observation site (or its antipode), which implies to study the same reversals at different sites. Records from sediments were appropriate because the transitions can be identified without ambiguity and thus correlated from widely separated sites. In the meantime the development of cryogenic magnetometers was very helpful as they provided the possibility of measuring weakly magnetized sediments. The results established that the VGP trajectories were effectively constrained in longitude but in many cases 90° away from the site meridian rather than centered above it.

The second objective was to investigate whether successive reversals were characterized by some recurrent or persistent features. This required studying sequences of reversals at the same site. Again long sequences of marine sediments were appropriate for this kind of study as well as the use of VGP paths, despite the dominance of nondipolar components. The most appealing observation emerged from a selection of sedimentary records (Clement, 1991; Tric et al., 1991), which were all showing VGP paths within two preferred longitudinal bands, over the Americas and eastern Asia. Going one step further Laj et al. (1992) noted that these areas coincide with the cold circum Pacific regions in the lower mantle (outlined by seismic tomography), thereby suggesting that density or temperature conditions in the lower mantle could control the geometry of the reversing field. However, this observation was controversial because it relied on a selection of records. Another intriguing characteristic (Valet et al., 1992; McFadden et al., 1993) was the fact that these VGP paths were also found 90° away from the longitude of their sites despite their relatively wide geographic distribution (Figure G43), which could suggest some artifacts in the recording processes. Several studies effectively questioned the fidelity of sediments as recorders of the field variations, particularly during periods of low field intensity. Many factors (compaction, alignment of the elongated particles) reduce the inclination of the magnetization, a process that moves the VGPs paths far away from the longitude of the observation sites (Rochette, 1990; Langereis et al., 1992; Quidelleur and Valet, 1994, 1995; Barton and McFadden, 1996,). There is also some indication that for some sediments the magnetic torque generated by a weak field is too low to provide accurate orientation of the magnetic grains, leaving in this case a prominent role to the hydrodynamic forces. These problems suggest that sediments could not be as appropriate as it was originally thought to study reversals.

## Recorded by volcanic lava flows

One must thus turn toward volcanic records keeping in mind that in this case we are faced to the very discontinuous character of the

**Figure G43** Distance between the mean longitudes of the virtual geomagnetic poles (VGPs) and their site meridian. Note that most lie 90° away from their site longitude.

eruption rates. Following the presentation of preferred longitudinal bands, Prévot and Camps (1993) compiled all volcanic records with VGPs latitudes lower than 60°, considering only one position for poles that were identical or very close to each other. They observed that no preferred longitudinal band emerged from this database. Love (1998) questioned this interpretation, arguing that similar directions from successive flows should not be averaged, because they do not necessarily result from a very rapid succession of eruptions. Instead he treated each individual flow as a single time event (implying no correlation between successive flows (Figure G44), or identically that the duration between flows was larger than the typical correlation times of secular variation). Because VGPs obtained from volcanics can reach latitudes as low as 45-50° during episodes of large secular changes (and of course excursions), it is also important to restrain the analysis to the most transitional directions, i.e., those with VGP latitudes less than 45°. Unfortunately in this case the number of points becomes too small to perform any robust analysis. This illustrates the difficulties of finding detailed records of reversals but also implies and confirms that indeed transitions occur very rapidly.

Using another selection of records, Hoffman (1991, 1992, 1996) pointed out the existence of clusters of VGPs in the vicinity of South America and above western Australia. Because of the apparent longevity of these directions they were interpreted as indicating the existence of a persistent inclined dipolar field configuration during the reversal process. This is an attractive suggestion, which would establish some link between the sedimentary and the volcanic records but limited to a selection of data.

It is striking that these interpretations depend on the chronology of the lava flows. Volcanism is mostly governed by short periods of intense eruptions alternating with quiet intervals. It is usually admitted that the active periods can be very short with respect to the intervals of quiescence. An indirect "magnetostratigraphic" indication has been given by three parallel sections of Hawaii (Herrero-Bervera and Valet, 1999, 2005), which are not distant, by more than a few kilometers. They all recorded the same reversal but do not show the same successions of transitional directions. Clusters of similar directions can be present in one section without being recorded 2 km away. Similarly apparent rapid changes can be observed in detail in one case and be absent 2 km away. In the first case, the field remained in the same position during a period short enough for not being recorded in the

**Figure G44** (a) Map of gray-scale histogram of the VGPs from volcanic lava flows with latitudes that are low enough for being considered as transitional (from Love *et al.*, 1998). (b) Histogram showing their longitudinal distribution. All lava flows were considered and thus not necessarily incorporated within a sequence of overlying flows. The similar directions that could be linked to a phase of rapid volcanic eruptions were considered as a result of a random process and thus were all taken in consideration. The database is strongly dominated by Icelandic lava flows.

nearby section. In the second case, the field variations occurred either over a short time interval or the field moved very rapidly and was thus recorded only at a single location. Thus we cannot rule out that the apparent concentrations of VGPs close to South America and western Australia can be purely coincidental so that it cannot be considered yet as certain that long-lived transitional states represent an actual characteristic of the reversing field.

Another approach is to rely exclusively on volcanic records with well-defined pre- and posttransitional directions and a sufficient number of intermediate directions. These records are more significant in terms of transitional field characteristics because they are not associated with uncertainties about the origin of the directions and their stratigraphic relation. The distribution of poles extracted from this limited database does not display any preferred location, nor does it show any evidence for systematics in the reversal process (Figure G45). Note also the presence of clusters at various longitudes and latitudes.

Despite the difficulties inherent to the interpretation of sedimentary and volcanic transitional directions, the two kinds of data may share some common characteristics. We already noted a possible link between the volcanic clusters and the preferred VGP paths in sediments but outlined some difficulties in reconciling these two aspects. Another important issue is that the two kinds of records are associated with very different timing in the acquisition of their magnetization, the almost instantaneous cooling of the lavas being almost opposite to the slow processes governing the lock-in of magnetization in sediments. It is thus more justified to attempt a comparison by considering sediments with very high deposition rates in order to reach a better resolution (for magnetization acquisition) thus closer to the volcanic characteristics. A few detailed sedimentary records with deposition rates exceeding 5 cm per 1 ka have been published (Valet and Laj, 1984; Clement and Kent, 1991; Channell and Lehman, 1997). A dominant and common characteristic is that they display a complex structure with large directional variations preceding and/or following the transition which reminds the features seen in the volcanics (Mankinen et al., 1985; Chauvin et al., 1990; Herrero-Bervera and Valet, 1999). These large loops share similarities with the secular variation of the present field. This observation reinforces the simplest model initially suggested by Dagley and Lawley (1974) of a rather complex transitional field which would be dominated by nondipole components following the large drop of the dipole field (Valet et al., 1989; Courtillot et al., 1992).

**Figure G45** Positions of the VGPs derived from the most detailed volcanic records of reversals published so far. In contrast with Figure G44 no Icelandic sequence of superimposed flows met the selection criteria. Note also the large number of clusters (surrounded by circles) at various locations of the globe.

The existence of fast impulses during the 16 Ma old reversal recorded at the Steens Mountain in Oregon (Mankinen *et al.*, 1985) was suggested from a puzzling progressive evolution of the paleomagnetic directions in the interiors of two transitional lava flows (Coe and Prévot, 1989; Camps *et al.*, 1999). Each lava unit recorded a complete sequence of directions going all the way from that of the underlying flow to the direction of the overlying flow. In the absence of any clear evidence for anomalous rock magnetic properties, these features have been interpreted in terms of very fast geomagnetic changes, which would have reached 10° and 1000 nT per day. For comparison values typical of the present-day secular variation of the field (of internal origin) are of the order of  $0.1^{\circ}$  and 50 nT per year, i.e., some  $10^4$  times slower. In this specific case the timing of these fast changes can be constrained by estimates of the cooling times of individual flows.

However, such rapid changes do not seem to be compatible with accepted values of mantle conductivity (Ultré et al., 1995). As a consequence this interpretation of the magnetization generated exciting controversy. Additional detailed investigations have been conducted in order to see whether this situation could not have arisen because of remagnetization of the flows. Remagnetizations of lava flows, yielding complex or unusual directions, have been detected at several locations where reversals have been recorded. A first interesting example was given by Hoffman (1984) from Oligocene basaltic rocks. Valet et al. (1998) observed the coexistence of both polarities (with similar characteristics as for the directions recorded at Steens Mountain) within flows marking the last reversal boundary (0.78 Ma) at the Canary Islands, and also in a lava flow associated with the onset of the upper Réunion subchron (2.13 Ma) in Ethiopia. In these cases, a purely geomagnetic interpretation would imply that a full reversal took place in only a few days. Similarly to the Steens Mountain, there is no striking difference between the rock magnetic properties of these units and the rest of the sequence, but a scenario involving thermochemical remagnetization is not incompatible with the results. Thermochemical magnetic overprinting can be particularly serious when it affects a flow emplaced at a time of very low field intensity, sandwiched between flows emplaced at a time of full (stable polarity) intensity. Recent investigation of additional flows at Steens did not shed more light on this problem but rather casts doubts on a geomagnetic interpretation of the paleomagnetic directions (Camps et al., 1999). Therefore, the existence of very large and rapid changes that have been documented from a single site by a unique team remains controversial. In the meantime no alternative explanation has been completely accepted yet.

#### Field intensity variations across reversals

Variations in field intensity accompanying the reversals provide important and unique information concerning the transition itself but also the evolution of the dipole prior and after the reversals. We mentioned earlier that a significant decrease of the dipole was reported since the earliest studies. It is well established, based on all sedimentary as well as volcanic records that field intensity drops significantly and in most cases these changes last longer than directional changes (see e.g., Lin et al., 1994; Merrill and Mc Fadden, 1999). Note that similar drops have been mentioned in all records of excursions with one exception (Leonhardt et al., 2000). Initially, the records were restrained to the transitional interval or to a few thousand years preceding and following the reversal. Several long records of relative paleointensity have now been obtained using sequences of deep-sea sediments, which make possible to observe the evolution of the field over a long period. These independent records from sediment cores in different areas of the world can be stacked together to extract the evolution of the geomagnetic dipole moment (Guyodo and Valet, 1996, 1999; Laj et al., 2000). There is a remarkable consistency between the first stacks published for the past 200 and 800 ka and a similar approach performed from field measurements immediately above bottom seafloor magnetic anomalies (Gee et al., 2000). There is also a good agreement with the cosmogenic isotopic records (Frank *et al.*, 1997; Baumgartner *et al.*, 1998; Carcaillet *et al.*, 2003, 2004; Thouveny *et al.*, 2004). Apart many other interesting observations a dominant feature is the existence of a large drop of intensity about every 100 ka, which coincide with excursions reported from various sequences in the world.

The most recent curve of relative paleointensity was extended to the past 2 Ma (Valet et al., 2005) and is in good agreement with the absolute dipole moments derived from volcanic lavas, which were used for calibration. It shows that the time-averaged field was higher during periods without reversals but the amplitude of the short-term oscillations remained the same. As a consequence, few intervals of very low intensity and thus less instability are expected during periods with a strong average dipole moment, whereas more excursions and reversals are produced during periods of weak field intensity. Prior to reversals, the axial dipole decays during 60 to 80 ka, but rebuilds itself in the opposite direction in a few thousand years at most (Figure G46). The most complete volcanic records confirm that recovery following a transition is short and culminates to very high values. The detailed volcanic records including determinations of absolute paleointensity provide support for such an asymmetry. Strong posttransitional field values have been reported in a Pliocene reversal recorded at Kauai (Bogue and Paul, 1993) and in the upper Jaramillo (0.99 Ma) subchron recorded from Tahiti (Chauvin et al., 1990) as well as for the lower Mammoth reversal (3.33 Ma) from Hawaii (Herrero-Bervera and Valet, 2005). The same characteristics emerge also from the 60 Ma oldest record obtained so far in Greenland (Riisager and Abrahamsen, 2000), from the 15 Ma old Steens Mountain reversal (Prévot et al., 1985) and from the last reversal (0.78 Ma) recorded from La Palma in the Canary Islands (Valet et al., 1999).

## Conclusion and perspectives

Several hundreds reversals have been documented from geological records and it is not unlikely, yet not demonstrated, that reversals always accompanied the existence of the geomagnetic field. Their internal origin neither makes any doubt. Many numerical models for the Earth's dynamo were produced during the last decade, including three-dimensional self-consistent dynamos that exhibit magnetic reversals. However, mostly for computation difficulties the parameters used remain far away from the Earth. This demonstrates the importance of

**Figure G46** Field intensity variations across the five reversals occurring during the past 2 Ma. In this figure we superimposed the changes in dipole moment during the 80 and 20 ka time intervals, respectively preceding and following each reversal. Note the 60–80 ka long decrease preceding the reversals, and the rapid recovery following the transitions.

accumulating data. For about 30 years the paleomagnetists attempted to acquire as many detailed records as possible using the magnetic memory of sediments and lava flows. One of the first objectives was to determine whether the field keeps its dipolar character when reversing. The complexity of the directional changes shown by the detailed records and the large decrease of the field intensity indicates that the dipolar component strongly decreases by at least 80%, if not vanishing completely. One of the major constraints is the rapidity of the reversal process. There is no clear estimate for reversal duration, which may vary. Indeed it seems easier to isolate transitional directions for some reversals than for some others. There is no estimate for a lower limit of the duration of a transition which could be as short as a few hundreds years, if not less. It is reasonable to consider that the upper limit does not exceed 20 ka. After many years the suitability of sedimentary records (which have the advantage of preserving continuous information on field evolution) has been heavily questioned because their direction of magnetization can be affected by other factors (climate, alignment of the magnetic grains, postdepositional reorientations), particularly in presence of low field intensity. It is thus wise to turn also toward volcanic records despite their intrinsic limits in terms of resolution and dating. If we refer to the existing volcanic database, different views are presently defended regarding the field configuration during the short transitional period. Some claim that there is a dominance of the pole positions within preferred longitudinal bands, particularly within the American and Australian sectors, while others oppose rock magnetic artifacts and defend that the distribution of the transitional directions is typical of a nondipole field that would be similar to the present one. These two views have different implications and impose different constrains. The first one assumes that the lower mantle exerts some control on the reversal processes while the alternative interpretation defends that the transitional field would result from intrinsic processes linked to the dynamic of the core fluid. Another aspect is the existence of precursory events. The complexity of the field evolution prior to reversals depicts some "excursions" of the directions that are interpreted as precursory events. This observation can be linked to the long-term decay of the dipole component prior to the reversal, which is responsible for the complexity of the directional changes observed at the surface. Under this scenario the "precursory" excursions simply reflect the dominance of the nondipole part of the field, which will then prevail during the transition. Finally, a fast and strong recovery takes place immediately after the transition. The amplitude of this restoration phase is certainly critical as recent observations suggest that the dipole field strength could be a dominant factor controlling the frequency of reversals.

## **GEOMAGNETIC SECULAR VARIATION**

#### Introduction

The term *secular* comes from the Latin *Seculum* which means the duration of the influence of a powerful family becoming steadily less. The Romans accounted 100 years for that, why it also was synon-ymous for century. In context of geomagnetism it implies a long-term variation of the Earth's magnetic field.

The observed temporal variations of the Earth's magnetic field cover timescales from milliseconds to a few million years and originate in two distinct (external and internal) source regions with respect to the Earth's surface. With this respect the fluctuations of the external field ranges from milliseconds to a few decades, where the longer periods are related to variations of the solar magnetic field, e.g., the turnover of solar magnetic field (about 22 years). Changes of the internal field are of the order of a few years to millions of years. This variation results from the effect of magnetic induction in the fluid outer core and from effects of magnetic diffusion in the core and the mantle. Here, we distinguish geomagnetic secular variation and paleomagnetic secular variation, where the latter includes temporal changes longer than several hundreds of years, such as reversals (see Reversals, theory). The overlap of periods of internal and external sources in the range of a few years to decades can be separated in internal and external contributions applying spherical harmonic analysis (see Internal external field separation).

The geomagnetic secular variation was first noticed by Gunter and "Gellibrand" in 1635, who collected measurements of magnetic declination made at Limehouse near London between 1580 and 1634. This component gradually changed over the period of 350 years from  $11^{\circ}$ E to  $24^{\circ}$ W in 1820, before turning eastward again. Figure G47 shows the declination measured in London and Danzig (Gdansk) for about 350 years. Whereas the main field is dominated by its dipolar nature, the secular variation is clearly nondipolar, which is reflected in regions of different magnitudes of secular variation. For example, in the pacific region the secular variation has been observed to be the feature of the main field and not of the local field.

One other prominent feature of the secular variation is the tendency of isoporic foci (areas of maximum secular variation) to drift westward. Analyzes by Vestine *et al.* (1947) and Bloxham *et al.* (1989) found an averaged drift rate of about  $0.3^{\circ}y^{-1}$ .

In addition to the slowly varying secular variation event-like features appear, the so-called geomagnetic jerks. Such jerks show up as a change of sign in the slope of the secular variation, a discontinuity in the second time derivative of the field, most clearly seen in the east (Y) component of the geomagnetic field. For the last 100 years at least seven jerks have been reported (1912, 1925, 1969, 1978, 1983, 1991, and 1999), some of them of global extent. The 1969 event (first described by Courtillot et al., 1978) was widely investigated; on the basis of observatory records. Courtillot et al. (1978) and Malin and Hodder (1982) showed its global extent, although it was not evident in all field components. This fact and the coincidental occurrence of jerks and sunspot maxima set off a lively discussion between Alldredge and McLeod in the 1980s (Alldredge, 1984; McLeod, 1985; Backus et al., 1987) about the causative processes of jerks. The general understanding is that jerks are of internal origin, mainly because of two reasons: First, the potential of the solar cycle has approximately the form of zonal spherical harmonics, therefore any contribution to the East component would be small. Jerks are most clearly visible in the East component of European observatories. The second argument is based on a comparison of the strength of the solar maxima adjacent to the 1969 jerk, 1958 and 1980. At both epochs the solar maxima were more pronounced than in 1969, so we would expect two jerks at those epochs, but nothing obvious happened in 1958 and the jerks around 1978 and 1983 do not fit well to the solar maximum in 1980 (see also entry on Geomagnetic jerks).

#### Determination of secular variation models

Before considering the generation of secular variation and its link to other observables of processes in the Earth's core, we shall first describe a modeling approach to map the secular variation at the source region, the core-mantle boundary (CMB).

In principle, the magnetic field and its variation can be separated in parts due to external and internal sources by spherical harmonic analysis (Gauss, 1839). The geomagnetic field is then represented by the so called Gauss coefficients (see entries on *Internal external field separation and Main field modeling*). The variations of the internal field can be modeled by expanding the internal Gauss coefficients in a Taylor series in time about some epoch,  $t_e$ , e.g.,

$$g_l^m(t) = g_l^m(t_e) + \dot{g}_l^m(t_e)(t - t_e) + \ddot{g}_l^m \frac{(t - t_e)^2}{2!} + \cdots$$
 (Eq. 1)

where the first time derivative  $\dot{g}_l^m$  is the secular variation and the second time derivative  $\ddot{g}_l^m$  the secular acceleration. The determinations usually have been truncated after some derivatives. The GSFC(12/ 66) model (Cain *et al.*, 1967) included second time derivatives and the GSFC(9/80) model of the magnetic field between 1960 and 1980 by Langel *et al.* (1982) included third time derivatives. These

Figure G47 The declination at London and Danzig (Gdansk).

representations are only adequate to represent the temporal variation over short periods, e.g., the GSFC(9/80) is only sufficient for the period 1955–1980. Outside this period the misfit increases drastically.

An alternative attempt to model the secular variation was put forward by Langel *et al.* (1986). The methodology is to model the secular variation directly from first time derivatives of observatory annual means. For example, using the differences between annual means for different years, i.e.,  $\dot{X} = \Delta X / \Delta t$ . Then performing with those  $\dot{X}, \dot{Y}, \dot{Z}$  spherical harmonic analysis. Langel *et al.* (1986) achieved a continuous representation of the secular variation model for 1903 to 1982 by fitting each coefficient with cubic B-splines.

In a series of publications Bloxham (1987); Bloxham and Jackson (1989); Bloxham and Jackson (1992) developed a method which gives the most favorable description of the secular variation. This method bases on the simultaneous construction of a time-dependent model of the secular variation and main field. Their description of the time-dependent geomagnetic potential at the CMB follows:

$$V(r,\theta,\phi) = \sum_{l=1}^{L} \sum_{m=0}^{l} \sum_{n=1}^{N} \left(\frac{a}{c}\right)^{l+2} (l+1) \times (g_{l}^{mn} \cos(m\phi) + h_{l}^{mn} \sin(m\phi)) P_{l}^{m} (\cos\theta) M_{n}(t),$$
 (Eq. 2)

where *a* is the Earth' radius, *c* is the radius of the Earth's core,  $M_n(t)$  are the temporal basis functions, i.e. cubic B-splines. The expansion (2) involves coefficients  $\{g_l^{mn}, h_l^{mn}\}$  which are related to the standard Gauss coefficients  $\{g_l^m, h_l^m\}$  by

$$g_l^m = \sum_{n=1}^N g_l^{mn} M_n(t)$$
 (Eq. 3)

and for the  $h_l^m$  likewise. The model is derived to meet some constraints, first it should be spatially smooth. Spatial smoothness, for instance could be controlled by the minimum ohmic dissipation based on the ohmic heating bound of Gubbins (1975). The second constraint to meet is the temporal smoothness of the model, which can be controlled by minimizing the second time derivative of the radial component of the field at the CMB. Further constraints, invoking satellite field models for certain epochs are conceivable as shown by Wardinski (2005) (see entry on *Time-dependent models of the geomagnetic field*).

## Periodicities in the geomagnetic secular variation and related phenomena

An analysis of the geomagnetic activity and the solar activity reveals periods which can be attributed to the effect of the sunspot cycle. These periodicities are linked to external field variations, such as fluctuation of the strength and position of the ring current and variations of the strengths of current systems in the magnetosphere. Therefore, geomagnetic field variations exhibit nearly the same periods. If we assume that the effect of sunspot cycle and its harmonics is independent of observatory longitudes, then the effect can be approximated by a series of zonal harmonics. We would expect that these contributions dominantly map into the first degree Gauss coefficients of the internal field. Langel *et al.* (1986) found evidence that some of the periods also exist in higher degree secular variation coefficients  $(\dot{g}_l^m, \dot{h}_l^m)$ . It is most likely, that this is due to induction in the mantle.

Beside the periods related to solar variations there exists a bundle of periods which are supposed to be inherent features of the geomagnetic secular variation. One prominent long period is the 23 (22.9) years period. It is found in the data of geomagnetic observatories (Alldredge, 1977b) as well as in secular variation coefficients (Langel *et al.*, 1986). Although the closeness of this period with the double solar cycle period may refer to a common cause, the origin of the 23 years period seems to be internal. Alldredge (1977b) showed that it does not appear in all analyzed observatories and is not in phase at those observatories at

which it is present. Further, Langel *et al.* (1986) argued for an internal origin, because it is only present in a few secular variation coefficients, namely  $\dot{g}_{1}^{2}, \dot{g}_{2}^{2}, \dot{h}_{3}^{3}$ .

The picture is less clear when considering longer periods such as the 60 years period. Slaucitajis and Winch (1965) provided evidence of this period by an analysis of five observatory data sets. They found an averaged period of  $61 \pm 6$  years. These results were confirmed by Jin and Jin (1989) with a slightly different period of  $60 \pm 12$  years, where the uncertainty is due to an average of the results from an analysis of inclination and declination data. But its true nature is not clear since the match with a period of about 60 years in geomagnetic activity and sunspot numbers suggests an external origin which may cause an inductive 60 years period. On the other hand, there also may be an internal origin of this signal related to the variation of the westward drift and torsional oscillations of the fluid outer core. A comparison of the variation of the "westward drift" of the eccentric dipole (which is part of the secular variation) with the variation of the "length of day" reveals a significant correlation between both variations at about 60 years (Vestine, 1953; Vestine and Kahle, 1968). Braginsky (1970) developed a theory which is capable of characterizing both observables as two aspects of one phenomenon related to torsional magnetohydrodynamic oscillations in the Earth's core. These oscillations can have periods of about 60, 30, and 20 years, and via coupling processes between mantle and core they should produce fluctuation of the Earth's rotation. (see Core-mantle coupling, Length of day variations and Torsional oscillations (q.v.)). Bloxham et al. (2002) suggested that the occurrence of geomagnetic jerks should be linked to "torsional oscillation," therefore also to the length of day variations. Indeed, recent analyzes by Holme and de Viron (2005) and Shirai et al. (2005) reveal that "geomagnetic jerks" are directly linked to the processes responsible for changes in the core angular momentum.

Further long periods may exist, such as 18.6 and 9.3 years resulting from the periodic gravitational action of celestial bodies on the equatorial bulge of the Earth. However, their spectral peaks are fairly close to those of the solar activity. Another was predicted by Yukutake (1972) to be the free modes of the electromagnetically coupled coremantle system, which has a length of about 6.7 years. Currie (1973) may have found this period. For other periods, e.g., 70, 55, 32, 29, and 13 years (Langel *et al.*, 1986) a theory is only vaguely outlined and needs further investigation.

### Generation of secular variation

Secular variation results from the effect of magnetic induction in the fluid outer core and from effects of magnetic diffusion in the core and the mantle. These processes are constituted by the induction equation, which follows from Faraday's induction law

$$\frac{\partial \mathbf{B}}{\partial t} = -\nabla \times \mathbf{E},\tag{Eq. 4}$$

where E is the electric field, showing that a spatially varying electric field can induce a magnetic field. And further, Ampere's law

$$\frac{1}{\sigma}\mathbf{j} = \mathbf{E} + \mathbf{u} \times \mathbf{B} = \frac{1}{\sigma\mu} \nabla \times \mathbf{B},$$
(Eq. 5)

where  $\sigma$  is the electric conductivity, **j** the current density, and  $\mu$  the magnetic permeability. Combining both and after some algebra we get

$$\frac{\partial \mathbf{B}}{\partial t} = \nabla \times (\mathbf{u} \times \mathbf{B}) + \eta \nabla^2 \mathbf{B}.$$
 (Eq. 6)

This is the induction equation, where the first term on the right-hand side displays the advection of the magnetic field due to the fluid motion in the liquid outer core, the second represents the action of magnetic diffusion. It is generally assumed that the diffusive timescale is factor 300 to 500 to the advective timescale. This implies that on short timescales, i.e., less than 100 years, the secular variation is entirely caused by the rigidly coupled movement of the magnetic field lines with the fluid motion in the liquid outer core and therefore diffusion can be neglected.

$$\frac{\partial \mathbf{B}}{\partial t} = \nabla \times (\mathbf{u} \times \mathbf{B}) \tag{Eq. 7}$$

That is the so-called frozen flux hypothesis (see Alfvén's Theorem and the frozen flux approximation (q.v.)).

The "frozen flux assumption" simplifies the inversion for the fluid motion  $\mathbf{u}$  of the liquid outer core (see *Core motions*), but it imparts an incomplete description of the mechanism of the secular variation generation, for two reasons. First, it reduces the algebraic order of the induction equation by one degree, therefore the solution for the fluid flow may not be expected to be complete or correct (Love, 1999). Second, there is evidence that the frozen flux assumption is violated in the last 40 or 50 years. Bloxham and Gubbins (1985); Bloxham (1986) evaluated the magnetic flux through individual flux patches at the CMB. A necessary condition for the "frozen flux approximation" to apply is that the flux *F* through a patch *S* on the core surface bounded by a contour of zero radial field must be constant with respect to time

$$F = \int_{S} B_{\rm r} dS = \text{const.}$$
 (Eq. 8)

Patches located in the southern hemisphere show a significant change of the flux during the period 1960–1980. On a global scale the unsigned flux integral

$$|F| = \oint_{\text{CMB}} |B_r| \mathrm{d}S = \text{const.},$$
 (Eq. 9)

must also be constant with respect to time. Recent analyzes by Holme and Olsen (2005) and Wardinski (2005) suggest that this is not the case for the period 1980–2000. Figure G48 shows the differences of this integral for successive years averaged over the period 1980 to 2000. The given error bars are the sample variance of the integral

Figure G48 The mean change of the unsigned flux integral for 1980–2000.

for a specific truncation degree. For truncation degrees less than 9 a conservation of unsigned flux is not achieved, for higher degree this seems to be achieved within error margins, but it should be mentioned that the higher degrees of the model more and more reflect the *a priori* beliefs, i.e., spatial and temporal damping applied in the computation of the secular variation model.

In a related discussion about the origin of the "westward drift" it has been suggested that waves rather than a bulk advective motion account for the "westward drift" and most of the secular variation. The possible set of wave types are: inner core oscillation, which can have very short periods of about a year (Gubbins, 1981; Glatzmaier and Roberts, 1996). And, "torsional oscillations" of coaxial cylindrical shells oscillating in a solid-body rotation, for which the force balance is between Lorentz force and inertia. The periods are of the order of decades (Braginsky, 1970; Zatman and Bloxham, 1997, 1999). On longer timescales (≥300 years) magnetohydrodynamic waves which are dependent on Magnetic, Archimedean (buoyancy), and Coriolis force could play a role. The difference between torsional oscillation and MAC-waves is the additional acting of buoyancy in MAC-waves. An interaction of these waves, core-surface flows and the morphology of the magnetic field on a timescale shorter than 300 years is likely. However, it should be mentioned that our distance to core surface and the mantle low conductivity attenuate any details in time and space.

#### The influence of the mantle on the secular variation

The secular variation as observed at the Earth's surface undergoes two principal processes when it permeates from the core through the mantle. First a geometrical attenuation determined by the factor

 $\left(\frac{a}{c}\right)^{l+2},$ 

where  $a/c \approx 1.8$ . The higher the harmonic number *l*, the stronger is the geometrical attenuation. The second effect concerns the magnetic diffusion. Here the temporal change of the field is entirely given by the diffusion of the magnetic field through the mantle implicitly assuming that there is no magnetic field generation in the mantle.

The shortest temporal variation of the core's magnetic field that can be seen at the Earth's surface is determined by the conductivity of the mantle and in particular boundary between core and mantle. This region of compositional variation, partial melting and heterogeneous high conductivity, known as D", may have a thickness of about 200 km and should have a significant impact to the permeability of the magnetic field (see D").

However, our understanding of the electrical conductivity of the mantle and its lower part is very poor. All method, which have been employed to deduce the mantle conductivity from the observed secular variation are based on the assumption that the mantle conductivity  $\sigma$  varies as a power law of the radius *r* 

$$\sigma = \sigma_0 \left(\frac{c}{r}\right)^{\alpha}.$$
 (Eq. 10)

This model permits high conductivity in the boundary layer as well as low values of conductivity in the upper mantle, well in agreement with "magnetotellurics." The values of  $\sigma_0$  ranges from 223 S m<sup>-1</sup> (McDonald, 1957) and 100 000 S m<sup>-1</sup> (Alldredge, 1977a) depending on the method of analysis (see *Electrical conductivity of the mantle*). A value between 600 and 3000 S m<sup>-1</sup> (the later preferred by Backus, 1983) would be in good agreement with length of day variation and electromagnetic core-mantle coupling (Stix and Roberts, 1984; Paulus and Stix, 1989; Stewart *et al.*, 1995).

Our knowledge of the mantle conductivity is far from being complete and a rigorous analysis, along theoretical lines as set by Backus (1983) remains to be done. This requires a consolidated knowledge about the secular variation. In order to achieve this the observation of the Earth's magnetic field have to be improved, either in terms of more geomagnetic observatories or satellite missions such as MAGSAT, ØRSTED, and CHAMP.

## GEOMAGNETIC SPECTRUM, SPATIAL

#### Introduction

Just as for a function defined round a circle it is useful to separate the contributions of different wavelengths/spatial frequencies, so for a function defined on the surface of a sphere it is useful to separate the contributions of different (two-dimensional) wavelengths/spatial frequencies. In the context of geomagnetism it is useful to apply this concept of a spatial spectrum to the main magnetic field (coming from the core) and its time variation (the secular variation), and to the field from the magnetization of the crust.

In the one-dimensional case we call this process Fourier analysis; if we have a variable *F*, which is known round a circle (and which is therefore a periodic function round the circle), we can express it in the form

$$F(\lambda) = \sum_{m} F_{m}(\lambda) = \sum_{n} (a_{m} \cos m\lambda + b_{m} \sin m\lambda), \quad (Eq. 1)$$

where  $\lambda$  is the angle round the circle, measured from some origin.  $a_m$  and  $b_m$  are numerical coefficients; the integers *m*, which start from zero, can be thought of as spatial frequencies, or wave numbers. Each term  $\cos m\lambda$  or  $\sin m\lambda$  is called a harmonic, though this name is sometimes also applied to the numerical values of  $a_m \cos m\lambda$  and  $b_m \sin m\lambda$ . The concepts of frequency and harmonic come from the analogous situation of a variable which is a periodic function in time; this function of time can be separated into harmonics specified by frequencies (in time) which are multiples of the fundamental frequency.

These harmonics are orthogonal; in the sense that the average value round the circle of the product of any two *different* harmonics is zero:

$$\langle F_m F_\mu \rangle = 0$$
 (Eq. 2)

unless  $m = \mu$  (and both harmonics use only either  $\cos m\lambda$  or  $\sin m\lambda$ ), where  $\langle x \rangle$  represents the average of x round the circle. Therefore, if we expand an arbitrary F in terms of its harmonic components  $F_m$ , and then square it, all the cross-terms vanish when we take the average round the circle. So the mean-square value of F round the circle,  $\langle F^2 \rangle$ , becomes

$$\begin{split} \left\langle F^2 \right\rangle &= \Sigma_m \left\langle F_m^2 \right\rangle = \sum_m \left\langle a_m^2 \cos^2 m\lambda + b_m^2 \sin^2 m\lambda \right\rangle \\ &= \sum_m (a_m^2 + b_m^2)/2; \end{split} \tag{Eq. 3}$$

the factor of (1/2) is the mean-square (ms) value of  $\cos m\lambda$  or  $\sin m\lambda$  round the circle. (For m = 0 the mean-square value is in fact 1, but I will ignore this minor complication.) We see that the two harmonics of a given spatial frequency m contribute to the overall mean-square value independently of all the other harmonics.

We can write  $F_m(\lambda) = (a_m \cos m\lambda + b_m \sin m\lambda)$  alternatively as  $c_m \cos(m\lambda - \varepsilon)$ ; it is a sinusoidal variation of amplitude  $c_m = (a_m^2 + b_m^2)^{1/2}$ , and phase  $\varepsilon$ . Our choice of the origin of the angle  $\lambda$  is arbitrary; while the numerical values of  $a_m$  and  $b_m$ , and the phase  $\varepsilon$ , will depend on this choice of origin, the variation of  $F_m$  round the real circle, and its amplitude  $c_m$ , is independent of this choice.

A plot of  $c_m^2$  against *m* is called the (power) spectrum of *F*. (The notation arises because for a wave-motion periodic in time,  $c_m^2$  is proportional to the average power (over the cycle) carried by the wave at that frequency.)

## Application to the geomagnetic field

The case of the geomagnetic field is more complicated for two reasons. The first complication is that the field is a vector (at each point in space it has direction as well as magnitude) rather than a scalar (which has only magnitude). However, in regions where there is no significant electric current (in practice this means throughout the upper mantle and the lower atmosphere) we can represent the vector magnetic field B as the gradient of a scalar potential, V,

$$\boldsymbol{B} = -\operatorname{grad} V, \tag{Eq. 4}$$

and can then work in terms of this scalar variable V.

The second complication is that the relevant geometry is threedimensional space rather than a one-dimensional circle. As we are concerned with a roughly spherical Earth, it is convenient to use a spherical polar coordinate system  $(r, \theta, \lambda)$  based at the center of the Earth, with  $\theta = 0$  being the direction of the north geographic pole, and  $\lambda = 0$  the direction of the Greenwich meridian. (The angle  $\lambda$  is the conventional longitude, but because the Earth is a slightly oblate ellipsoid the (geocentric)  $\theta$  is not quite the same as the (geodetic) colatitude.)

Provided that there is also no significant magnetization in the region of interest, it is convenient to approximate the scalar potential V as a finite sum of "spherical harmonics" (see *Harmonics, spherical*). (In practice, although the rocks of the crust are magnetized, even in the crust they produce a field which is small compared with that of the electric currents in the core, and we can often ignore this minor complication. See the last section below for the relative magnitude of the fields.)

We then have

$$V(r, \theta, \lambda) = \sum_{n,m} V_n^m(r, \theta, \lambda)$$
  
=  $a \sum_{n,m} P_n^m(\cos \theta) (g_n^m \cos m\lambda + h_n^m \sin m\lambda) (a/r)^{n+1}$   
(Eq. 5)

for that part of the field having sources internal to the region of interest. The  $P_n^m(\cos \theta)$  are (scaled versions of) the mathematical functions of  $\theta$  called Legendre polynomials. The different harmonics are labeled by two integers, the degree *n* and the order *m*, with  $m \le n$ . (Note that some authors use the symbol *l* rather than *n* for the degree.) The factor *a*, the mean radius of the Earth, is incorporated so that the numerical coefficients  $g_n^m$  and  $h_n^m$  have the dimensions of magnetic field, conventionally expressed in units of nanotesla.

The particular variation with radius in Eq. (5) is valid only for internal sources, and only in a region free from sources of magnetic field. But on any given spherical surface, whatever the source

350

distribution, a scalar such as V can be represented uniquely as a function of  $(\theta, \lambda)$  given by the sum of a set of *surface* harmonics, where any radial variation is incorporated numerically into the coefficients. For simplicity, considering a field of internal origin on the surface r = a (approximately the surface of the Earth), we have

$$V(\theta,\lambda) = \sum_{n,m} V_n^m(\theta,\lambda) = \sum_n V_n(\theta,\lambda)$$
(Eq. 6)

where

$$V_n^m(\theta,\lambda) = aP_n^m(\cos\theta)(g_n^m\cos m\lambda + h_n^m\sin m\lambda).$$
 (Eq. 7)

We can think of these "surface harmonics,"  $P_n^m(\cos\theta)\cos m\lambda$  and  $P_n^m(\cos\theta)\sin m\lambda$ , as being the two-dimensional analogs of the one-dimensional Fourier harmonics on a circle.

For a given physical field, the numerical values of the coefficients,  $g_n^m$  and  $h_n^m$  will depend on the origin of our coordinate system. If, for example, we used the meridian of Paris, rather than that of Greenwich, to define  $\lambda = 0$ , we would find that the coefficients would be different. However, for a given pair of  $g_n^m$  and  $h_n^m$  we find that the sum of their squares,  $(g_n^m)^2 + (h_n^m)^2$  is a constant, independent of our choice of the origin  $\lambda = 0$  (exactly as in one-dimensional Fourier analysis). More generally, even if we also move the  $\theta = 0$  axis to another point on the sphere, it turns out that we have

$$C_n^2 = \sum_m [(g_n^m)^2 + (h_n^m)^2] = \text{constant},$$
 (Eq. 8)

where the sum is over m = 0, 1, 2, ..., n. (This particularly simple result is true provided that we use the Schmidt seminormalized definitions for the Legendre polynomials  $P_n^m$ , as is conventional in geomagnetism. It is also true if we use fully normalized  $P_n^m$  (as do workers in gravity), but *not* if we use the basic mathematical definitions (sometimes denoted by  $P_{nm}$ ) which give unnormalized functions, the mean-square of which varies with *m* as well as with *n*.) In fact any one of the  $V_n$  of Eq. (6) is physically the same, whatever our choice of coordinate system; the processes producing the fields do not "know" of our arbitrary choice of coordinate system.

We can think of all the contributions of a given degree n as having essentially the same minimum (surface) wavelength on the sphere, of value (approximately) the circumference divided by degree n. *Mathematically*, the three terms for n = 1 correspond to the potentials given by three dipoles at the center, the n = 2 terms to five quadrupoles at the center, and so on, but of course *physically* the sources are distributed current systems.

Just as in Fourier analysis the various harmonics are orthogonal round the circle, these surface harmonics are orthogonal over the spherical surface; the average value over the sphere of the product of two *different* surface harmonics is zero. Now using <...> for the average over the sphere r = a, the mean-square value of V over the surface can be expressed as the sum

$$\langle V^2 \rangle = \sum_n \langle V_n^2 \rangle \text{ where } \langle V_n^2 \rangle$$
  
=  $a^2 \sum_m [(g_n^m)^2 + (h_n^m)^2]/(2n+1),$  (Eq. 9)

the factor 1/(2n+1) is the mean-square value of each harmonic over the surface for our Schmidt seminormalized  $P_n^m$ .

However we are using the scalar potential V only as a convenient mathematical simplification. What we are really interested in is the magnetic field **B** itself. It turns out that if we represent each harmonic  $P_n^m(\cos \theta) \cos m\lambda$  or  $P_n^m(\cos \theta) \sin m\lambda$  by (say)  $W_n^m$ , and put

$$\boldsymbol{B}_{n}^{m} = -\operatorname{grad} W_{n}^{m}, \qquad (\text{Eq. 10})$$

then the vector fields  $B_n^m$  are themselves also orthogonal over the sphere: using the scalar product for the multiplication, we have

$$\left< \boldsymbol{B}_n^m \cdot \boldsymbol{B}_v^\mu \right> = 0$$

unless n = v,  $m = \mu$  (and both harmonics use only either  $\cos m\lambda$  or  $\sin m\lambda$ );

$$\langle \boldsymbol{B}_{n}^{m} \cdot \boldsymbol{B}_{n}^{m} \rangle = (n+1).$$
 (Eq. 11)

The factor (n + 1) is the mean-square value over the sphere of the vector fields corresponding to each of the individual harmonics of the degree *n* part of the scalar potential *V* (Lowes, 1966). (This factor (n + 1) is valid only if the sources of the field are internal to the sphere. For external sources, e.g., ionospheric or magnetospheric currents, the factor is *n*.)

So if **B** is the observed field (X, Y, Z), where X, Y, Z are Cartesian components of the vector, the mean-square value of the field vector over the sphere r = a becomes

$$\langle \boldsymbol{B} \cdot \boldsymbol{B} \rangle = |\boldsymbol{B}|^2 = \langle X^2 + Y^2 + Z^2 \rangle = \sum_n R_n$$
 (Eq. 12)

Where

$$R_n = (n+1) \sum_{m} \left[ \left( g_n^m \right)^2 + \left( h_n^m \right)^2 \right].$$
 (Eq. 13)

If we plot  $R_n$  as a function of n, we have the geomagnetic spatial spectrum.

An alternative interpretation of Eq. (13) is that if it is multiplied by  $1/2\mu_0$  (and the coefficients are expressed in units of tesla) it gives the stored magnetic energy density **B**·**H**/2 (the energy stored per unit volume in the magnetic field, in J m<sup>-3</sup>) averaged over the surface; so this spatial spectrum (of the vector field) is sometimes called the geomagnetic power spectrum, or the geomagnetic energy spectrum. ( $R_n$  is roughly analogous to the "degree variance" used in gravity. But note that while  $R_n$  is zero for n = 0 in geomagnetism, as there are no magnetic monopoles, the n = 0 term completely dominates in gravity.)

#### Results for the geomagnetic field

If we apply Eq. (13) to the results of a spherical harmonic analysis of the geomagnetic field of internal origin, as observed globally by satellites such as Ørsted and CHAMP, and plot  $R_n$  on a logarithmic scale against *n*, we obtain the spectrum of Figure G49. Formally, given observation of the field only at and above the Earth's surface, we cannot tell whereabouts inside the surface are the currents producing the field. But if we look at the plot, we see that to a first approximation it can be represented as the sum of two straight lines (two power-law functions on a linear scale). Although there is argument about the exact shape of the best-fitting curves, it is now accepted that (almost all of) the field from harmonics up to about degree n = 14 comes from electric currents in the Earth's core, while (almost all of) the field of higher degrees comes from the magnetization of crustal rocks.

As is well known, at the Earth's surface the geomagnetic field is dominated by its dipole component, and indeed the n = 1, dipole, point lies well above the first line. But the line is a good fit for values of *n* from 2 to about 12. If we go back to the definition of Eq. (5), and remember that taking the gradient in effect introduces another power of (a/r), we see that to draw the equivalent plot for a radius r different from a, we have to multiply each  $R_n$  by the factor  $(a/r)^{2n+4}$ . This has more effect on the points for larger *n*, so that for r < a the line becomes less steep. In fact, if we go down to the radius of the core-mantle boundary (CMB) the line becomes nearly horizontal, and if we continued the extrapolation a little further we would find that just below the CMB the line becomes horizontal; each degree would make about the same contribution to the total ms field. Strictly, because there will be electric currents in this region, this further extrapolation is not allowable, but this result is a convincing argument that these fields do have their origin in the core.

**Figure G49** Spatial spectrum of the internal part of the geomagnetic field at 2000.0. The circles are the values of  $R_n$ , the mean-square vector field produced by the harmonics of degree n over the surface r = a, plotted on a logarithmic scale against n; right-hand scale. The squares are the corresponding values for the secular variation; left-hand scale. The coefficients used are those of CM4, Sabaka *et al.* (2005).

The other line, for higher spatial frequencies/shorter wavelengths, is already sloping upward, so we cannot use such a simple argument to indicate the source depth. The results for even higher frequencies (see below) show that the curve does in fact eventually turn downward, as it must for the crust to contribute only a finite field, and the overall shape is consistent with reasonable models of crustal magnetization.

So there is no doubt that this separation into core and crustal origin must be largely correct; the division is usually put at about n = 14. But note that the spectrum of the core field will continue above this value, and that of the crustal field will continue below this value. We do not know the detailed physics that lies behind each of the two spectra, so we can only guess at how they are to be extrapolated. But if we simply extrapolate the straight lines, then we find that at the Earth's surface the core field (of total root-mean-square (rms) magnitude about 45000 nT) would contribute about 10 nT rms from degrees beyond 13, while the crust (total rms about 300 nT) would contribute about 10 nT from degrees below n = 14.

While the spectrum of the main field itself is now quite well determined (by measurements from polar-orbiting satellites such as Magsat, Ørsted, and CHAMP), the spectrum of the crustal field (see *Crustal magnetic field*) is much more uncertain. All the points shown on Figure G49 are obtained from satellite measurements. However at satellite altitudes the crustal field is small, and for individual measurements is often not much larger than the instrument noise. Probably more importantly, there are also comparable or larger time-varying fields of external origin, and the separation of the spatial-variation and time-variation of the field seen by a moving satellite is very difficult. In fact, as techniques improve there has been a tendency for the derived crustal spectrum to become lower on a graph such as that of Figure G49! For degrees above about 30–40 it is at present difficult

to do a formal spherical harmonic analysis of the satellite data, though it is sometimes possible to do a Fourier, one-dimensional, analysis along individual tracks. Similarly we can use the long tracks of the Project MAGNET airborne vector magnetometer (see Project MAGNET), and a much larger number of tracks from oceanographic vessels towing a scalar magnetometer; these approaches can extend the data out to about n = 1000. However these are only onedimensional cross sections of the field variation over the two-dimensional sphere, so some assumptions have to be made (see, e.g., Korte et al,, 2002); also, the near-surface tracks are almost all over the oceans, where the crust is systematically thinner than under the continents. Such results however do suggest that the mean-square field per degree does in fact start to decrease at higher degrees. In theory, for the very high degrees, we could analyze data from the large number of detailed aeromagnetic surveys which have been carried out (though mostly over land), but there are many problems, and this has not yet been attempted.

This concept of a spatial spectrum can obviously be extended to the secular variation, the time variation of the main field. A complication is that there are many external sources of field variations, of period of a year or less, the effects of which are most easily removed by taking averages over one year. This averaging is most easily done with the long-term surface observations at magnetic observatories and repeat stations; unfortunately these have only a very poor global coverage. Satellites have much better global coverage, and are now also giving continuous coverage in time, though unfortunately their measurements are subject to more interfering effects. However, at present it looks as though we can estimate the secular variation over the last year or so, and hence its spectrum, up to about n = 10 (see, e.g., Langlais et al., 2003). The spectrum for 2000.0 is shown on Figure G49; it is much flatter than that of the main field, so that (in this range) at the CMB the shorter wavelengths are varying more rapidly than the longer wavelengths.

#### History

Lowes (1966) was the first to introduce to the English-speaking community the expression for mean-square field, Eq. (11) of this article, in the context of geomagnetism; he also produced the first power spectrum, analogous to Figure G49, in Lowes (1974). However, essentially the same expression had been introduced earlier in Germany, by Lucke in a colloquium in 1955, referred to by Fanselau and Lucke (1956). Lucke worked in terms of the energy per unit volume stored in a magnetic field, which (in modern notation) is

$$E = (1/2)\boldsymbol{B} \cdot \boldsymbol{H} = (1/2\mu_0)\boldsymbol{B} \cdot \boldsymbol{B}.$$
 (Eq. 14)

So, when he averaged over the sphere r = a, he obtained

$$\langle E \rangle = (1/2\mu_0) \langle \boldsymbol{B}.\boldsymbol{B} \rangle = (1/2\mu_0) \sum_n (n+1) \left[ \left( g_n^m \right)^2 + \left( h_n^m \right)^2 \right]$$
  
=  $(1/2\pi\mu_0) \sum_n R_n,$  (Eq. 15)

or

$$\langle E \rangle = (1/2\mu_0) \sum_n R_n, \qquad (\text{Eq. 16})$$

in the notation of this article.

Lucke's lecture was also referred to by Mauersberger (1956), who produced the same expression for the mean energy density, but using a different derivation. Hence graphs such as those of Figure G49 are sometimes referred to as a "Lowes spectrum," "Lowes-Mauersberger spectrum," or "Mauersberger-Lowes spectrum."

## **GEOMAGNETIC SPECTRUM, TEMPORAL**

The geomagnetic field varies on a huge range of timescales, and one way to study these variations is by analyzing how changes in the geomagnetic field are distributed as a function of frequency. This can be done by estimating the spectrum of geomagnetic variations. The power spectral density S(f) is a measure of the power in geomagnetic field variations at frequency f. When integrated over all frequencies it measures the total variance in the geomagnetic field.

Figure G50/Plate 2 shows a schematic of the various processes that contribute to the geomagnetic field, and these can be roughly divided according to the frequency range in which they operate. The bulk of Earth's magnetic field is generated in the liquid outer core, where fluid flow is influenced by Earth rotation and the geometry of the inner core. Core flow produces a secular variation in the magnetic field, which propagates upward through the relatively electrically insulating mantle and crust. Short-term changes in core field are attenuated by their passage through the mantle so that at periods less than a few months most of the changes are of external origin. The crust makes a small static contribution to the overall field, which only changes detectably on geological timescales making an insignificant contribution to the long-period spectrum. Above the insulating atmosphere the electrically conductive *ionosphere* (q.v.) supports Sq currents with a diurnal variation as a result of dayside solar heating. Lightning generates high-frequency Schumann resonances in the Earth/ionosphere cavity. Outside the solid Earth the magnetosphere (q.v.), the manifestation of the core dynamo, is deformed and modulated by the solar wind, compressed on the dayside and elongated on the nightside. At a distance of about 3 earth radii, the magnetospheric ring current acts to oppose the main field and is also modulated by solar activity. Although changes in solar activity probably occur on all timescales the associated magnetic variations are much smaller than the changes in the core field at long periods, and only make a very minor contribution to the power spectrum.

With an adequate physical theory to describe each of the above processes one could predict the power in geomagnetic field variations as a function of frequency. The inverse problem is to use direct observations or paleomagnetic measurements of the geomagnetic field to estimate the power spectrum. Power spectral estimation is usually carried out using variants of one of the following well-known techniques: (1) direct spectral estimation based on the fast Fourier transform, and using extensions and improvements to the time-honored periodogram method introduced by Schuster in 1898 to search for hidden periodicities in meteorological data; (2) the autocovariance method which exploits the Fourier transform relationship between the time-domain autocovariance and frequency-dependent power spectral density of a process; (3) parametric modeling schemes like the maximum entropy method based on a discrete autoregressive process. The relative merits of these techniques have been widely discussed (see Constable and Johnson, 2005: or Barton, 1983, for the geomagnetic context), while all have been used in analyzes of geomagnetic intensity and directional variations. It is generally acknowledged (e.g., Percival and Walden, 1993) that direct spectral estimation combined with tapering and averaging of nearly independent spectral estimates can provide highresolution estimates and be used to optimize the unavoidable trade-offs between variance and bias.

The parameter often chosen to represent the geomagnetic spectrum is the field strength at midlatitudes, or a proxy form for times where it is not possible to obtain a direct measurement. This is the case for paleomagnetic time series derived from lacustrine or marine sediments which provide only directional information and/or relative intensity variations. Barton (1982) combined spectra from lake sediment directional paleomagnetic records with those from full vector data recorded at magnetic observatories and used periodogram analysis in the first attempt to provide an integrated power spectrum for periods ranging from less than a year to  $10^5$  years. Courtillot and Le Mouël (1988) merged Barton's result with other spectral estimates at longer and shorter periods extending the timescales from seconds to millions of years. They debated whether the result was compatible with an overall  $1/f^2$  spectrum, and concluded that it was too early to make such an inference.

A recent version of such a composite spectrum (Constable and Constable, 2004) uses spectral estimates from relative paleointensity variations (Constable et al., 1998) at long periods and is shown in Figure G51 (note that this is an amplitude rather than a power spectrum, that is the square root of power spectral density). Between  $10^{-10}$  and 1 Hz, the spectrum is from Filloux (1987). Above 1 Hz, the results are those of Nichols et al. (1988). Internal variations reflecting motions of the fluid core dominate at periods longer than a few months, and the spectrum generally rises toward longer period (low frequency) with reversals (q.v.) of the dipolar part of the field the dominant influence on 10<sup>5</sup> to 10<sup>6</sup> year timescales. The 11-year sunspot cycle, solar rotation, and Earth's orbit modulate the distortions of the field associated with geomagnetic storms, which themselves have energy in the several hour to several second band. Energy at the daily variation and harmonics comes from diurnal heating of the ionosphere. Lightning creates high frequency energy in the Earth/ionosphere cavity, which resonates at 7-8 s and associated harmonics. At the highest frequencies there is presumed to be a continued fall-off in the natural spectrum. The upturn seen in Figure G51 reflects the dominant influence of human-made sources.

The spectrum in Figure G51 lacks information at very long periods where the spectrum is dominated by the intensity variations associated with changing geomagnetic reversal rate, and between about 10 ka and 10-year periods, where the timescales for processes of internal and external origin overlap. Figure G52/Plate 4c provides a range of estimates at centennial to 50 Ma periods for the spectrum of the geomagnetic *dipole moment* (q.v.). The longest period power spectrum is estimated from reversal times given by the magnetostratigraphic

timescale and shown in black. Further information comes from various sedimentary relative paleointensity records with varying accumulation rates and the dipole moment estimate of a time varying global paleomagnetic field model for the past 7 ka.

In constructing a paleomagnetic power spectrum like that in Figure G52/Plate 4c there are a number of challenges. A basic requirement for spectral analysis is a time series of observations, but there is no single record that covers the time span of interest. The magnetostratigraphic record appears to be nonstationary with long-term changes in reversal rate, and provides no information about intensity variation on long timescales. The relative paleointensity records from sediments not only lack an absolute scale, but are usually unevenly sampled in time so that some stable calibration and interpolation scheme is required before using the standard analysis techniques. It is likely that some sediments record a smoothed version of the geomagnetic signal because of low sedimentation rates, while in others it may be necessary to consider the possibility of aliasing. Nongeomagnetic signals may be inadvertently interpreted as arising from geomagnetic variations with time.

The choice of dipole moment (as opposed to some other geomagnetic field parameter) is motivated in large part by the dominance of the geocentric axial dipole when the field is averaged over long time intervals: the strength of the axial dipole is representative of the global field, and may be related to the amount of energy required by the geodynamo or to the geomagnetic reversal rate. Although it is possible that other properties of the field (such as nondipole field contributions) directly reflect particular physical processes controlling the secular variation, resolving such variations in paleomagnetic time series remains controversial. Overall, it is likely that the power in geomagnetic field variations is underestimated.

There is substantial scope for improving the spectra in both Figures G51 and G52/Plate 4c. Relative intensity records from sediments are steadily improving, and new modeling techniques may extend time-varying geomagnetic field models providing better dipole moment estimates on million year timescales. This may give new insight into what controls very long-period secular variation. Many newer observations could be used for direct spectral estimates to replace the current schematic spectrum at periods from decades down to 1 s. Although the general form of the spectrum is quite well understood in this region, detailed analyzes could provide further insight

into the underlying physical processes. Techniques such as wavelet analysis, that can take account of nonstationarity in the underlying geomagnetic processes, have yet to be fully exploited for geomagnetic data (Guyodo *et al.*, 2000) and may prove useful. However, despite the relatively crude nature of existing spectral estimates it is apparent that the geomagnetic power spectrum does not follow a simple power law fall-off with increasing frequency. The form is instead influenced by the characteristic timescales that reflect the distinct physical processes contributing to the geomagnetic field.

## GEOMAGNETISM, HISTORY OF

In its present form, the geophysical discipline of geomagnetism is of relatively recent origin (the term "geomagnetism" was coined in 1938 by *Sydney Chapman*, (q.v.)), yet interpretations of the Earth's magnetic field have been propounded by scholars from the Middle Ages onward, in the broader context of cosmologies, natural philosophies, and oceanic navigation. In this historical overview, geomagnetism will be considered as the scientific study of the Earth's internal field and its secular change, encompassing both descriptive and causal hypotheses; paleomagnetism and the external field are treated elsewhere. Furthermore, since most of this volume is dedicated to current issues, stress will here be placed on earlier times.

## Main developmental stages

The history of geomagnetism can be subdivided into three main periods: firstly, a proto-scientific stage (up to the 16th century), during which awareness slowly grew of the existence of a global magnetic property worthy of investigation. At this time, causal hypotheses almost exclusively identified the heavens as the seat of magnetic attraction. Secondly, an early-modern stage took place (16th to early 19th century), during which directional data (magnetic declination and inclination) were increasingly measured, compiled, and mapped. These efforts led to the discovery of secular variation and causal models involving one to three crustal or nuclear dipoles (terrestrial polar attraction). Thirdly, a modern stage emerged (from the 1830s), characterized by measurement of the full magnetic vector (direction and intensity) in dedicated scientific surveys, observatories, and satellites; by the description of the field as a whole, both at the surface and at the top of the source region; and by the mid-20th century introduction of geodynamo theory (q.v.), leading to a multitude of numerical and laboratory magnetohydrodynamic simulations.

These developments are summarized per century in Table G8, which pays separate attention to empirical (data and mapping) and theoretical aspects (hypotheses). As is apparent, the main watershed between the early-modern and modern stage pervades both. The most influential scientist in bringing about this change was *Carl Friedrich Gauss*

(1777-1855) (*q.v.*), who not only invented the first absolute magnetometer (1832) but, moreover, developed for geomagnetic application the mathematical techniques of spherical harmonic expansion (1839) and least-squares analysis (independently discovered by Adrien-Marie Legendre, 1752–1833). Furthermore, around the same time occurred a shift in the realm of data acquisition, up till then performed mostly by navigational practitioners and hydrographers, thereafter predominantly by professional astronomers and physicists. This article will therefore apply the same temporal caesura in discussing geomagnetic data processing and theory formation before, and after Gauss's contributions.

#### The era of polar attraction

Although the phenomenon of magnetic attraction had been known since antiquity, it was in the Middle Ages that the notions of polarity and orientation were first discovered, and several cultures recorded its potential (or actual) utility. The Chinese record goes back furthest in this respect, with magnetized objects being employed in geomancy from at least the A.D. 6th century, and a wire-suspended magnetic needle first described in 1096. Moreover, in the next few decades appeared the first Chinese references to mariners relying for direction on needles made to float in a bowl of water (Needham, 1962), a technique independently discovered in Europe. By the 13th century, the magnetic needle was commonly relied upon in both Asian and European navigation at sea, in particular when overcast skies made an astronomical fix impossible. In subsequent centuries, the dry-pivoted compass (q.v.) was moreover increasingly relied upon on land, in surveying and to meridionally align portable instruments and some newly planned official buildings (churches, temples, and palaces). The difference between magnetic and true north was as of yet unappreciated; in keeping with Aristotelian cosmology, the needle was still thought to respect the imagined immutable perfection of the supralunary spheres (Smith, 1992).

This view is epitomized in the "Epistle on the Magnet" (1269) in which engineer Pierre de Maricourt (Petrus Peregrinus) related his experiments with a spherical lodestone. This *magnes rotundus* represented the firmament, its two magnetic poles coinciding with the celestial poles (the only fixed points in a diurnally rotating field of stars). Given this arrangement, magnetic and true meridian would always coincide (declination was zero everywhere), and inclination would change as a function of geographical latitude. The concept of a celestial axial dipole was reiterated over the next two centuries by many medieval and Renaissance authors. Some, however, attributed the magnetic force to the nearby Polestar, relying on the Classical concept of sympathy to establish an occult bond between compass and star. These tenets would be challenged when magnetic declination was finally acknowledged as a real phenomenon, rather than being ascribed to an error in instrument or measurement.

The first tacit evidence thereof can be found on German portable sundials from the second quarter of the 15th century. Craftsmen in Augsburg and Nuremberg then started to mark local declination in the base of the instrument, adjacent to a small inset compass, used to enable proper orientation in the geographical meridian. Around that time, similar markings also started to appear next to the wind rose on some German maps (e.g., by cartographers Etzlaub, Waldseemüller, Ziegler, and Murer). But it would take another century before the spatial variability of the Earth's magnetic field became overwhelmingly clear, and with it the need for global descriptive and causal geomagnetic hypotheses.

## The 16th century

The advent of oceanic navigation, without the benefit of land sightings, soundings, or a practical method with which to measure longitude, meant that mariners had to rely on compass and astronomical observations to a hitherto unequalled degree. Off the continental shelves, steering, dead reckoning, log keeping, charting, and sailing instructions consequently came to incorporate true compass directions. Any local magnetic declination had to be measured regularly, and compensated for in courses and calculations. Fortunately, establishing this so-called compass allowance was a fairly simple calculation, based on sighting the Sun or other stars at rise and/or set. As Portuguese and Spanish explorers traversed increasing parts of the Atlantic and Indian Oceans, the peculiar spatial distribution of needle behavior was slowly recorded, collated, and compared, both by navigators at sea and hydrographers at home. In large parts of the Atlantic, the compass northeasted, whereas in the Indian Ocean, variable northwesting was the rule; near-zero declination was furthermore associated with the mid-Atlantic, South Africa, Southeast Asia, and Middle America.

These early data sets seemed to suggest that the Earth's dipole was tilted relative to the Earth's rotation axis, since local declination was assumed to have a direct bearing on the position of the dipole. By applying spherical trigonometry, two observations of declination at places far apart in longitude could provide a cross bearing of two great circles, each through one of the points and at the given angle to true north. Where the two circles intersected, the geomagnetic poles were supposed to lie. Once the position of the dipole was known, a similar calculation at sea would yield the longitude of a place where declination and latitude were measured.

In other words, given a tilted dipole at a fixed position, an observer traveling around the globe at the same latitude would see his compass needle diverge from true north as a function of longitude. At the meridian of the dipole's longitude and on the antimeridian ( $180^{\circ}$  E) the great circle through the place of the observer and the dipole would cut the geographical pole as well, resulting in zero degrees declination; deflection from true north would reach a maximum near 90° longitude east and west from either meridian. Actual measurements of zero declination near the Azores led to the mistaken belief that such a meridional agonic line was found, forming a "natural" indicator of a prime meridian to reckon longitude from. Geomagnetic considerations have thereby greatly affected early-modern cartography. The combination of reigning northeasting in Western Europe and northwesting on the American east coast furthermore led to the conclusion that the dipole was situated on longitude  $180^{\circ}$  E (of the Azorean prime meridian).

The notion of the tilted dipole neatly concurred with a more ancient conjecture, that of the "magnetic mountain." This lodestone rock, GEOMAGNETISM, HISTORY OF

mountain, or island, often located in Arctic regions, was not only supposed to affect compass needles all over the globe, but, according to some legends, could even draw, capture, or destroy iron-bearing vessels that sailed too close by (Balmer, 1956). Several scholars have repeatedly tried to calculate its exact coordinates, among them cartographer Gerard Mercator (1512–1594) and astronomer Johannes Kepler (1571–1631). Others instead interpreted the postulated tilted dipole as evidence that the points of magnetic attraction were identical with the poles of the ecliptic. Nevertheless, by this time, the majority opinion tended to favor magnetic poles on the Earth's surface.

This shift from celestial to terrestrial magnetism was reinforced by the discovery of magnetic inclination. In a qualitative sense, it was made by German mathematician and instrument maker Georg Hartmann (reported in a letter to his patron in 1544). It would take until about 1580 before London compass maker Robert Norman constructed the first inclinometer (a magnetized needle rotating in the vertical plane on a horizontal axis), with which the first quantified readings were taken. Inclination too was briefly considered as a navigational aid; in the 1590s, English mathematician Henry Briggs (1561–1630) assumed an axial dipole and produced a table of dip for each degree of latitude. Its lasting impact, however, was to strengthen the growing conviction that the origin of the Earth's field was located deep inside the planet, instead of on, or above its surface.

The consideration of additional sites of observed zero declination meanwhile led Iberian and Dutch cosmographers to postulate a more complex arrangement of two tilted dipoles, resulting in two perpendicular great circles that quartered the world into alternating sections of northeasting and northwesting. In the Dutch Republic, cartographer Petrus Plancius (1552–1622) turned such a hypothesis into a practical method to find longitude, which was used at sea for about three decades. His compatriot Simon Stevin (1548–1620) instead put forward the first sextupole hypothesis. Other schemes developed by European navigators proposed a locally valid ratio between distance traveled along a parallel of latitude and change in needle stance.

The striking diversity of explanations formulated during the 16th century bears evidence, not just of the numerical paucity of geomagnetic data, but also of poor charts (longitudinal uncertainty) and lack of standardization in instruments and measurement, generating error margins large enough to tentatively confirm the witnessed variety of (one or multiple) tilted dipole arrangements and other explanations.

## The 17th century

With the arrival of overseas trading companies, missionary networks, and better instruments, both the quantity and quality of geomagnetic data substantially increased in the 17th century. Moreover, this period witnessed several official efforts to process and publish these measurements, such as by the newly founded scientific societies (Royal Society, Académie Royale des Sciences), and the hydrographic office of some East India Companies. Observations of declination and inclination also appeared in printed compilations, sometimes ordered by latitude or longitude, both for mariners' and scholars' benefit. In addition, the first manuscript chart (now lost) depicting curved isogonics (lines connecting all points with equal declination) was produced in the 1620s by the Italian Jesuit Christoforo Borro (or Bruno), a teacher of navigation in Portugal. Although isogonic charts would never attain prominence as a tool in navigational practice, they did serve to underline that geomagnetism implied more than a collection of isolated data points, enabling global visualization of both a priori and empirically derived patterns. The continuing stream of readings from places near and far furthermore stressed the inadequacy and simplification of imposing a tilted dipole model on observed reality.

The nascent geomagnetic discipline therefore avidly sought more appropriate explanations, while being increasingly influenced by competing paradigms of natural philosophy. The stage was set with the publication of *De Magnete* in 1600, by Elizabethan court physician *William Gilbert* (1544–1603) (*q.v.*). This work contained the famous

conclusion that "the Earth itself is a great magnet." Gilbert posited an axial dipole field distorted by the attraction of iron-rich continental landmasses (and more localized sources); a single Arctic magnetic pole was thus supplemented by global crustal heterogeneity, dispensing with any perceived regularity. Regarding cosmology, the Englishman maintained that the geomagnetic force was likewise responsible for the Earth's orientation and diurnal rotation, and the orbit of other planets, a view that brought him into conflict with the religious order of the Jesuits (q.v.). To the likes of Nicolo Cabeo (1629), Athanasius Kircher (1639), and Jacques Grandamy (1645), who supported geocentrism, Gilbert's universal "magnetic philosophy" was anathema; they claimed instead that it was geomagnetism which held the Earth firmly fixed at the center of creation. However, upon closer examination, Jesuit interpretations of the Earth's (seemingly irregular) field proved far from consistent themselves, attributing its source to quasiorganic magnetic "fibers," mines of iron ore, subterranean heat, chemical processes, and the Earth's heterogeneous crustal constitution (Daujat, 1945). Outside of religious circles, the composition of the deep Earth also evoked much speculation and debate; Galileo Galilei postulated intense pressures at the core, while others imagined an infernal furnace there, driving hot sulfurous gases through a huge system of caverns. The notion of a hollow Earth would become even more important after the discovery of secular variation.

The first sustained series of measurements at a single site, which gave rise to the realization that the geomagnetic field was subject to time-dependent change, was compiled in east London (foremost by naval commander William Borough, instrument maker John Marr, and Gresham astronomers Edmund Gunter and Henry Gellibrand. It was *Gellibrand* (q.v.) who eventually published all findings in 1635, concluding "a sensible diminution" at London of about seven degrees westerly over the period 1580–1634 (Chapman and Bartels, 1940). It was one of the earliest scientific conclusions based on averaging sets of measurements, a procedure through which observational error was substantially reduced.

The notion of geomagnetic change over time was accepted by scholars across Europe within two decades, forcing a reassessment of all earlier work. Compiled undated measurements became useless, as did all time-invariant geomagnetic hypotheses put forward so far. The acceptance of secular variation thus inaugurated the third phase of geomagnetic models, which introduced a temporal parameter. Nonetheless, this variable was not necessarily always quantified. Kircher, for example, interpreted time-variance as resulting from the slow "generation" and "deterioration" of iron mines in the crust, a view shared by the philosopher René Descartes (1596–1650), who additionally blamed atmospheric circulation as affecting the vortices of tiny magnetic particles he postulated as the essence of the magnetic force (1644). A more atomistic (but equally qualitative) micromechanistic hypothesis was formulated by his compatriot Pierre Gassendi (1592–1655).

Once (geo)magnetic corpuscularism reached English soil, research into magnetic particle circulation was initially promoted by the Royal Society, but by the 1680s, "magnetic philosophy" lost much of its former identity, becoming subsumed in broader theories involving the ether and effluvial emanations of matter in general. Although these speculations would eventually lead to the formulation of the laws of electromagnetism, none of these concepts made much impact on English geomagnetic hypotheses throughout the 17th century. The path followed here led scholars instead to reinstate the notion of polar attraction in dynamic terms, through one or more dipoles precessing around the Earth's rotation axis in hundreds of years. Such solutions were launched by Henry Bond (1639), Henry Phillippes (1659), Robert Hooke (1674), Peter Perkins (1680), Edmond Halley (1683 and 1692) (q.v.), and Edward Harrison (1696). In addition to an array of parameters to define these geomagnetic models (precessional period and direction, dipole colatitude and longitude at a given year), a physical rationale was added by some, for example, Halley's magnetic core rotating relative to the crust, separated from the latter by a fluid or gaseous intermediary layer. Even more parameters were required

in the 18th century multipole variant (several hollow spheres nested around a common kernel), which allowed dipoles at different depths to precess with distinct speeds. This greatly expanded the scope for accommodating the observed asymmetrical global distribution of surface declination, as visualized on the first printed isogonic charts. These were based on the first scientific naval surveys, by Edmond Halley in 1698–1700.

## The 18th century

Halley's declination charts were revised twice, by mathematics teachers William Mountaine and James Dodson (1744, 1756). Isogonics were likewise drawn on near-global-scale by engineer Frezier (1717), physicist Van Musschenbroeck (1729, 1744), Captain Nicolaas van Ewyk (1752), cartographer Samuel Dunn (1775), natural philosopher Johann Heinrich Lambert (1777), and astronomer Le Monnier (1778). Physicist Johann Karl Wilcke published the first world chart depicting isoclinics (lines of equal dip) in 1768, based on inclinations observed on board Swedish Eastindiamen. In the last decade of the century, surveyor John Churchman moreover published several editions of his "Magnetic Atlas," which delineated both isogonics and isoclinics worldwide.

These efforts were based on unprecedented data compilations, mostly derived from maritime sources. Mountaine and Dodson's, for instance, used over 50000 geomagnetic observations for their 1756 world chart. More accurate compasses with enlarged sights, a greater volume of world shipping than ever before, and improved infrastructures for processing and disseminating magnetic data, allowed increased data accuracy at higher resolution over larger parts of the globe. Strenuous regimes of daily or hourly observations at fixed locations furthermore offered workers the chance to explore diurnal variation, secular acceleration, and the link between erratic needle behavior and the *aurora polaris*. In this century, major cities such as London and Paris maintained almost uninterrupted series of annual observations at astronomical observatories.

Eighteenth century geomagnetic hypotheses displayed the full gamut of existing explanations, with proponents of static and dynamic tilted dipoles and multipoles in numerous countries. Nevertheless, data and theory still continued to disagree to an appreciable extent. In 1732, Royal Society Fellow Servington Savery was the first to propose that irregular surface topography of the magnetic core might be to blame. Mathematical work by Leonhard Euler (1757) furthermore laid the groundwork for the abandonment of the assumption of pairs of poles in diametrical opposition (Fleury Mottelay, 1922). Implicitly, some earlier multipole solutions had featured nonantipodal configurations, but only after Euler did the fourth phase of geomagnetic hypothesis receive explicit attention, with detailed discussion of each pole's position and movements inside the Earth. In the most extreme cases (from the 1790s), the two disjointed poles of a dipole were assigned different coordinates, directions, and velocities. And like in earlier phases, when a single dipole was no longer deemed sufficient to account for the observations, another one was added. The disjointed quadrupole solution (1819) developed by Norwegian mathematician Christopher Hansteen (1784-1873) is a case in point, incorporating compass readings from 74 sea voyages. But eventually, even four independent magnetic poles proved insufficient, heralding the end of the belief that magnetized needles were solely governed by the attraction of a few, distant, all-powerful geomagnetic poles. The four main phases of geomagnetic hypotheses up till then are illustrated in Figure G53.

## The era of the global field

## The 19th century

Relative geomagnetic intensity data began to be compiled in earnest from the 1790s, by comparing the time it took a magnetized needle (horizontally or vertically) displaced by a standard distance from its

**Figure G53** The four phases of geomagnetic hypotheses based on polar attraction. *Top left*, axial dipole (static); *top right*, tilted dipole (static); *bottom left*, precessing dipole (dynamic, tilted, antipodal); *bottom right*, disjointed dipole (dynamic, tilted, nonantipodal). preferred orientation to return to it, or by timing a given number of such oscillations. Admiral de Rossel, on d'Entrecasteaux's voyage in search of the lost expedition of La Pérouse, obtained such readings (1791–1794) relative to Brest. Naturalist Alexander von Humboldt (1768–1859), on his south American explorations (1799–1804), instead chose the number of dip oscillations in 10 min on the magnetic equator (where vertical geomagnetic intensity is lowest) at Micuipampa, Peru as his reference value. Other readings obtained at intermediate latitudes led him to postulate the "law" of decreasing (vertical) magnetic force from the magnetic poles to the magnetic equator. After Humboldt's return to Paris, this initial standard of relative intensity soon became eclipsed by the Paris unit, whereas similar local units based on swing times at London, Christiania (Oslo), and St. Petersburg found more limited application elsewhere. Global isodynamics (lines of equal intensity) were drawn from 1825.

Two periods in the 19th century stand out as of particular significance for geomagnetism: the first of these was 1820–1840. After Hans Christian Ørsted's (1777–1851) discovery in 1820 of electromagnetism, and André Marie Ampère's (1775–1836) "Theorie Mathématique des Phénomènes Électro-dynamiques" (1826), it was Michael Faraday (1791–1867) who discovered electromagnetic induction in 1831, and who applied it to build the first dynamo (a copper disk rotating in a strong magnetic field, with an electrical circuit connecting rim and center). The year thereafter, Carl Friedrich Gauss built the first absolute magnetometer in his Göttingen laboratory (21 May 1832). Units of absolute intensity soon replaced all relative scales, and apart from an increasing number of surveys on land, networks of fixed observatories were set up in numerous countries. Geomagnetism gradually became separated from traditional ferromagnetic studies, championed instead by professional astronomers as one of a range of interconnected "telluric" forces (including heat, volcanism, and atmospheric electricity), in a framework of terrestrial or cosmic physics.

Such phenomena obviously warranted globally coordinated data collection. Already from 1828, von Humboldt had tirelessly advocated international cooperation in geomagnetism, personally establishing a string of observatories in Europe and Asia that made simultaneous measurements at specific intervals. In 1834, Gauss and his colleague Wilhelm Weber (1804-1891) joined this scheme, expanding it to about 50 stations, known as the "Göttingen Magnetic Union" (1836-1841). At the time, the three recorded elements were declination, inclination, and intensity. When these had all been mapped on a global scale for (approximately) the same era (declination 1833, inclination 1836, intensity 1837), it became possible to interpolate the complete magnetic vector for any point on Earth. This is what Gauss set out to do in 1839. He promulgated the idea of representing the magnetic field by the gradient of a potential function, to be written as a linear combination of a series of spherical harmonic coefficients (or Gauss coefficients), to be derived by least-squares analysis. Assuming a spherical Earth, and converting the charted data into X, Y, and Z components at fixed intervals of colatitude and longitude, Gauss obtained the first 24 coefficients (equivalent to an expansion up to degree and order 4). The results, laid down in his 1839 "Allgemeine Theorie des Erdmagnetismus" showed that the strength of the internal field overwhelmingly dominated any possible external sources affecting the surface field.

This conclusion contrasted starkly with the "cosmological" interpretation, which emphasized the importance of the external field. While many workers employed, expanded, and refined Gauss's method in subsequent decades (over 300 such field models have been computed since, Jacobs, 1987), army officer *Edward Sabine* (1788–1883) (*q.v.*), rejected Gauss's theory, reverting instead to Hansteen's disjointed quadrupole as a working hypothesis, the verification of which culminated in the British movement known as the "Magnetic Crusade" of the 1840s. This consisted mainly of two Antarctic exploration voyages (1839–1842) under James Clark Ross (1800–1862), and a network of colonial observatories (1840–1848) run by the British Admiralty, the War Office, and the English East India Company, supplemented by over twenty, mostly European, Russian, and American stations (Cawood, 1979).

At a new geomagnetic observatory at Kew (est. 1841), Sabine and his staff processed the network data, plus those from ship's logbooks, land surveys, and earlier compilations, to be published in 15 "Contributions to Terrestrial Magnetism" (1840–1877) in the Royal Society's "Philosophical Transactions." The most notable results were Sabine's distinction of diurnal variation of internal and external origin, and his 1851 discovery that the periodicity of magnetic storms was correlated with the 11-year sunspot cycle. Nevertheless, some observatories proved less permanent than originally envisaged, and geomagnetic land surveys in the second half of the century often had to rely on more established disciplines for funding, as part of grand empirical programmes.

Whereas France and Russia were the main sponsors of oceanic circumnavigations up to the midcentury (acquiring substantially better coverage in geomagnetic field measurements, not least in the Pacific Ocean), a plethora of nations (Germany, Sweden, Austria-Hungary, Britain, Norway, the United States, Denmark, and others) partook in the Arctic exploration frenzy characteristic of the second peak period of geomagnetism in the 19th century, from about 1870 to 1885. These ventures, partly stimulated by the First International Polar Year (1882– 1883), followed the policy adopted on naval surveys of carrying geomagnetic instruments as standard equipment. Other significant empirical contributions were made on the British "Challenger" (1872–1875), the German "Gazelle" (1874–1876), and the Swedish "Vanadis" (1883–1885) expedition. On land, networks of repeat stations rose to prominence where observatory coverage was sparse (eventually reaching a total of about 3000). These carefully chosen, fixed and marked locations were to be revisited for a few days at regular intervals (1, 2, 5, or 10 years) to study secular and diurnal variation. Time-dependent change on the historical timescale was meanwhile studied in the 1890s by physicist *Willem van Bemmelen* (1868–1941) (*q.v.*), who reconstructed 16-and 17th century isogonics from nautical data in 165 historical ship's logbooks (based in part on original manuscripts). Arctic and observatory data were also reexamined time and again, forming the basis for new spherical harmonic expansions. By this time, geomagnetism (and related geoelectricity) had become almost exclusively the field-theoretical domain of physicists.

#### The 20th century

Empirical geomagnetism continued to prosper in the 20th century. Besides the European colonial powers, the United States, Russia, and Japan likewise established new observatories and organized new surveys to track the field's appearance and change. Moreover, Antarctica became a novel focal point of investigation, for example, on Robert Falcon Scott's (1868-1912) first Antarctic expedition (1901-1904), and later during the Second International Polar Year (1932-1933). In 1904, Louis Agricola Bauer (1865-1932) (q.v.), at the Carnegie Institution in Washington (q.v.), established the "Department of International Research in Terrestrial Magnetism," which employed the freighter "Galilee" (1905-1908) and the nonmagnetic vessel Carnegie (1909-1929) (q.v.), for oceanic geomagnetic surveys. A similar initiative, with the "Zarya," was launched by the USSR in 1956, just before the International Geophysical Year (1957-1958) renewed interest in geomagnetic observations through its "World Magnetic Survey." From 1953, novel magnetometers were towed at distance behind a ship to avoid deviation effects, a practice still routinely carried out on recent ocean-bound scientific missions.

With the advent of new technology, land observatories no longer recorded the local vector in terms of angles and total intensity, but adopted the three orthogonal vector components (*X*, *Y*, and *Z*). Airborne magnetic surveys (in particular to study the crustal field) became increasingly common in the second half of the century, for example, in the "World Magnetic Modelling and Charting" programme of the US. Defence Mapping Agency. Satellite measurements of the Earth's magnetic field started with the Soviet "Sputnik 3" (1958), maintained in subsequent decades by their "Vostoks" and the American "OGO" series (see *POGO*). In 1979 the United States launched *Magsat* (*q.v.*), the first geomagnetic vector satellite, followed by the European "Orsted" (1999) (*q.v.*), and "*CHAMP*" (2000) (*q.v.*). Once workers were able to compare the near-global, uniform coverage provided by satellites with earlier field maps and historical datasets, the continuity of some static and dynamic features provided theoreticians new food for thought.

Important strides forward were also made in the theoretical domain before that time. At the turn of the 20th century, a great number of *nondynamo theories* (*q.v.*) were launched, based on thermoelectricity and (gravitational or geochemical) charge separation. Another hypothesis explored by several workers is the one often associated with the work of *Patrick M.S. Blackett* (1897–1974) (*q.v.*), which posited that the Earth's magnetic field could be due to its rotation (Good, 1998). Two of Blackett's former students explored this idea: *Edward C. Bullard* (1907–1980) (*q.v.*) suggested that such a distributed source would cause the field to be weaker at greater depth, whereas actual measurements made in deep mine shafts by *S. Keith Runcorn* (1922–1995) (*q.v.*), ultimately concurred with Blackett's own laboratory research, in supporting a negative conclusion.

A different hypothesis, more in keeping with a growing body of seismological evidence that delineated a fluid outer core and solid inner core, originated with the supposition of Joseph Larmor in 1919 that the Sun's magnetic field might operate as a self-exciting dynamo. 360

Building on the mathematical foundations of electromagnetism laid down by James Clark Maxwell (1831-1879) in 1861-1864, and armed with new methods of analysis, workers in the 1940s and 1950s developed the theory of the fluid geodynamo, which still forms the basis of current understanding regarding geomagnetism. In 1939, Walter Elsasser published "On the Origin of the Earth's Magnetic Field," in which turbulent convective motions were deemed to create inhomogeneities in the liquid metallic interior of the Earth's core, giving rise to thermoelectric currents. After World War II, Elsasser focused on kinematic instabilities, positing in 1946 that a toroidal core field could play a vital role in generating and sustaining a self-exciting dynamo process. In the late 1940s and 1950s, the theory was elaborated further by Bullard and George E. Backus (q.v.), among others. Despite initial skepticism, first after publication of Cowling's theorem (1934, q.v.), and later, after the demise of the Bullard-Gellman numerical solution, dynamo theory has since gained, in broad outline, near universal acceptance. Nevertheless, important areas of controversy remain (for example, regarding the magnetohydrodynamic wave and frozen flux hypotheses), and to date, no causal geomagnetic model exists that simultaneously and accurately mimics physics and behavior of the Earth's field on all relevant timescales.

By the end of the 20th century, the discipline of geomagnetism, which in the 1930s had split into the three subdisciplines of paleomagnetism, internal field modeling, and investigations of the external field, had initiated a move toward reintegration, combining data, theories, and constraints from all. In addition, field maps no longer only captured the surface field, but likewise displayed geomagnetic features at the top of the source region, at the *Core-Mantle Boundary* (q,v.), and increasing attention was being devoted to possible coupling mechanisms at work across this interface. Advances in mathematics, instruments, and computing power likewise opened up vast new horizons to explore. Together, these developments promise geomagnetists in the 21st century many exciting, more comprehensive insights into the myriad fascinating aspects of their chosen field of study.

## **GILBERT, WILLIAM (1544–1603)**

William Gilbert (sometimes spelled "Gilberd") was born in Colchester, England, in 1544, the son of Jerome, a successful Burgess and Recorder of the town, and his wife Elizabeth. From St John's College, Cambridge, where he graduated M.D. in 1569, and of which foundation he became a Senior Fellow, serving the College in a variety of offices, William Gilbert began to practice medicine in London. Sometime before 1581, he was admitted into the prestigious Royal College of Physicians, and over the years occupied several of its senior offices. His professional career was crowned in 1600 when he was appointed Physician to Queen Elizabeth I, though as that monarch wisely avoided medical attention, one suspects that this distinguished appointment was, in practical terms, a sinecure. When King James I ascended to the throne in March 1603, Gilbert continued as Royal doctor, only to die later that year on November 30, 1603. Gilbert never married.

Gilbert's enduring fame, however, lies not in his medical achievements, which were conventional, but in his pioneering and privately conducted researches into magnetism, geomagnetism, and electrostatics, which he published in *De Magnete, magneticisque corporibus, et de magno magnete tellure; physiologia nova, plurimis et argumentis, et experimentis demonstrata* (London, 1600). For as this long title tells us, Gilbert's book was far more than just a book on magnets, but developed an argument, based on abundant experimental evidences, that magnetism was a property of the terrestrial globe itself. In short, it was the first coherent treatise on geomagnetism, and in this respect, is a foundation text of modern experimental physics, having a profound impact on all subsequent researches, and influencing figures such as Kepler, Galileo, Hooke, Newton, Halley, and the early Fellows of the Royal Society. At the heart of Gilbert's scientific rationale was his skepticism about aspects of the philosophy of Aristotle, which was enshrined in university curricula across Europe, and which saw the earth as essentially passive and made of a fundamentally different stuff from the dynamic and shining heavens. Magnetism, however, tended to challenge such an attitude, suggesting that the earth possessed a lively dynamic force of its own: a force, moreover, that was amenable to experimental investigation. For it is very clear that Gilbert was part of a tradition of emerging experimental practice in Elizabethan England. A practice sometimes seen as closer in principle to the mechanic practice of artisans than to the refined philosophy of university men, and which Gilbert's younger contemporary, Sir Francis Bacon, would develop into a coherent model of how to investigate nature by means of experiments in his *Novum Organon* (1620) (q.v.).

Central to the argument of *De Magnete* is that the earth itself is a spherical magnet, with a north and south pole. Moving between these poles in what we might call a curved field was the invisible magnetic force deriving from the very being, or "soul," of the earth itself. This force was actively present in all magnetite stone and ferrous metals, and Gilbert knew, from writers going back to Petrus Peregrinus in 1269 and before, that suspended iron needles would orientate themselves along it. He also knew from his Elizabethan contemporary, the compass-maker and artisan-scientist, Robert Norman, in 1581, that this force not only acted in a lateral plane, but also in a vertical one, to produce the magnetic dip.

Central to Gilbert's geomagnetic ideas, and probably picked up initially from Peter Peregrinus' Epistola, were his experiments conducted upon what he called "terrellae," or little earths. These were spheres of magnetic material, probably lumps of spherically chiseled magnetite, all of which were found to have magnetic poles, equators, and contours, just like the earth. These characteristics were discovered with an instrument, which Gilbert sometimes called his magnetized "Versorium" (presumably from Latin versare, "to turn around"), which was a delicately poised magnetic needle, capable of moving both horizontally and vertically when held near the terrella. Over the terrella's magnetic equator, for instance, the needle tended to position itself north-south horizontally, or in a tangent to the equator. But as it moved forever closer to a pole, it dipped in its angle, and stood vertically upon reaching one or other pole. This suggested a continuous force field emanating from and connecting the poles in a series of invisible arches, which were at their flattest over the equator. Gilbert also found that the slight irregularities in the terrella produced in turn local force fields irregularities, which he saw as analogous to local variations in the magnetic field of the earth itself.

The major aspect of Gilbert's genius as an experimental physicist was his realization that one could study and model phenomena with the terrella in the laboratory that were physically identical to the phenomena exhibited by the globe of the earth itself as it hung in space. A concept, indeed, so familiar to modern scientific practice as to be taken for granted, but outrageous for the 16th century, for Aristotle taught not only that the heavens were fundamentally different from the earth, but that beneath the fire, air, and water that surrounded our planet, there was a primary element of Earth. Yet how could this Earth be homogeneous or at one with itself, if parts of it were magnetic and other parts were not?

Gilbert's terrella experiments enabled him to develop a coherent and verifiable model for the Earth's magnetic field, explaining the northfinding properties of compass needles, local irregularities, and the dip. It was arguably the first experimentally based comprehensive theory in the history of physics, and it is hardly surprising that several subsequent generations of scientists found inspiration in his work.

From his laboratory and terrestrial studies, Gilbert then took the portentous step of developing a magnetic cosmology in Book VI of *De Magnete*. For one thing, he argued that the Earth's magnetic field suggested that our planet rotated on its axis, *contra* Aristotle, Ptolemy, and the classical philosophers, who said that it was stationary, with the universe rotating around us. And while he never formally proclaimed

himself a Copernican, all of Gilbert's cosmological arguments presumed the Sun, and not the Earth, to be at the center of the solar system. He also argued that, instead of being made of a unique cosmological fifth element, as the ancients had thought, the planets themselves were probably made of magnetic material, and moved through space under the influence of magnetic force fields. Very important in this context, moreover, was his abandonment of Aristotle's cosmological divide of the Moon's orbit, which was believed to separate the terrestrial from the celestial realms. Substantiated in part from Tycho Brahe's recent astronomical discoveries, And in his posthumously published De Mundo (Amsterdam, 1651), Gilbert suggested that space was, in effect, homogeneous and empty: without qualitative divisions, yet traversed by magnetic forces which were themselves the sources of all motion. He also speculated that the diffuse light of the Milky Way might be occasioned by masses of very distant stars, no individual star of which we could see from Earth, though here, in some respects, Gilbert was in keeping with earlier medieval writers such as Jean Buridan, Nicolas Oresme, and Simon Tunsted, to name but a few.

There is no evidence to suggest that Gilbert's failure to openly embrace the Copernican theory derived from a fear of religious persecution. Copernicanism only became a contentious issue for the Roman Catholic Church after Galileo used it for his own highly adversarial purposes after 1612, while the Church of England never had any official policies on scientific issues one way or the other. One suspects that his reluctance comes from covering his back professionally, as an eminent physician. Academic medicine was a deeply conservative art in Gilbert's time, and learned physicians risked professional suicide if they openly proclaimed novel ideas, which cast doubt on the timehonored wisdom of the ancients. After all, Gilbert's Royal doctor and Physicians' College colleague of the next generation, William Harvey, found that his published discovery of the circulation of the blood in 1628 badly damaged his practice as a society doctor. Writing a book about magnetism was one thing, but openly espousing a theory, so contradictory to common sense as Copernicanism then seemed in 1600 was risking being branded an unsound man. Not a good trait for a Royal doctor to have attributed to him, indeed!

In addition to his experimental and speculative cosmological work, De Magnete also aspired to present a history of and devise a taxonomy for magnetic phenomena. And very significantly, in Chapter 2 of Book II (out of the six books into which De Magnete is divided) Gilbert set out his researches into the properties of amber, jet, and other substances, which displayed what he called *Electric* characteristics. (The term, which introduced the words electric and electrical into the modern world, was derived by Gilbert from the Greek word for amber: electrum.) From his experiments, he differentiated between magnetic phenomena proper, which he saw as innate and permanent properties of the stuff from which God had created the world, and friction-generated *electric* phenomena, which were a short-lasting product of the residual moisture or effluvium of once-fluid substances, such as those resins which solidified into amber, and which could be temporarily excited, and draw things to themselves by rubbing. Though by modern standards Gilbert's explanations were wrong, his recognition that magnetism and electrical phenomena were two quite different forms of attraction was correct.

Gilbert's *De Magnete* was one of those milestone books in the history of science which turned a hitherto vague and confused collection of observations that was magnetics into a coherent discipline, the phenomena of which could be tested at leisure by its readers and applied to new situations and monitored with refined instruments. Its taxonomy of phenomena, moreover, introduced new terms, such as *magnetic polarity* and *electric* into general usage. And very portentously, it began that transformation away from the Aristotelian doctrine of motion to something much more dynamic, and, by its exploration through a series of tests and hypotheses, laid the foundation for modern experimental physics.

## **GRAVITATIONAL TORQUE**

The expression can be given a wide definition. We will restrict the presentation to the torques mutually exerted one on the other by the three envelopes of the internal Earth (inner core, outer core, and mantle) through the perturbative gravitational force field superimposed on the gravitational field of an equilibrium state—hydrostatic in the fluid core.

#### The equilibrium state

For the sake of simplicity we consider the inner core and mantle to be rigid. In fact the mantle is convecting, and density anomalies exist, as well as bumps at the core-mantle boundary (CMB). A disturbed gravitational potential results in the mantle, liquid outer core (Wahr and de Vries, 1989), and inner core. Our hydrostatic state is the state in which the mantle, outer core and inner core are at rest with respect to one another under self-gravitation potential  $\Psi_0(\hat{r})$  ( $\hat{r}$  is the current point), the whole Earth rotating with uniform angular velocity  $\overline{\Omega_0}$ around its polar axis of inertia fixed in space (we ignore precession, although an external gravitational force is responsible for driving it). Let  $\rho_0(\hat{r})$  and  $p_0(\hat{r})$  be the corresponding density and pressure fields in the liquid outer core. We have:

$$\rho_0 \vec{\nabla} (\Psi_0 + U_0) = \vec{\nabla} p_0, \vec{\nabla} \Psi_0 = - \overrightarrow{\Omega_0} \wedge (\overrightarrow{\Omega_0} \wedge \vec{r})$$

$$\nabla^2 U_0 = -4\pi \, G\rho_0$$

*G* is the gravitational constant,  $\Psi_0$  the rotational potential. Level surfaces of  $U_0 + \Psi_0$ ,  $\rho_0$ ,  $\rho_0$  are parallel. It is essential in the following that  $U_0$  be nonaxisymmetric. In fact  $\rho_0$  changes with time, but we consider time constants much shorter than the time constant of the convection in the mantle. This (pseudo) static equilibrium state corresponds to a minimum gravitational energy, and no mutual torque exists.

We will now consider perturbations from this state and the resulting gravitational torque. We separate different problems for the sake of clarity.

## The mantle—inner core gravitational coupling and l.o.d.

Let us ignore in a first step the convection in the core (density heterogeneities responsible for this convection are of the order of  $10^{-8}\overline{\rho_0}$ ,  $\overline{\rho_0}$ being the mean core density, whereas those generated by mass anomalies in the mantle are of the order of  $10^{-4} \overline{\rho_0}$ .

Consider that  $\rho_0(\hat{r})$  is not axisymmetric, for example

$$\rho_0(\hat{r}) = \rho_0(r) \ (1 + \Delta_2^2(r) \ P_2^2(\cos\theta) \cos 2(\varphi - \varphi_0)),$$

 $\theta$  and  $\varphi$  being colatitude and longitude; (this quadrupole term is evidenced by seismic studies) and that a difference ( $A_S-B_S$ ) results between the equatorial moments of inertia of the inner core. Let the mantle and inner core be rotated by angles  $\varphi_m$  and  $\varphi_s$ , respectively,

from their equilibrium positions. A restoring gravitational torque is exerted by the mantle on the inner core (and vice versa), proportional to the relative rotation (Buffet, 1996a):

 $\Gamma_{\rm i} = \bar{\Gamma}(\varphi_{\rm m} - \varphi_{\rm s}) \tag{Eq. 1}$ 

(the action of the outer core is just to contribute to the value of  $\overline{\Gamma}$ ). That means that the inner core is gravitationally locked to—aligned with—the mantle in the equilibrium figure.  $\overline{\Gamma}$  can be computed from the gravitational energy, which is minimum in the equilibrium state.

Small oscillations of the inner core and mantle around the rotation axis  $\overline{\Omega_0}$ —i.e., oscillations in the length of the day—arise whose period is proportional to the polar momentum of inertia of the inner core (approximately) and inversely proportional to  $\overline{\Gamma}$ . Periods of few years are obtained with current models of density anomalies in the mantle.

The liquid outer core does not play an important role in the former mechanism, but it can be the seat of the so-called torsional oscillations (Braginsky, 1970; Zatman and Bloxham, 1998; Hide et al., 2000; Dumberry and Bloxham, 2003; Jault and Legaut, 2005) made of rotations  $\omega(s)$  of the geostrophic cylinders C(s) of radius s (whose axis is the rotation axis  $\Omega_0$ ). The adjacent cylinders are coupled through electromagnetic forces due to the radial cylindrical component of the main field, and the inner ones are coupled with the solid inner core through magnetic friction. The inner core and mantle are as before coupled by gravitational forces. Again, if the inner core and mantle happen to be moved with respect one to the other, restoring gravitational torques will generate small oscillations around the equilibrium configuration. Their periods are increased up to several decades due to the involvement of geostrophic cylinders (Buffet, 1996b). As for the excitation of these necessarily damped oscillations, it could be due to the dynamo process itself.

## The mantle—inner core gravitational coupling and nutations

The system made of the rotating mantle, outer core and inner core displays small motions of the rotation axes of the three envelopes, called nutations. Forced nutations are generated by the lunisolar tidal potential. Free nutations are rotational eigenmodes of the system. Two modes are nearly diurnal in a frame corotating with the mantle  $(\overline{\Omega_0})$ , the free core rotation (FCN) and the free inner core nutation (FICN). Two modes have periods much longer than a day in this same frame, the Chandler wobble and the inner core wobble (Mathews *et al.*, 1991).

The gravitational torque exerted by the mantle and outer core on the ellipsoidal inner core has a profound effect on the inner core wobble and FICN. This torque results from the tilt of the inner core (due to the equatorial component of its rotation  $\overline{\omega_s}$ ) or misalignment of the figure axes of the inner core and the mantle (Xu and Zseto, 1996). In other words, as before in the axial problem, the restoring gravitational torque tends to lock the inner core with respect to the mantle (here the flattening of an axisymmetric earth is to be invoked). If the inner core is rigid, or purely elastic, the locking is strong. If it is viscous, it yields to the gravitational forces and tends to cancel the torque. In the limit of a liquid inner core, the inner core wobble disappears. As for the period of the FICN (in an absolute frame), it may vary, in the absence of magnetic field, from 75 days (liquid inner core) to 485 days (elastic inner core) (Greff-Lefftz *et al.*, 2000).

## Gravitational forces due to the convective density heterogeneity in the core

Consider now the independent of  $(\rho_0)$  density heterogeneity  $\rho'$ , thermal or compositional, generating the convective flow  $\vec{u}$  driving the dynamo. Extra gravitational and rotational potentials appear:

$$\rho_{0} \rightarrow \rho_{0} + \rho', \ U_{0} \rightarrow U_{0} + U', \ \overrightarrow{\Omega_{0}} \rightarrow \overrightarrow{\Omega_{0}} + \ \Omega'', \ \Psi_{0} \rightarrow \Psi_{0} + \Psi'$$

A gravitational torque is exerted on the mantle by this density distribution (in this section we ignore the inner core):

$$\overrightarrow{\Gamma_{g}} = \iiint_{M} \rho_{0} \left( \vec{r} \wedge \vec{\nabla} U' \right) dv$$
(Eq. 2)

(we ignore the effect of  $\Psi'$  for the sake of simplicity); of course an equal and opposite torque is applied on the core by the mantle.

(a) The axial problem

 $\hat{k}$  being the unit vector of  $\overrightarrow{\Omega}$  (or  $\overrightarrow{\Omega_0}$ )

$$\Gamma_{\rm gz} = \overrightarrow{\Gamma_{\rm g}} \cdot \overrightarrow{k} = -\iiint_M \rho_0 \frac{\partial U'}{\partial \varphi} \, \mathrm{d}v = \iiint_M U' \frac{\partial \rho_0}{\partial \varphi} \, \mathrm{d}v$$

that makes it clear again that only the non axisymmetric part of  $\rho_0$  intervenes in the axial torque. If  $I_{\rm M}$  is the polar moment of inertia of the mantle and  $\omega_z$  the component of  $\Omega'$  along  $\overline{\Omega_0}$ , we have

$$I_{\rm M} \frac{{\rm d}\omega_{\rm z}'}{{\rm d}t} = \Gamma_{\rm gz}$$

if  $\overrightarrow{\Gamma_g}$  is only acting.

The effect of the gravitational forces on the fluid core itself is more subtle since it does not react like a rigid body. Let us again consider the cylinders C(s) of radius *s* and thickness *ds*. The axial gravitational torque acting on C(s) is (Jault and le Mouel, 1989):

$$\Gamma_{\rm gz} (s) = {\rm d}s \int \left( \rho' \frac{\partial U_0}{\partial \varphi} - U' \frac{\partial \rho_0}{\partial \varphi} \right) {\rm d}z {\rm d}\varphi$$

*s*,  $\varphi$ , *z* being the cylindrical coordinates. An accelerated rotation of C(s) results, with linear velocity  $\vec{t_1}(s,t) = t_1(s,t) \hat{\varphi}$ , governed by the equations

$$I(s)\left(\frac{\partial t_1(s,t)}{\partial t} - \frac{\mathrm{d}\omega'_z}{\mathrm{d}t}\right) = \Gamma_{\mathrm{g}}(s) \tag{Eq. 3}$$

$$I_{\rm M} \frac{{\rm d}\omega_{\rm z}'}{{\rm d}t} = -\int_0^a \Gamma_{\rm g}(s) \; {\rm d}s = \Gamma_{\rm gz} \tag{Eq. 4}$$

I(s) is the moment of inertia of cylinder C(s), *a* is the radius of the core. The reason why the geotrophic flow  $t_1(s, t)$  is accelerated is that it is the only one for which the growing Coriolis force can be balanced by a growing pressure torque. Equations (3) and (4) would govern changes in  $\omega'_z$ , i.e., changes in lo.d generated by gravitational forces linked to  $\rho'$ , should  $\overrightarrow{\Gamma_g}$  be only acting. In fact it is rather artificial to separate here the gravitational torque from the topographic torque (action of the pressure field linked to flow  $\vec{u}$  on the CMB bumps). Furthermore the electromagnetic forces which couple the adjacent cylinders (and the outer core with the inner core and the poorly conducting mantle) provide the dissipative mechanism, which prevents rotation of the core relative to the mantle to grow indefinitely.

Unfortunately the evaluation of the gravitational torque, which requires the knowledge of both the anomalous (nonaxisymmetric) part of  $\rho_0$  and the convective density heterogeneity  $\rho^{*}$ , is far from being easy. It could generate significant variations in l.o.d.

(b) The gravitational torque  $\overrightarrow{\Gamma_g}$  and the pole motion

Let us consider the equatorial component of the gravitational torque Eq. (2) and the Euler equations for the mantle (i.e., the equations of the equatorial components of the angular momentum of the mantle in a frame rotating with angular velocity  $\overline{\Omega_0}$ ):

$$A_{\rm M} \frac{\mathrm{d}\Omega'}{\mathrm{d}t} - \mathrm{i} \left( C_{\rm E} - A_{\rm E} \right) \Omega_0 \; \Omega' + i \; \Omega_0^2 \; c = \Gamma_{\rm g}$$

with the usual notations:  $A_{\rm M}$  is the equatorial moment of inertia of the mantle,  $C_{\rm E}$  and  $A_{\rm E}$  the polar and equatorial moments of inertia of the whole Earth (taken axisymmetric),  $\Omega' = \omega'_1 + i\omega'_2$ ,  $\Gamma_{\rm g} = \Gamma_{\rm g1} + i \Gamma_{\rm g2}$ ,  $\omega'_1$  and  $\omega'_2$  being the two equatorial orthogonal components of  $\overline{\Omega'}$ ,  $\Gamma_{\rm g1}$  and  $\Gamma_{\rm g2}$  the same components of  $\overline{\Gamma_{\rm g}}$ ,  $i = \sqrt{-1}$ . And  $c = c'_{\rm E1} + i c'_{\rm E2}$  is the change in the Earth equatorial moment of inertia due to the perturbations  $\rho'$ .

Again, it is artificial to separate here the gravitational torque from the pressure torque (Hulot and Le Mouel, 1996). The gravitational torque linked to a time varying  $\rho'$ —i.e., a flow—might be invoked to excite the Chandler wobble; but short time constants ( $\ll$ 435 days) are requested; or to generate the so-called Markovitz wobble; but balances with other torques have to be considered (Hulot and Le Mouel, 1996).

Note that dynamo modeling could now provide estimates of the gravitational torque due to the corresponding core flow.

## GRAVITY-INERTIO WAVES AND INERTIAL OSCILLATIONS

Earth's outer core is a predominantly iron, rotating liquid body, bounded by a silicate mantle, that is quasispherical. Thus an understanding of the global dynamics of the core can be had by considering it to be an incompressible fluid contained by an approximately spherical, rigid boundary. If the core were rotating at a constant rate as though it were a solid, individual parcels of fluid would be at rest relative to Earth's surface. A parcel of fluid displaced from equilibrium would experience a buoyancy force if the density were not uniform, and a coriolis force due to Earth's rotation, resulting in what are called core undertones, their periods being large compared to Earth's free (elastic) oscillations. The combined result of these two restoring forces would produce gravity-inertio waves or gravito-inertial waves as they are sometimes termed. In Earth's atmosphere they are usually termed inertio-gravity waves while in the Sun they are called g-modes; more generally they are described as internal gravity waves modified by rotation or simply gravity waves. If there were no density effects, just inertial waves result. The local motion of a fluid parcel in this latter case is an inertial oscillation. A member of the triply infinite set of inertial modes can be excited in a contained rotating fluid like the core if there is a global source of excitation at an appropriate frequency and will decay by viscous dissipation in the boundary layers and interior. The physics of these modes is discussed below where the range of frequencies for each type of response is found heuristically from basic physical principles.

## Inertial oscillations

Starting with the simplest case, assume that there are no density differences from place to place in the core and consider a uniform core rotating at the diurnal rate. A ring of fluid encircling the axis of rotation is held in equilibrium by the balance between centrifugal and radial pressure gradient forces on the ring. Expanding the ring slows it down to conserve angular momentum so that the centrifugal force in the expanded position is now less than the local, axially directed radial pressure gradient. Accordingly, the ring is forced back to its starting position just as it would be if the ring had been initially contracted toward the axis of rotation. Thus the ring of fluid is stable with respect to radial perturbations so it oscillates.

## Frequency of oscillations

A ring of fluid displaced in a direction perpendicular to the axis of rotation will oscillate at frequency  $\omega = 2\Omega$  where  $\Omega$  is the assumed steady rotation rate of Earth. If instead of a radial displacement of the fluid ring, it were moved axially with its motion parallel to the rotation axis, no restoring force would exist so that  $\omega = 0$ . Displacement of the ring in any other direction would produce a component of restoring force only in the direction perpendicular to the rotation axis giving

$$\omega = 2\Omega \cos\theta \tag{Eq. 1}$$

)

where  $\theta$  is the colatitude of the ring as shown in Figure G54. Thus any frequency of oscillation  $\omega$  in the range  $0 < \omega < 2\Omega$  is allowed so that for the idealized constant density core considered here (see also *adiabatic gradient in the core*), the shortest period of oscillation would be approximately 12 h.

Individual particle motions follow elliptical paths that are the same in every meridional plane. These are axisymmetric inertial oscillations (Aldridge and Toomre, 1969; Greenspan, 1969) that have particle motions predominantly parallel to the rotation axis when  $\omega \rightarrow 0$  and perpendicular to this axis when  $\omega \rightarrow 2\Omega$ . In a bounded rotating fluid like the core, a doubly infinite set of axially symmetric inertial oscillations can exist, usually called inertial modes. Surfaces on which disturbance pressure vanishes form nodal lines which are ellipses in meridional planes. Some examples of these lines which divide the fluid into cells are given in Figure G55 for a unit sphere. The small ticks at the surface show what is known as the critical colatitude for the mode where  $\theta$  satisfies Eq. (1). Tangents to the surface at this location define a direction within the fluid, called a *characteristic*, along which small disturbance will propagate as illustrated in Figure G54.

**Figure G54** Characteristic lines for an inertial wave of frequency  $\omega = \Omega$  propagating in a sphere. The critical colatitude  $\theta = 60^{\circ}$  is shown corresponding to the point where a tangent to the sphere parallels a characteristic line.

**Figure G55** Nodal surfaces of pressure for some axisymmetric inertial oscillations with velocity shown by sketched curves. Index (*n*, *m*) corresponds to the *m*th root of the Legendre polynomial  $P_{2n+2}(\omega/2\Omega) = 0$ . (From Aldridge and Toomre, 1969. With permission.)

The source of these characteristics is that the differential equation describing the gravity waves is hyperbolic in space and it must satisfy a no-slip boundary condition at the surface of the core-mantle boundary (CMB). A boundary value problem which is hyperbolic (rather than elliptic) is said to be ill-posed. No continuous solutions are guaranteed for such problems so that approximate and laboratory methods must be used to solve them. A notable example is the limiting case  $\omega = 0$  (steady motion) where  $\theta = 90^{\circ}$  so the tangent is parallel to the rotation axis; this is a Taylor column, the axial column seen in a rotating fluid when an object is towed steadily through the fluid. These disturbances are *inertial waves* and are discussed below.

## Amplitude of oscillations

Inertial oscillations could be excited in Earth's core through coupling of the interior fluid at the boundary by viscous forces. If the boundary motion is sufficiently well-coupled spatially to a mode-e.g., the semidiurnal tide has very similar spatial structure to a mode with azimuthal dependence  $\cos 2\phi$  where  $\phi$  is geographic longitude. There are several modes with periods near the semidiurnal tide (Aldridge et al., 1988). Modes coupled to the CMB by viscosity will be excited on a timescale of spin-up or  $E^{-1/2}\Omega^{-1}$  where E is the Ekman number for the core. For laminar flow this turns out to be about 5 ka. This is also the timescale for free decay, which is mostly caused by boundary layer dissipation (see also Boundary layers in the core) with additional internal dissipation which increases dramatically for modes of smaller spatial structure. Theorems have been developed (Zhang et al., 2001) that imply no dissipation for inertial modes in a sphere; though elegant they are not relevant for real fluids since they only apply to ideal (inviscid) fluids.

#### Inertial waves

At frequencies  $\omega \rightarrow 2\Omega$  the waves travel in the direction of the axis of rotation while at intervening frequencies they travel in directions given by  $\theta$  in Eq. (1). The particle motion of the waves is perpendicular to the propagation direction since it is the Coriolis force that is acting on the particle. Thus the inertial waves are transverse. The waves are reflected at boundaries such that they maintain equal angles of reflection and incidence with the direction of the rotation axis rather than a normal to the reflecting boundary. Thus these waves will have multiple reflections in a closed container. In a spherical shell of fluid, multiple reflections lead to repeated paths (Hollerbach and Kerswell, 1995; Tilgner, 1999) which are known as *attractors* and have been studied extensively (Rieutord *et al.*, 2001).

The assumption of axial symmetry can be relaxed by introducing azimuthal dependence and this reveals that there is a triple infinity of inertial modes. The critical directions become cones that define the propagation of waves in the fluid.

Inertial waves have been excited in laboratory experiments (Noir *et al.*, 2001) on precession of a spheroidal shell of fluid (see also *Fluid dynamic experiments, Precession and core dynamics*). Since an observer in the rotating frame of reference with the container's spin will see the precession as a diurnal disturbance,  $\theta = \arccos(1/2) = 60^{\circ}$  which corresponds to the characteristics illustrated earlier in Figure G54. It is estimated that the precession will excite inertial waves of amplitude  $6 \times 10^{-6}$  m s<sup>-1</sup> in a band 20 km wide in Earth's core, thus setting a level for their detectability.

At semidiurnal periods, inertial modes with azimuthal dependence  $\cos 2\phi$  that are viscously coupled to the CMB will produce a semidiurnal wobble as angular momentum of Earth must be conserved. In principle this wobble should be detectable using both VLBI and supergravimetry as changes in latitude of observatories but so far only limited success has been achieved in the search for evidence of these modes in the core (Aldridge and Cannon, 1993).

#### **Gravity-inertio waves**

The previously ignored buoyancy force can be returned by assuming the fluid is stratified. Stratification is characterized by

$$N^2 = -\frac{g}{\rho} \frac{\mathrm{d}\rho}{\mathrm{d}r}$$

where N is the Brunt-Väisälä frequency, g is acceleration due to gravity, and  $\rho(r)$  is the fluid density assumed to be a function of spherical radius r. (The - sign is included to ensure  $N^2 > 0$  as  $\rho(r)$  is a decreasing function of r.)

With rotation both coriolis and buoyancy forces act on a fluid parcel. If buoyancy dominates coriolis in the sense that  $N > 2\Omega$  then wave gravity wave frequencies are such that

$$2\Omega \le \omega \le N$$

while if stratification is very weak so that  $N < 2\Omega$ , then

$$2\Omega \geq \omega \geq N$$
.

In the presence of stratification, the characteristics shown in Figure G54 become curved (Dintrans *et al.*, 1999).

In principle gravity waves should be detectable at Earth's surface since there must be a redistribution of mass when fluid parcels oscillate (Crossley *et al.*, 1991). Changes in gravity are due to this redistribution of mass directly as well as the movement of Earth's surface through the gradient of the gravity field. Amplitudes are extremely small, estimated at  $10^{-11}$  m s<sup>-2</sup>, and are only likely to be detectable by using a global array of superconducting gravity meters as organized under the Global Geodynamics Project (GGP). Successful detection of gravity waves in Earth's core would constrain the *core's density* (*q.v.*) distribution as has already been demonstrated for the Sun (see also *Helioseismology*).

### Instability of inertial modes

The stable inertial modes described above can be destabilized by straining of the fluid streamlines (Kerswell, 1993, 2002). This fact has significant implications for Earth's core as it provides for a mechanism to pump energy parametrically into the core at a diurnal rate and cause a disturbance to grow at a rate determined by the strain. For Earth, this strain is very small leading timescales of instability growth of several thousand years (Aldridge and Baker, 2003) (see also *Turbulence in the core*). The strain comes from two sources, Earth's *precession* (q.v.) that introduces a predominately shearing of the core fluid's streamlines and Earth's semidiurnal tide which deforms the streamlines into ellipses. The former is small because of the relatively long period of the precession compared to the diurnal rotation while the latter owes its small size to the amplitude of tidal deformation in the core.

At present there is a small amount of evidence for the existence of parametric instability in Earth's fluid core. Based on laboratory observations of rotating parametric instabilities (Aldridge, 2003), a search has been made for a signature of these instabilities in records of relative *paleointensity* (*q.v.*) obtained from seafloor sediments. Initial results of this work (Aldridge and Baker, 2003) confirmed that a 400 ka record of relative paleointensities yielded a sequence of geophysically plausible growths and decays of magnetic field intensity over several thousand years that is consistent with what would be expected for rotating parametric instabilities. On longer timescales, tidal deformation and precessional forcing have been identified in paleomagnetic records. For example, variation in relative paleomagnetic intensity corresponding to Earth's obliquity has been reported (Kent and Opdyke, 1977). Although the origin of these variations has been often considered to be climatic, recent paleomagnetic records have revealed robust

evidence of external forcing that is independent of climatological variations. Spectral analysis of the relative paleointensity record from ocean sediments (Channell *et al.*, 1997) show modulation of intensity corresponding to orbital obliquity and eccentricity periods. The inclination error found in a 2 Ma long record from the west Caroline basin (Yamazaki and Oda, 2002) correlates to orbital eccentricity.

Although gravitational energy released through compositional convection is considered to drive the core's geodynamo that maintains the geomagnetic field, other phenomena like rotational parametric instabilities may prove to play a significant role in maintaining the geodynamo.

# GRÜNEISEN'S PARAMETER FOR IRON AND EARTH'S CORE

#### Introduction

The Grüneisen parameter  $\gamma$  is a necessary tool for assessing Earth's thermal properties. Here we emphasize aspects of  $\gamma$  that are pertinent to Earth's core.  $\gamma$  has various definitions, many of which are derivable one from another by thermodynamic identities. The following equation for  $\gamma$  quantifies the relationship between the thermal and elastic properties of a solid. The parameter  $\gamma$  can be considered as a measure of the change in pressure *P* resulting from an increase in energy density at constant volume *V*. It is dimensionless, since pressure and  $\Delta U/V$  have the same units

$$\gamma = V \left(\frac{\partial P}{\partial \mathcal{U}}\right)_V \tag{Eq. 1}$$

where  $\mathcal{U}$  is the internal energy. From Eq. (1) it is seen that  $\gamma$  connects pressure and energy, and therefore, pressure and temperature. Elasticity properties of Earth's core (especially pressure) come from seismological data. Gamma is useful to obtain energy and temperature from these seismological data. Another example of the importance of  $\gamma$  is in the expression used for thermal pressure at high temperature

$$P_{\rm TH} = \frac{\gamma}{V} E_{\rm TH} \tag{Eq. 2}$$

the so-called Mie-Grüneisen relationship ( $E_{\text{TH}}$  is the thermal energy and  $P_{\text{TH}}$  is the thermal pressure). This equation is often used with an isothermal equation of state,  $P(V,T_0)$ . Equation (1) is the general statement of the relationship between pressure and energy of which Eq. (2) is a special case. Equation (2) can be considered as the historical presentation of  $\gamma$ , attributed to Grüneisen (1926), who derived the equation for pressure as a function of volume and temperature in an early version of lattice dynamics.

For many physical properties of the Earth's interior, we need to know the value of  $\gamma$  of a solid at the pressure and temperature of the Earth's interior, not just at ambient conditions. We need to know how  $\gamma$  changes with *T*, especially at high *T*, if at all, and how  $\gamma$  changes with pressure (or rather, volume), especially at high compression.

### Thermodynamic derivations of gamma

In order to evaluate Eq. (1) in parameters representing measurable physical properties, start with the following equation

$$\left(\frac{\partial P}{\partial \mathcal{U}}\right)_{V} = \left(\frac{\partial P}{\partial T}\right)_{V} \left/ \left(\frac{\partial \mathcal{U}}{\partial T}\right)_{V} \right.$$
(Eq. 3)

The definition of specific heat is  $(\partial U/\partial T)_V = C_V$  at unit mass (all quantities are per unit mass). The numerator on the right side of Eq. (3) is found from calculus:  $(\partial P/\partial T)_V =$  $-(\partial V/\partial T)_P/(\partial V/\partial P)_T = \alpha K_T$ , where  $\alpha$  is the volume thermal expansivity, and  $K_T$  is the isothermal bulk modulus. Equation (3) is therefore equivalent to

$$\left(\frac{\partial P}{\partial \mathcal{U}}\right)_{V} = \frac{\alpha K_{T}}{C_{V}} \tag{Eq. 4}$$

Using Eq. (4) in Eq. (1), the most useful definition of  $\gamma$  is found:

$$\gamma = V \left(\frac{\partial P}{\partial \mathcal{U}}\right)_V = \frac{\alpha K_T V}{C_V}$$
(Eq. 5)

 $\gamma$  as given by Eq. (5) is composed of individual measurable physical properties, each of which varies significantly with temperature. The ratio of these properties as given by Eq. (5), however, does not vary greatly with temperature, and often not at all. There are many approximations to Eq. (5) for  $\gamma$ . The few approximations we will use here will be given special subscripts and names.

Another method of finding  $\gamma$  involves adiabatic compression. Start with one of Maxwell's relationships:

$$\left(\frac{\partial T}{\partial V}\right)_{S} = -\left(\frac{\partial P}{\partial S}\right)_{V}$$
(Eq. 6)

Expand the right side of Eq. (6):  $(\partial P/\partial S)_V = (\partial P/\partial T)_V (\partial T/\partial S)_V$ . By using  $(\partial P/\partial T)_P = \alpha K_T$  and  $(\partial S/\partial T)_V = C_V$ , the right side of this equation becomes  $-T\alpha K_T/C_V$ . Using Eq. (5), the right side becomes  $T_Y/V$ , so that Eq. (6) can also be written as

$$\gamma = -\left(\frac{\partial \ln T}{\partial \ln V}\right)_{S} = \left(\frac{\partial \ln T}{\partial \ln \rho}\right)_{S}$$
(Eq. 7)

Equation (7) is the thermodynamic basis for finding the adiabatic thermal gradient in the core and mantle.

Equations (1), (2), (5), and (7) are thermodynamically equivalent definitions of  $\gamma$ . The choice of the equation to use depends on the parameters at hand and the result desired.

### Lattice dynamic derivations of gamma

The lattice dynamic view of a solid is that of statistical mechanics: a solid is composed of *N* atoms (where *N* is Avogadro's number); each atom is an oscillator having three degrees of freedom and connected to neighboring atoms by a spring. The solid's thermodynamic properties are found from the dynamics of 3*N* vibrations with modal frequencies  $v_1, v_2, v_3, \ldots, v_{3N}$ . Each modal vibration arises from a simple harmonic oscillation, the energy of which is given by an Einstein function, and the frequency of which is classically related to the atomic mass and the spring constant. For a monatomic solid, such as iron, all the masses are equal. A standard treatment of this subject shows that the Helmholtz free energy for a monatomic solid of *N* degrees of freedom is (Slater, 1939)

$$\mathcal{F} = \mathcal{U}_0 + \sum_{j}^{3N} kT \ln\left(1 - e^{-\hbar v_i/\kappa T}\right)$$
(Eq. 8)

where  $\kappa$  is Boltzmann's constant and  $\hbar$  is  $h/2\pi$ , where *h* itself is Planck's constant, and where the quantity under the summation sign is the Einstein function.

The isothermal equation of state P(V) is found by differentiating Eq. (8) with respect to V at constant T, giving

$$P = -\left(\frac{\partial \mathcal{U}_0}{\partial V}\right)_T + \frac{1}{V} \sum_{j}^{3N} \gamma_j \frac{\hbar v_j}{\left(e^{\hbar v_j/\kappa T} - 1\right)}$$
(Eq. 9)

Attention is directed to  $\gamma_j$ , called the mode gamma, which arises from the V derivative

$$\gamma_j = -\left(\frac{\partial \ln v_j}{\partial \ln V}\right)_T \tag{Eq. 10}$$

Although  $\gamma_j$  is dimensionless, its value is influenced by the rate of change of mode frequency with volume. Thus, in order for  $\gamma_j$  to be nonzero, it must change with volume, and for it to be positive, it must decrease with volume. It is customary to make an assumption (called the quasiharmonic assumption) that the mode gammas depend on volume but are independent of temperature.

For core physics, where the temperature is high, the high-temperature limit of the above equations is needed. The Debye temperature  $\Theta_D$  marks the division between the high temperature region and the quantum state region of a solid. For a monatomic solid,  $\Theta_D$  is (Anderson, 1995)

$$\Theta_{\rm D} = 251.2 \left(\frac{\rho}{\mu}\right)^{1/3} v_{\rm m} k$$
 (Eq. 11)

where  $\rho$  is density (in g cm<sup>-3</sup>),  $\mu$  is the atomic mass number (55.85 for iron), and  $v_m$  is the mean sound velocity (in km s<sup>-1</sup>), given in terms of the longitudinal and shear velocities as

$$\frac{3}{v_{\rm m}^3} = \frac{1}{v_{\rm s}^3} \left[ 2 + \left( \frac{v_{\rm p}}{v_{\rm s}} \right)^3 \right]$$
(Eq. 12)

The numerical factor in Eq. (11) is composed of the atomic constants  $\hbar$ , k, and N.

Body-centered cubic (bcc) iron is the phase of iron that exists at ambient conditions. There is much data on this well-known phase. We use the properties of bcc iron to explain principles such as the evaluation of Eq. (11), but our chief interest lies in hexagonal closepacked (hcp) iron, which is the most likely pure iron phase at core conditions. In the evaluation of Eq. (11), properties of ambient bcc iron are  $\rho$ , 7.87 g cm<sup>-3</sup>;  $v_p$ , 5.9 km s<sup>-1</sup>;  $v_s$ , 3.25 km s<sup>-1</sup>;  $v_m$ , 3.62 km s<sup>-1</sup> (note that  $v_m$  is only slightly larger than  $v_s$ ). This gives  $\Theta_D(T = 300) = 415$  K at ambient conditions. Thus, above 415 K, bcc iron is a classical solid, and below, it is a quantum solid. Since the core is in the 5000–6000 K temperature range, its properties are in the high *T* regime. Since the value of  $\Theta_D/T$  at core temperatures is of the order of 0.1, the exponential term in Eq. (8) is of the order of 10<sup>-5</sup>, insignificant compared to unity.

To find the lattice dynamical equation for  $\gamma$ , divide Eq. (5) into two factors as follows:

$$\gamma = \frac{(\alpha K_T)}{C_V/V} \tag{Eq. 13}$$

and evaluate each of the two parts separately from Eq. (8). From calculus,  $\alpha K_T = (\partial P/\partial T)_V$ .  $C_V = (\partial U/\partial T)_V$ , where U is the internal energy. Using Eq. (9),

$$\left(\frac{\partial P}{\partial T}\right)_{V} = \frac{\hbar}{V} \sum y_{j}^{2} \left\{ \gamma_{j} \frac{e^{y_{i}}}{\left(e^{y_{i}} - 1\right)^{2}} \right\}$$
(Eq. 14)

where  $y_j = \hbar v_j / kT$ .

Since  $\mathcal{U} = \mathcal{F} - (\partial \mathcal{F} / \partial T)_V$ , then

$$\mathcal{U} = E_0 + kT \sum_{j=1}^{3N} \frac{y_j}{(e^{y_j} - 1)}$$
(Eq. 15)

and

$$C_V = k \sum_{j=1}^{3N} \frac{y_j^2 e^{y_j}}{(e^{y_j} - 1)^2} = \sum_{j=1}^{3N} C_{V_j}$$
(Eq. 16)

Following Eq. (13), there are major cancellations, leaving

$$\overline{\gamma} = \frac{\sum_{j}^{3N} \gamma_j C_{V_j}}{\sum_{i}^{3N} C_{V_i}}$$
(Eq. 17)

where the  $\overline{\gamma}$  means that this Grüneisen parameter may be affected by the approximation of the quasiharmonic assumption. Note that all factors containing  $y = \hbar v_j/kT$  have cancelled out, leaving the temperature dependence alone in  $C_B$  but since there is input of  $C_V$  in both the numerator and the denominator, there is very little temperature dependence in either the low- or high-temperature regimes. In the very hightemperature regime (such as found in the core), all  $C_{V_j}$  are equal to k, so the denominator in Eq. (17) is equal to 3Nk, while the numerator is equal to  $k \sum_{j=3N}^{3N} \gamma_j$ . Thus, the high-temperature limit of the lattice dynamical Grüneisen parameter is the arithmetic average of all mode gammas (Barron, 1957).

$$\overline{\gamma} = \frac{1}{3N} \sum_{j=1}^{3N} \gamma_j \tag{Eq. 18}$$

## Simplifications made by assuming a Debye solid

Evaluation of Eq. (18) is complicated by the fact that N (Avogadro's number) is quite large. We wish to reduce the summation in this equation from a limit of 3N to a lower value. We accomplish this by invoking the assumptions of a Debye solid (Debye, 1912), which are: the solid is monatomic and isotropic; its frequency spectrum (modal frequency versus wave number k) is quadratic with a sharp cutoff at the maximum frequency called the Debye frequency,  $v_D$ ; the slope of the longitudinal and shear  $v_j$  versus k curves is constant; and there are no optic modes. Barron (1957) showed that invoking the properties of a Debye solid reduces the sum over 3N modes in Eq. (18) to a sum of 3 modes.

$$\gamma_{ac} = \frac{1}{3}(\gamma_p + 2\gamma_s)$$
 (Eq. 19)

where  $\gamma_p$  is related to the longitudinal sound velocity and  $\gamma_s$  to the shear sound velocity. In Eq. (19),  $\gamma_{ac}$  has replaced  $\overline{\gamma}$  from Eq. (18) because acoustic information is the sole input to gamma.

The mode gammas can be expressed in terms of velocity derivatives (Anderson, 1995),

$$\gamma_{\rm p} = \frac{1}{3} - \frac{V}{v_{\rm p}} \left( \frac{\partial v_{\rm p}}{\partial V} \right)_T \tag{Eq. 20}$$

$$\gamma_{\rm s} = \frac{1}{3} - \frac{V}{v_{\rm s}} \left( \frac{\partial v_{\rm s}}{\partial V} \right)_T \tag{Eq. 21}$$

Sumino and Anderson (1984) evaluated  $\gamma$  for bcc iron using Eq. (5) and experimental values of  $\alpha$ ,  $K_T$ , and  $C_P$ . They found that  $\gamma = 1.81$ . They also evaluated  $\gamma$ , using the acoustic approximation to  $\gamma$ (Eq. (19)) and the measured elastic constant data under pressure and found  $\gamma = 1.81$ . Since the derivation of Eq. (19) starts with Eq. (5), it is concluded that the quasiharmonic assumption and the assumptions of the Debye solid do not modify the value of  $\gamma$  for bcc iron. This is a way of demonstrating that bcc iron is a Debye solid. Debye's theory of a solid assumes that the whole vibrational spectrum can be represented by the long wave limit where frequency is proportional to the wave number (v = vk). All modes are acoustic, each with the same average velocity. Equation (19) can also be written in terms of the derivatives of the bulk modulus and the shear modulus, *G* 

$$\gamma_{\rm ac} = \frac{K_T}{6} \frac{(\partial K_S / \partial P)_T + (4/3)(\partial G / \partial P)_T}{K_S + (4/3)G} + \frac{K_T}{3} \frac{(\partial G / \partial P)_T}{G} - \frac{1}{6}$$
(Eq. 22)

(Stacey and Davis, 2004).

Stacey and Davis (2004) stated, "The acoustic formula (for  $\gamma$ ) withstands critical scrutiny well. For application to the lower mantle it has no serious rival."

Thus, for the Debye solid, the 3N modal frequencies are replaced by one frequency,  $v_D$ , and one gamma,

$$y_{\rm D} = -\left(\frac{\partial \ln v_{\rm D}}{\partial \ln V}\right) \tag{Eq. 23}$$

Since  $\hbar v_0 = k \Theta_D$ , the above can be replaced by

$$y_{\rm D} = -\left(\frac{\partial \ln \Theta_{\rm D}}{\partial \ln V}\right)_T \tag{Eq. 24}$$

A variant of Eq. (24) is

$$\left(\frac{\Theta_{\rm D}}{\Theta_{\rm D_0}}\right) = \left(\frac{\rho}{\rho_0}\right)^{\gamma_{\rm D}} \tag{Eq. 25}$$

which is true only for a Debye solid.

Equation (24) is used as follows. Measure  $\Theta_D$  as a function of *V*, and thus determine  $\gamma$  as a function of *V*. Equation (25) is used to find a shift in  $\Theta_D$  corresponding to a shift in density.

A stringent test of the applicability of the theory of Debye solid to properties of bcc iron is that the frequency spectra of the real solid (called the phonon density of states, PDOS) has a sharp cutoff at a frequency corresponding to the Debye temperature.

## Proving epsilon (hcp) iron is a Debye solid

In the last section, bcc iron was proven to be a Debye solid. That is only one of many proofs that have been made for this solid. Early in the 20th century, a popular proof was to measure the entropy versus *T* data for temperatures below the Debye temperature and show that there was good agreement with the entropy calculated from the Debye theory. Unquestionably, bcc iron is taken as a Debye solid. It is not evident however, that hcp iron should be a Debye solid because this phase of iron has hexagonal symmetry, which requires two atoms in the lattice dynamic cell. Consequently, there are vibrational modes in which both atoms move in the cell, but the center of mass remains fixed. Such a vibration is an optical mode, and thus hcp iron has an optical branch in its frequency spectrum, which usually implies that there are modes with frequencies much higher than  $v_D$ . For hcp iron, however, the two masses in the cell have equal values, and lattice dynamic theory shows that in this case the frequencies found in the optic branch are contained within a narrow band anchored close to the maximum acoustic frequency. This means that within the frequency spectrum f(v), called the phonon density of states (PDOS), there is a clustering of modes near the maximum acoustic value of f(v).

A criterion for the validity of the Debye solid is that the high-frequency edge of the PDOS is the same (or nearly the same) as  $v_D$ , which is determined by  $\Theta_D$ . Debye (1965) said, "it is not too important to know the details of the frequency spectrum because at high temperature one only has to know the number of degrees of freedom [see Eq. (18)] and at low temperature the high frequency modes carry less and less energy." It is the maximum frequency of the PDOS that is significant. The crucial test for hcp iron is to show that the PDOS has a high-frequency, sharp cutoff close in value to  $v_D$ .

A recent paper by Giefers *et al.* (2002) reported the measured PDOS of hcp and bcc iron by nuclear inelastic scattering. Since hcp iron is a high-pressure phase and does not exist at room pressure, the experiment was done at P = 28 GPa. An experiment was also done for bcc iron at P = 0 GPa (resulting data for both shown in Figure G56). Their plots of the density of states, G(E), are reported in units of energy (meV) instead of the usual units of frequency, but they report the cut-off in terms of temperature, so the comparison with the Debye temperature is eased. Note that for both phases of iron there is a sharp cutoff of the spectrum with only a very small percentage of modes seen above the cutoff. This is proof that both phases are Debye solids. Further proofs come from the value of  $\Theta_D$ .

The authors report that the value of the temperature corresponding to the cutoff is 511 K for hcp iron (at 29 GPa) and 417 K for bcc iron (at P = 0). The value for hcp iron is to be compared with the measurement of  $\Theta_D$  reported by Anderson *et al.* (2001), 521 K at 29 GPa and discussed in the next section. These values are sufficiently close to conclude that hcp iron is a Debye solid. The value of  $\Theta_D = 417$  K for bcc iron reported by Giefers *et al.* (2002) is to be compared with  $\Theta_D = 415$  K found from Eq. (11).

Anderson *et al.* (2001) also report that for hcp iron, the value of  $\Theta_D$  at P = 0 is 446 K. This value can also be used to predict the cutoff of bcc iron by the bcc-hcp phase change using Eq. (25), and the ratio of the uncompressed density of bcc iron to hcp iron is (7.87/8.28) with  $\gamma = 1.7$ . The predicted  $\Theta_D$  is 410 K, to be compared with 417 K from the cutoff of the PDOS for bcc iron.

**Figure G56** Experimental phonon density of states g(E) of bcc iron and hcp iron by Giefers *et al.* (2002). For hcp iron, the pressure is 28 GPa. The cutoff of bcc iron at P = 0 is 40 meV (with a corresponding temperature of 417 K). For hcp iron, the cutoff is 45 meV (with a corresponding temperature of 511 K). The Debye temperature of bcc iron is 415 K, according to Eq. (11), and the Debye temperature of hcp iron is 520 K according to Anderson *et al.* (2001) and as seen in Figure G57.

## Experimental determination of lattice $\gamma(V)$ for iron from Eq. (24)

The state of the art in diamond anvil pressure cells at high pressure has improved so that by using a controlled intense x-ray beam from a synchrotron radiation facility, determination of high quality powder x-ray diffraction data is possible. (The intensity of the diffracted x-ray beam is a measurable function of pressure.) For a Debye solid, the intensity of the beam is given by the mean-square amplitude of atomic displacements  $\langle u^2 \rangle$ . Classical x-ray theory relates  $\langle u^2 \rangle$  to the Debye temperature, which Gilvarry (1956) gives as

$$\langle u^2 \rangle = \frac{c\hbar^2 T}{\mu k \Theta_{\rm D}^2}$$
 (Eq. 26)

where c is a numerical constant, and  $\mu$  is the atomic mass. Equation (26) with c = 3 is found in Willis and Pryor (1975). Using this equation and the measured values of  $\langle u^2 \rangle$  versus V, Anderson *et al.* (2001) measured the experimental values of  $\Theta$  versus V for hcp iron from ambient pressure to P = 300 GPa; these values are plotted in Figure G57.

The value of  $\gamma$  versus *V* was then found from Eq. (24). The data are plotted in  $\gamma - P$  space as the lower curve in Figure G58. It is seen that at 330 GPa,  $\gamma_{\rm vib}$  decreases with pressure from the zero pressure value of 1.7 to 1.2, the normal trend for nonmetallic solids. But metals have an additional contribution to gamma not found in nonmetallic solids arising from conduction electrons (often called free electrons). This contribution to  $\gamma$  is especially important at high temperature. Since this electron contribution adds to the Helmholtz energy,  $\gamma$  as defined by Eq. (1) will be sensitive to the electronic contribution. This means that for metals, the gamma found in this section is only a part of that defined by Eq. (1) at core temperatures. We therefore give the gamma shown in the lower curve of Figure G58 a special name,  $\gamma_{\rm vib}$ , indicating vibrational energy, or that arising from the PDOS.

**Figure G57** The experimental variation of Debye temperature  $\Theta_D$  for hcp iron (Anderson *et al.*, 2001). For P = 28 GPa, V = 5.95 cm<sup>3</sup> mol<sup>-1</sup> with a corresponding  $\Theta_D = 519$  K.

**Figure G58** Variation of  $\gamma_{vib}$  and  $\gamma$  for pure hcp iron with pressure (Anderson *et al.*, 2003). For the core range of pressure,  $\gamma$  varies between 1.62 at 135 GPa and 1.51 at 330 GPa. The calculations were made with temperatures from the hcp solidus, so the values of  $\gamma$  represent the solid state edge of melting.

## Accounting for the electronic contribution to gamma for iron

The electronic contribution to the specific heat in a metal has a dominant effect at low T and sometimes at high T. The electronic contribution to specific heat, for example, is given by Kittel (1956) as

$$C_{V_{\rm e}} = \frac{1}{3} \pi^2 D(\varepsilon_{\rm F}) k^2 T \tag{Eq. 27}$$

where  $D(\varepsilon_{\rm F})$  is the electronic density of states at the Fermi energy level.<sup>1</sup> The important point is that  $C_{V_{\rm c}}$  increases steadily with *T* at high *T*, whereas the lattice specific heat levels out for  $T > \Theta_{\rm D}$  and remains independent of *T* (neglecting anharmonic terms). At 6000 K, the specific heat of iron is 37% greater than the classical value of 3*k* per atom, due to Eq. (27). From Eq. (27), the electronic Grüneisen parameter is

$$\gamma_{\rm e} = \frac{\partial \ln D(\varepsilon_{\rm F})}{\partial \ln \rho} \tag{Eq. 28}$$

Numerical evaluation of Eq. (28) (Bukowinski, 1977) gives  $\gamma_e = 1.5$ . Thus, for iron the thermodynamic gamma of Sections and consists of  $\gamma_{\rm vib}$ , suitably modified by  $\gamma_e$ . The formalism for finding  $\gamma$  for metals is found in Bukowinski (1977); it requires the electronic specific heat found from the electronic density of states (EDOS). Anderson (2002a) found  $\gamma_e$  and  $\gamma$  from  $\gamma_{\rm vib}$  by using the PDOS and  $C_{V_e}$ , as presented by Stixrude *et al.* (1997). The theory of Bukowinski (1977) results in the useful equation,

$$\gamma = \frac{C_{V_{\rm vib}}}{C_V} \gamma_{\rm vib} + \frac{C_{V_{\rm e}}}{C_V} \gamma_{\rm e}$$
(Eq. 29)

where

$$C_V = C_{V_{\rm vib}} + C_{V_{\rm e}} \tag{Eq. 30}$$

<sup>1</sup> For further information on the Fermi energy level for metals, see Kittel, Introduction to Solid State Physics, 2nd edn. New York: John Wiley & Sons, 1956.

Some of the detailed calculations for hcp iron are given in Table G9. Values in Table G9 were found for *T* increasing with *P* along the solidus of hcp iron, as calculated by Anderson *et al.* (2003). The value of  $\gamma$  descends from 1.62 at *P* = 135 GPa to 1.53 at 330 GPa, a gradual decrease. The values of  $\gamma$  in Table G9 are for the solid state edge of melting, called the solidus. It is seen that  $\gamma$  for the ICB pressure (330 GPa) is 1.53, and for the CMB (135 GPa) it is 1.62. Figure G58 shows  $\gamma$  (the top curve), as well as  $\gamma_{\rm vib}$ , versus *P*.

#### First principles calculations of gamma for liquid iron

The value of  $\gamma$  is likely to be different for the liquid state than for the solid state. Verhoogen (1980) first emphasized that the liquid state  $\gamma_1$ should be used for calculations of properties of Earth's core. The difference between the values of the liquid gamma ( $\gamma_1$ ) and the solid gamma  $(\gamma_s)$  for iron is quite large at low pressure but small at high pressure. The value of  $\gamma_1$  is 2.44 at P = 0 (Stevenson, 1981), but that of  $\gamma_s$  is 1.66 at P = 0 (Boehler and Ramakrishnan, 1980) for bcc iron. The value of  $\gamma_1$  decreases with pressure, becoming 1.63 at 30 GPa (Chen and Ahrens, 1997), and then changes much more slowly with further pressure, as we shall see. Measurements and/or calculations of  $\gamma_1$  at core pressures have long been needed. Important progress has been made in the theory of thermodynamic properties of condensed matter by calculations of parameter-free *ab initio* techniques using quantum mechanics. The use of ab initio techniques for several decades by many physicists has resulted in considerable advances in understanding of solid state properties. Recently, ab initio methods have advanced to the point that successful calculations of properties of the liquid state at high pressure and high temperature have been made.

Using *ab initio* methods, Alfè *et al.* (2002a) calculated 1.51 for  $\gamma_1$  at P = 330 GPa for iron along with the liquidus, giving  $T_m = 6350$  K. This is quite close to the value of  $\gamma_s$  (1.53) at P = 330 GPa for hcp iron reported by Anderson *et al.* (2003), who found  $T_m = 6050$  K for the solidus (see Table G9). Thus,  $\Delta\gamma$  at the ICB pressure is small, substantially smaller than at the CMB pressure, where  $\gamma_1 = 1.52$  (Alfè *et al.*, 2002a), while  $\gamma_s = 1.62$  (Anderson *et al.*, 2003).

For the solid state, Stixrude *et al.* (1997) reported  $\gamma_s = 1.5$  for hcp iron at ICB pressure from their *ab initio* calculations. Alfè *et al.* (2001) reported  $\gamma_s = 1.52$  for hcp iron at P = 330 GPa, where the solidus is found to be 6250 K, as compared to 1.53, as obtained by Anderson *et al.* (2003). Thus, three laboratories have found very close values of  $\gamma_s$  at 330 GPa,  $1.5 < \gamma_s < 1.53$ .

The various values for gamma are plotted on the phase diagram of iron in Figure G59 (in the diagram, T is versus V with isobars as solid lines).

We see that as the pressure increases, at core conditions, the difference between liquidus and solidus temperature values decreases and  $\Delta\gamma$  decreases, as well. This is interpreted to mean that as pressure increases, the volume of crystallization diminishes. Indeed, Vocadlo *et al.* (2003) report  $\Delta V_{\rm m} = 0.77$  cm mol<sup>-1</sup> at 330 GPa, while Anderson (2002b) report  $\Delta V_{\rm m} = 0.55$  also at 330 GPa from an analysis of shock wave data. The values of  $\gamma_1$  and  $\gamma_s$  approach each other at deep core pressures.

## Core's gamma: Consideration of impurities in iron

#### Structural changes

One approach for finding the properties of the core is to learn all that is possible of pure iron at core pressure and then insert a certain quantity of light elements into the iron structure and determine the resulting changes. A number of problems arise, one of which is that the crystallographic structure is reported to change from hcp when impurities are added. The consensus is that hcp is the stable phase of pure iron, but there is strong evidence that for the light impurities in iron, light silicon, sulfur, and oxygen, the high-pressure stable structure is bcc.

Vocadlo *et al.* (2003) suggest that a mole of 4% silicon or sulfur, either in combination or separately, may change the structure of hcp iron to the bcc phase above 3000 K at high pressure.

When light impurities are placed in iron, its density decreases. The percentage change in density, called the "core density deficit" (cdd), is reported to be 4% to 7% for the outer core. The cdd is used to find the  $\Delta T$  drop at the ICB, giving the value of the liquidus temperature at P = 330 GPa for the core. This  $\Delta T$  is called the "freezing point depression."

The effects of Si, S, and O impurities on the value of  $\gamma_1$ Alfè *et al.* (2002a) found from *ab initio* calculations that the core density deficit due to O, Si, and S, is 6.6%. The concentrations of these light elements were found in a series of papers in which chemical equilibrium between coexisting solid and liquid was treated. *Ab initio*  calculations by Alfè *et al.* (2002b) incorporating as a boundary condition the seismically determined density jump at the inner core-outer core boundary found that substantial oxygen was required in the outer core because silicon and sulfur could not account for the size of the jump. From their conclusions of the amount and type of impurities in the core, Alfè *et al.* (2002c) found the freezing point depression at  $\Delta T = -700 \text{ K} \pm 100 \text{ K}$ . In a subsequent paper, Alfè *et al.* (2002d) reported the freezing point depression to be  $\Delta T = -800 \text{ K}$ , a value they have used in subsequent work. They estimated the core density deficit, the isobaric density of pure hcp iron, less the corresponding density of the core, to be 6.6% (Alfè *et al.*, 2002c). The core temperature at the ICB was found by subtracting 800 K from the value 6350 K (the *ab initio* calculation of  $T_{\rm m}(330 \text{ GPa})$  for hcp iron), giving 5550 K.

As seen in the previous paragraph, it is concluded from *ab initio* studies that

- 1. The difference between  $\gamma_1$  for pure iron and  $\gamma_1$  for the core at the ICB is only ~0.02 despite the addition of 9% oxygen and 9% Si/Si to the hcp structure. This difference is trivial.
- 2. The difference between  $\gamma_1$  and  $\gamma_s$  at the ICB for both the core and hcp iron is ~0.01; again, it is trivial.
- 3. The value of  $\gamma_1$  at the ICB of the core found by Alfè *et al.* (2002b) is so close to 1.5 that it has been taken to be 1.5 in the paper by Gubbins *et al.* (2003) in which D. Alfè and G.D. Price were coauthors.
- 4. The value of  $\gamma_1 = 1.5$  at the ICB is associated with a cdd of 6.6% and a freezing point depression of -800 K.
- 5. The value of  $\gamma_1$  is virtually unchanged from the CMB pressure to the ICB pressure.

The effect of Ni in the core on the value of  $\gamma_{c}$ 

The relative abundances of Fe and Ni in the core are probably about  $10^{-1}$  (McDonough and Sun, 1995). Thus, we consider the effect of Fe<sub>0.90</sub>-Ni<sub>0.10</sub> in place of Fe. Mao *et al.* (1990) found that  $\rho$  for Fe<sub>0.80</sub>-Ni<sub>0.20</sub> at 330 GPa and 300 K is about 2% higher than for pure Fe. Therefore, the alloy Fe<sub>0.90</sub>-Ni<sub>0.10</sub> at the ICB is 1% denser than hcp iron.

A 1% increase in density would have virtually no effect on  $\gamma_1$  or  $\gamma_s$  because  $\gamma$  is nearly constant with pressure in the vicinity of the ICB (Figures G58 and G59). From the data plotted in both figures, a 1% change in density changes  $\gamma$  only slightly in the third significant figure. Thus, the value of  $\gamma_1$  is insensitive to the addition of nickel to iron.

In the *ab initio* approach, all physical properties are found from derivatives of the Helmholtz free energy, F, which is made to account for all atoms (Fe and impurities, if any) in their respective lattice sites. The physical properties of the core are found from the core's free energy. These properties are different from those found from the free energy of pure iron, except for the value of  $\gamma_1$ , which is virtually the same for both cases. How can this be explained? The value of  $\gamma_1$  changes with volume, but in the case of iron, the value of gamma changes very slowly with volume at core pressures, as shown in Figure G58. Consider the drop in temperature called the freezing point depression,  $\Delta T_{\rm m} = -800$  K. The relative change in volume due to freezing point depression is  $\Delta V/V = -\Delta \rho/\rho = \alpha \Delta T$  at the ICB. The value of  $\alpha$  varies from  $1.07\times 10^{-5}$  at 6350 K and 330 GPa (for pure iron) to  $0.99 \times 10^{-5}$  and 330 GPa for the core (D. Alfè, personal communication). If we know  $\alpha$  and  $\Delta T$ , then we can calculate  $\Delta \rho / \rho$ , the percent density change. The average  $\alpha \times \Delta T$  gives  $\Delta \rho / \rho = -0.85\%$ , less than but opposite to the 1% increase arising from placing 10% Ni in the Fe-Ni alloy.

# Finding core properties independent of pure iron properties

Stacey (2000) introduced a new equation of state called the K-primed approach because he found all EoSs used in geophysical treatment of Earth's mantle to be in error with regard to the higher derivatives, especially the derivative of  $K_{\rm S}$  with respect to V. Stacey successfully

applied his K-primed equation of state to the Earth's mantle and core. In Stacey and Davis (2004), thermal core properties were extracted directly from seismic data of Earth without the intermediate step of using properties of pure iron. The values of gamma for the core they report, to three significant figures, are 1.39 at the CMB pressure and 1.44 at the ICB pressure. They also report that the values of  $T_{\rm m}$  for the liquidus are 5000 K and 3739 K, for the ICB and CMB, respectively.

# Summary and conclusions

Our prime focus is on the value of  $\gamma$  at pressures of 135 GPa (CMB) and 330 GPa (ICB) for the liquidus and the solidus of hcp iron and for the liquidus of the outer core and the solidus of the inner core. The values of  $\gamma$  and associated properties of thermal expansivity  $\alpha$  and melting temperature  $T_{\rm m}$  described in the previous sections are summarized in Table G10.

It is noted that the values of  $\gamma_s$  at the ICB from the two approaches (*ab initio* and thermal physics) agree quite well. There is good agreement on the value of  $\gamma_1$ , but the value reported from the K-primed EoS approach is about 0.1 less than that reported from the *ab initio* approach.

The *ab initio* approach yields the largest range of results, giving values for both  $\gamma_1$  and  $\gamma_s$  and for both hcp iron and the core, whereas the thermal physics approach is limited to  $\gamma_s$  for hcp iron and the inner core. The K-primed EoS approach is limited to  $\gamma_1$  for the outer core and  $\gamma_s$  for the inner core. An advantage of the K-primed EoS approach is that information about the chemistry—in particular, the concentrations of the various impurity elements—is not required to obtain  $\gamma_1$  of the core. However, this is also a disadvantage because no information can be given to geochemists about impurities. In contrast, the

*ab initio* approach can give valuable results about core impurities: it was shown that sulfur and silicon as impurities in iron cannot account for the seismic density jump at the ICB, but about 8 mol% oxygen in the outer core is consistent with the seismic jump.

From the results of the *ab initio* calculations, the value of  $\gamma_1$  is virtually constant from the ICB pressure to the CMB pressure, varying by 1.3%. The variation using the K-primed EoS approach is somewhat larger, 5.7%. If  $\gamma_1$  is assumed to be constant over this range, the relationship between  $T_m$  and density  $\rho$  given by Eq. (7) is simplified,

$$\left(\frac{T_{\rm m_1}}{T_{\rm m_0}}\right) = \left(\frac{\rho_1}{\rho_0}\right)^{\gamma} \tag{Eq. 31}$$

Using the ratio of the seismic density of the core at the CMB to that at the ICB (12166.34/9903.49), Eq. (31) becomes

$$\left(\frac{T_{m_1}}{T_{m_0}}\right) = 0.7344$$
 for  $\gamma_1 = 1.5$   
= 0.7466 for  $\gamma_1 = 1.42$ 

Thus, if Eq. (31) is used to find  $T_{\rm m}$  (CMB) from  $T_{\rm m}$  (ICB), the answer will differ by only 1.2% if one uses the ab initio gamma in comparison with the K-primed EoS gamma (starting out with the same value of  $T_{\rm m_0}$ ). If one uses the *ab initio* data or the thermal physics data and is satisfied that the value of  $T_{\rm m}(P)$  is rounded to three significant figures, then the value of  $\gamma_1$  can be rounded to three significant figures for the entire outer core region. The value of  $\gamma_1 = 1.5$  was used by Gubbins et al. (2003) throughout the core in their analysis of the geodynamo. The value of  $\gamma_s$  for the inner core decreases very slowly with the depth from its value at the ICB pressure. Table G9 shows that  $\gamma_s$ (listed in the table as gamma) drops from 1.53 at the ICB (330 GPa) to 1.52 at a pressure of 372.8 GPa; by interpolation gamma is 1.525 at the Earth's center, which has a pressure of 363.9 GPa. One may as well use  $\gamma_s = 1.53$  for calculation of  $T_m$  at the Earth's center. We need to know the temperature of the core; this requires  $\Delta T_{\rm m}$ , the freezing point depression from pure iron. Alfè et al. (2002c) report  $\Delta T_{\rm m} = -800$  K. Thus, for the temperature at the ICB pressure, one finds  $T_{\rm m}(\text{core}) = 5550 \text{ K}$  from the solidus at ICB (6250 K) for the *ab initio* approach, and  $T_{\rm m}({\rm core}) = 5250$  K from the thermal properties approach. The K-primed EoS approach leads to  $T_{\rm m}({\rm core}) = 5000$  K. This calculation using Eq. (31) is  $T_{\rm m}({\rm E~center})/$  $T_{\rm m}(\rm ICB) = 1.1213$ , giving, for Earth's center, 6111 K for the *ab initio* ICB value (5450 K) and 5456 K for the thermal physics ICB value (5250 K). The K-primed EoS approach gives 5030 K for Earth's center

# HALLEY, EDMOND (1656–1742)

Edmond Halley (Figure H1) was born in London in 1656 and educated at St. Paul's School in London and the Queen's College, Oxford, which he left in 1676 without a degree to catalog southern stars and observe a transit of Mercury on the island of St. Helena. He also measured magnetic inclination on this voyage, in the Cape Verdes and on St Helena. On his return the Royal Society elected him a fellow. He visited Johannes Hevelius in Danzig and G.D. Cassini in Paris and observed with them. He became clerk to the Royal Society in 1686. He prompted Newton to write the *Philosophiae Naturalis Principia Mathematica* and published it himself. He was often at sea, surveying and diving for salvage until he was elected Savilian Professor of Geometry in Oxford in 1704. He became the second Astronomer Royal in 1720.

## The Westward Drift (q.v.)

In 1680, it was known that the major deviations of the Earth's field from that of a uniformly magnetized sphere appeared to move westward. Halley selected representative observations of the variation (magnetic declination) from 1587 to 1680, and from New Zealand  $(170^{\circ} \text{E})$  to Baffin Bay (80°W). They came from mariners' reports, and perhaps from collections not to be found now. He found that the westward drift was not the same everywhere (Halley, 1683). He argued that the extensive anomalies had much deeper sources than iron near the surface that Descartes (Descartes, 1644) and *Gilbert (q.v.)* proposed. He suggested that the Earth had a shell with one pair of poles and a core with another pair, the two in relative rotation (Halley, 1692). Would there be life in the space between the core and the shell? Other worlds in other places and at other times were then seriously contemplated.

# The Atlantic cruises

In October 1698, Halley sailed as a captain in the Royal Navy in a ship built for him by the government, to cruise around the Atlantic and observe the magnetic variation for navigation, the first-ever scientific naval surveys (Thrower, 1981). He measured the angle between compass north and geographic north as established by the Sun's position at rise or set. He found his latitude from the elevation of the Sun at

noon. Longitude at sea was much more difficult, and sometimes had gross errors. Halley had delays, bad weather, and difficult officers, and was too late in the season to go into the South Atlantic. His second cruise from September 1699 to September 1700 accomplished much more, and he went further into the Antarctic ice than anyone before.

Halley's chart of isogonic lines over the Atlantic hung in the Royal Society building for many years but is now lost. Many printed copies were published, the first isarhythmic chart of any variable to have been published. There may already have been private manuscript charts and *Athanasius Kircher* (q.v.) had written of one in his *Magnes*. (Kircher, 1643) Halley claimed, justly, that his chart was the first with isogonic lines to have been printed and published: He was a founder of modern cartography. His lines were known as Halleyan lines, and were soon used for other data such as temperature and depth of water. About two hundred years later *Christopher Hansteen* (q.v.) and *W. van Bemmelen* (q.v.), having access to the logs of Dutch ships, compiled worldwide isogonic charts at regular epochs. His chart for 1700 is generally close to Halley's where they overlap.

Figure H1 Edmond Halley.

#### Aurorae

In 1716 Halley observed an intense auroral display over London (Halley, 1716). He collected reports from distant places and plotted the forms of the auroral arcs. They followed the lines of the Earth's magnetic field and were most intense around the magnetic, not the geographic, pole. Halley argued that matter circulating around the field lines produced the aurorae. He thought the matter leaked out of hollow spaces in the Earth, perhaps between the core and the mantle. He did not explain the colors. As there were then no instruments to detect the daily variation of the geomagnetic field or magnetic storms, Halley could not relate aurorae to events on the Sun.

Halley established entirely new lines of enquiry in his three principal contributions to geomagnetism. He was buried with his wife in the churchyard of St Margaret's Lee, not far from the Royal Observatory where a wall now carries his gravestone with its memorial inscription. There is a tablet in the cloisters of Westminster Abbey, and the observatory at Halley Bay on Antarctica recalls his magnetic and auroral observations and the cruise that went so close to the Antarctic continent. A recent biography is in Cook (1998).

HANSTEEN, CHRISTOPHER (1784–1873)

Christopher Hansteen (1784–1873) was born in Christiania (now Oslo), Norway. In the years 1816–1861 he was professor of applied mathematics and astronomy at the institution today denoted as the

University of Oslo. His pioneering achievements in terrestrial magnetism and northern light research are today widely appreciated (Brekke, 1984; Josefowicz, 2002), though it has not always been the case earlier. Hansteen was selected as university teacher because of his successful participation in a prize competition, answering the question posed by the Royal Danish Academy of Sciences in 1811: "Can one explain all the magnetic peculiarities of the Earth from one single magnetic axis or is one forced to assume several?" The prize, a gold medal, was won by Hansteen. In his treatise he meant to demonstrate the necessity to assume that the Earth possesses two magnetic axes, implying our globe to be a magnetic quadrupole. The terrestrial magnetism became his main scientific interest through the rest of his life. For economic reasons Hansteen's one-volume treatise was not published until 1819, but then in a considerably extended form. The book has the title Untersuchungen über den Magnetismus der Erde (Hansteen, 1819). It is still quoted in the literature. This work appeared in print only one year ahead of the discovery of the connection between electricity and magnetism by his Danish friend and colleague H.C. Ørsted. With his well-formulated treatise, Hansteen thus obtained a central position in the development of the geophysical sciences taking place in that period (see Figure H2).

A Norwegian expedition under the leadership of Hansteen operated in Siberia in the years 1828–1830, traveling to the Baikal Sea and crossing the border into China (Hansteen, 1859). One measured the numerical values of the total magnetic field strength, the inclination, and the declination. Hansteen found no evidence of any additional magnetic pole in Siberia. To him this was an enormous disappointment. Nevertheless, in a letter to H.C. Ørsted of June 21, 1841, he proudly relates the written statement of Gauss, that to a large extent, it was the measurements of Hansteen, that had made Gauss devote himself to the study of magnetism.

Furthermore, Hansteen also made contributions to the investigation of northern light phenomena (Hansteen, 1825, 1827) as indicated in Figure H3. Related to his extensive studies of the Earth's magnetic

Figure H2 Christopher Hansteen, drawn by C.W. Eckersberg ca. 1828. Shown is also an instrument constructed by Hansteen for the determination of the magnetic intensity. It exploits the fact that a magnetic needle suspended in a magnetic field, when set in motion; its movement in time will among other factors depend on the field strength. This device received international acclaim and

was used during the so-called Magnetic Crusade (Cawood, 1979).

**Figure H3** Picture from work of Hansteen (1827) on the concept of the aurora, showing an auroral ring encircling the polar cap. The figure is presumably one of the first drawings of the auroral ring. The illustration also demonstrates how to measure the height of the aurora from one point only.

field he claimed that the center of the auroral ring to be situated somewhere north of Hudson's bay (Brekke, 1984).

At the meeting of the Scandinavian natural scientists in Stockholm in 1842, Christopher Hansteen gave a talk on the development of the theory of terrestrial magnetism (Hansteen, 1842). He points to the discovery of Ørsted of the connection between magnetism and electricity as a possible way to explain the interplay between the processes in Earth's interior and the terrestrial magnetic phenomena. The modern dynamo theory is a development of this highly intuitive idea.

The scientific results from the Siberian expedition were published as late as 1863 (Hansteen and Due, 1863). It represents a dignified finish to Christopher Hansteen's contributions to this part of geoscience.

It deserves attention that Christopher Hansteen was also active as a nation builder in the first 50 years after 1814 of Norwegian independence. Important subjects of his activities were the mapping of the Norwegian costal area together with inland triangulation, exact time determination, and many years of almanac edition, to mention just a few of his undertakings.

# HARMONICS, SPHERICAL

# Introduction

Spherical harmonics are solutions of Laplace's equation

$$\frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} + \frac{\partial^2 V}{\partial z^2} = 0$$
 (Eq. 1)

in three dimensions, and they are collected together as homogeneous polynomials of degree l, with 2l + 1 in each group. The simplest spherical harmonics are the three Cartesian coordinates x, y, z, which are three homogeneous polynomials of degree 1. Inverse distance 1/r satisfies Laplace's equation everywhere, except at the point r = 0, forming a spherical harmonic of degree -1, and the Cartesian derivatives of inverse distance generate spherical harmonics of higher degree (and order). Because inverse distance is the potential function for gravitation, electric, and magnetic fields of force, the theory of spherical harmonics has many important applications.

It is a simple matter to observe that on taking the gradient of Laplace's equation (1), that if V is a solution, then so also is the vector  $\nabla V$ , and also the tensor  $\nabla (\nabla V)$ , showing clearly the need to consider vector and tensor spherical harmonics. As a simple example, the gradients of the Cartesian coordinates x, y, z, lead to  $\mathbf{i}, \mathbf{j}, \mathbf{k}$ , as vector spherical harmonics, and gradients of  $x\mathbf{i}, x\mathbf{j}, x\mathbf{k}, y\mathbf{i}, \ldots$ , lead to Cartesian tensors  $\mathbf{i}, \mathbf{i}, \mathbf{j}, \ldots$  as tensor spherical harmonics.

With increasing interest in atomic structure and electron spin, the study of Laplace's equation in four dimensions,

$$\frac{\partial^2 V}{\partial p^2} + \frac{\partial^2 V}{\partial q^2} + \frac{\partial^2 V}{\partial r^2} + \frac{\partial^2 V}{\partial s^2} = 0,$$
 (Eq. 2)

which is satisfied by  $1/(p^2 + q^2 + r^2 + s^2)$  and its derivatives, is important. The solution uses surface spherical harmonics from Eq. (1), and "spin weighted" associated Legendre functions.

# Spherical polar coordinates

In three dimensions, the spherical polar coordinates of a point *P* on the surface of the sphere are  $r, \theta, \phi$ , where *r* is the radius of the sphere,  $\theta$  is the colatitude of the point measured from the point chosen as the north pole of the coordinate system, and  $\phi$  is the east longitude of the point measured from the meridian of longitude chosen as the prime meridian,

$$\begin{aligned} x &= r \sin \theta \cos \phi, \\ y &= r \sin \theta \sin \phi, \\ z &= r \cos \theta. \end{aligned} \tag{Eq. 3}$$

If a spherical harmonic of degree l is denoted  $V_l$ , then in spherical polars, by virtue of being a homogeneous polynomial of degree l, we may write

$$V_l(r,\theta,\phi) = r^l S_l(\theta,\phi) \tag{Eq. 4}$$

and the function  $S_l(\theta, \phi)$  is called a surface spherical harmonic of degree *l*. From the theory of homogeneous functions,

$$(\mathbf{r} \cdot \nabla) V_l = r \frac{\partial V_l}{\partial r} = x \frac{\partial V_l}{\partial x} + y \frac{\partial V_l}{\partial y} + z \frac{\partial V_l}{\partial z} = l V_l.$$
 (Eq. 5)

Conversely, it can be shown that if a function  $V_l$  satisfies Eq. (5), then it is a homogeneous function of degree l in x, y, z.

The four-dimensional case arises when considering rotations through and angle w, about an axis of rotation with which is in the direction that

has colatitude *u* and east longitude *v*. For rotations, the hypersphere has unit radius, for we include a value  $\rho$  here, and the four-dimensional Cartesian coordinates p, q, r, s, are

$$p = \rho \sin u \cos v \sin \frac{1}{2}w,$$
  

$$q = \rho \sin u \sin v \sin \frac{1}{2}w,$$
  

$$r = \rho \cos u \sin \frac{1}{2}w,$$
  

$$s = \rho \cos \frac{1}{2}w.$$
 (Eq. 6)

With  $\rho = 1$ , the coordinates p, q, r, s, are better known as quaternions.

## Separation of variables

In spherical polar coordinates, the Laplacian  $\nabla^2 V$  is

$$\nabla^2 V = \frac{1}{r^2} \left[ \frac{\partial}{\partial r} \left( r^2 \frac{\partial V}{\partial r} \right) + \frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \left( \sin \theta \frac{\partial V}{\partial \theta} \right) + \frac{1}{\sin^2 \theta} \frac{\partial^2 V}{\partial \phi^2} \right].$$
(Eq. 7)

The method of separation of variables is used to solve Laplace's equation in spherical polars. With  $V(r, \theta, \phi) = R(r)S_l(\theta, \phi)$ , and with l(l+1) as a constant of separation, then

$$\frac{\mathrm{d}}{\mathrm{d}r}\left(r^2\frac{\mathrm{d}R}{\mathrm{d}r}\right) - l(l+1)R = 0,$$
(Eq. 8)

and

$$\frac{1}{\sin\theta} \frac{\partial}{\partial\theta} \left( \sin\theta \frac{\partial S_l}{\partial\theta} \right) + \frac{1}{\sin^2\theta} \frac{\partial^2 S_l}{\partial\phi^2} + l(l+1)S_l = 0.$$
 (Eq. 9)

Note that the constant of separation l(l+1) remains unchanged if *l* is replaced by -l-1.

Radial dependence of the spherical harmonics is given by (8),

$$R(r) = A_l r^l + \frac{B}{r^{l+1}}.$$
 (Eq. 10)

Equation 9 can be solved by further separation of variables, using  $S_l(\theta, \phi) = \Theta(\theta) \Phi(\phi)$ , with  $m^2$  as the constant of separation,

$$\frac{\mathrm{d}^2\Phi}{\mathrm{d}\phi^2} + m^2\Phi = 0, \qquad (\mathrm{Eq.}\ 11)$$

and

$$\frac{1}{\sin\theta} \frac{\mathrm{d}}{\mathrm{d}\theta} \left( \sin\theta \frac{\mathrm{d}\Theta}{\mathrm{d}\theta} \right) + \left[ l(l+1) - \frac{m^2}{\sin^2\theta} \right] \Theta = 0.$$
 (Eq. 12)

From Eqs. (7) and (9), the Laplacian of the surface spherical harmonic  $S_l(\theta, \phi)$  is

$$\nabla^2 S_l(\theta,\phi) = -\frac{l(l+1)}{r^2} S_l(\theta,\phi)$$
 (Eq. 13)

Solutions of Eq. (11) are the trigonometric functions  $\cos V$  and  $\sin V$ , and the complex exponential functions  $e^{iV}$  and  $e^{-iV}$ . The concept of "irreducibility" favors the use of the complex exponential expressions, because, with the transformation  $V \rightarrow V + \alpha$ , the trigonometric functions become mixed,

$$\cos V \to \cos(V + \alpha) = \cos V \cos \alpha - \sin V \sin \alpha,$$
  

$$\sin V \to \sin(V + \alpha) = \sin V \cos \alpha + \cos V \sin \alpha.$$
(Eq. 14)

and are "reducible", whereas the complex exponential functions do not become mixed, and are therefore "irreducible."

$$\begin{split} \mathbf{e}^{\mathbf{i}V} &\to \mathbf{e}^{\mathbf{i}(V+\alpha)} = \mathbf{e}^{\mathbf{i}V}\mathbf{e}^{\mathbf{i}\alpha}, \\ \mathbf{e}^{-\mathbf{i}V} &\to \mathbf{e}^{-\mathbf{i}(V+\alpha)} = \mathbf{e}^{-\mathbf{i}V}\mathbf{e}^{-\mathbf{i}\alpha}, \end{split} \tag{Eq. 15}$$

# Orthogonality of surface spherical harmonics

A number of properties of spherical harmonics can be established using only the definition, namely, that they are homogeneous functions of degree *l* that satisfy Laplace's equation, and specific mathematical expressions are not required.

Let  $S_l(x, y, z)$  and  $S_L(x, y, z)$  be two surface spherical harmonics of degree *l* and *L* respectively. A vector **F** is defined by

$$\mathbf{F} = (\nabla S_l)\overline{S_L} - S_l(\nabla \overline{S_L}),\tag{Eq. 16}$$

when, by Eq. (13), the divergence of **F** is

$$\nabla \cdot \mathbf{F} = \frac{1}{r^2} \left[ -l(l+1)S_l \overline{S_L} + L(L+1)S_l \overline{S_L} \right],$$
$$= \frac{1}{r^2} (L-l)(L+l+1)S_l \overline{S_L}.$$
(Eq. 17)

Gauss's theorem, applied to a spherical surface and the enclosed spherical volume, is

$$\iiint_{\text{spherical}} \nabla \cdot \mathbf{F} \, \mathrm{d}v = \iint_{\substack{\text{spherical} \\ \text{surface}}} \mathbf{F} \cdot \mathrm{d}\mathbf{S}, \tag{Eq. 18}$$

where, in this case,  $dS = r^2 \mathbf{e}_r \sin \theta \, d\theta \, d\phi$ , and  $\mathbf{e}_r$  is the unit radial vector. The vector **F** has no radial component, and therefore the spherical surface integral is zero, and the volume integral, after integrating with respect to radius, reduces to

$$\int_0^r \int_0^{2\pi} \int_0^{\pi} \nabla \cdot \mathbf{F} \, \mathrm{d}\nu = (L-l)(L+l+1)$$
$$\int_0^r \mathrm{d}r \int_0^{2\pi} \int_0^{\pi} S_l(\theta,\phi) S_L(\theta,\phi) \sin\theta \mathrm{d}\theta \mathrm{d}\phi, = 0,$$

and therefore, when  $l \neq L$  or when  $l \neq -L - 1$ , then

$$\int_0^{2\pi} \int_0^{\pi} S_l(\theta, \phi) S_L(\theta, \phi) \sin \theta \, \mathrm{d}\theta \, \mathrm{d}\phi = 0.$$
 (Eq. 19)

#### Legendre polynomials

In the case m = 0, the spherical harmonics are independent of longitude  $\phi$  and are said to be "zonal". The differential equation is obtained from Eq. (12) with m = 0, namely

$$(1-\mu^2)\frac{\mathrm{d}^2\Theta}{\mathrm{d}\mu^2} - 2\mu\frac{\mathrm{d}\Theta}{\mathrm{d}\mu} + l(l+1)\Theta = 0, \qquad (\mathrm{Eq.}\ 20)$$

The factor  $(1 - \mu^2)$  of the second derivative shows that the solution has singularities at  $\mu = \pm 1$ , corresponding to colatitudes  $\theta = 0$ and  $\theta = \pi$ , at the north and south poles respectively of the chosen reference frame. The two independent solutions of Eq. (20) are Legendre functions of the first and second kind,  $P_l(\mu)$  and  $Q_l(\mu)$ , respectively, where

$$P_{l}(\mu) = \frac{1}{2^{l} l!} \left(\frac{\mathrm{d}}{\mathrm{d}\mu}\right)^{l} (\mu^{2} - 1)^{l}, \qquad (\text{Eq. 21})$$

$$Q_{l}(\mu) = P_{l}(\mu) \ln \sqrt{\frac{1+\mu}{1-\mu}} - \frac{2l-1}{1l} P_{l-1}(\mu) - \frac{2l-5}{3(l-1)} P_{l-3}(\mu) - \frac{2l-9}{5(l-2)} P_{l-5}(\mu) + \dots, |\mu| < 1.$$
 (Eq. 22)

Legendre polynomials are orthogonal over the range  $-1 \le \mu \le 1$ , and the normalization of  $P_l(\mu)$  has been chosen so that

$$\frac{1}{2} \int_{-1}^{1} P_l(\mu) P_L(\mu) d\mu = \frac{1}{2l+1} \delta_l^L,$$
 (Eq. 23)

where  $\delta_l^L$  is the Kronecker delta.

The descending power series expansion for the Legendre polynomials is

$$P_{l}(\mu) = \frac{(2l)!}{2^{l}l!l!} \left[ \mu^{l} - \frac{l(l-1)}{2(2l-1)} \mu^{l-2} + \frac{l(l-1)(l-2)(l-3)}{2 \cdot 4(2l-1)(2l-3)} \mu^{l-4} - \dots \right], \quad (Eq. 24)$$

and the first few are

$$P_0 = 1, \qquad P_1 = \mu, \quad P_2 = \frac{1}{2}(3\mu^2 - 1),$$
  

$$P_3 = \frac{1}{2}(5\mu^3 - 3\mu), \qquad P_4 = \frac{1}{8}(35\mu^4 - 30\mu^2 + 3). \quad (Eq. 25)$$

Note that  $P_l(1) = 1$  and that  $P_l(-1) = (-1)^l$  for all values of *l*.

A series expansion for Legendre functions of the second kind,  $Q_l(\mu)$  is

$$\begin{aligned} \mathcal{Q}_{l}(\mu) &= \frac{2^{l} l! l!}{(2l+1)!} \bigg[ \frac{1}{\mu^{l+1}} + \frac{(l+1)(l+2)}{2(2l+3)} \frac{1}{\mu^{l+3}} \\ &+ \frac{(l+1)(l+2)(l+3)(l+4)}{2 \cdot 4(2l+3)(2l+5)} \frac{1}{\mu^{l+5}} + \cdots \bigg]. \end{aligned}$$

# Neumann's formula

Neumann's formula, given by

$$\sum_{l=0}^{\infty} (2l+1)P_l(\zeta)Q_l(\mu) = \frac{1}{\mu-\zeta}, \qquad |\mu| > |\zeta|,$$
 (Eq. 26)

can be used to show that the recurrence relations for  $Q_l(\mu)$  are the same as those for the Legendre polynomials  $P_l(\mu)$ . Therefore, rounding errors, regarded as proportional to  $Q_l(\mu)$ , in the generation of Legendre polynomials using recurrence relations, are likely to become large at or near the poles. Neumann's formula (26) can also be written in the form

$$Q_{l}(\mu) = \frac{1}{2} \int_{-1}^{1} \frac{P_{l}(\zeta)}{\mu - \zeta} d\zeta,$$
 (Eq. 27)

which can be used to derive the Christoffel formula (22) for  $Q_l(\mu)$ .

# Generating function

The function

$$V(r,\mu) = \frac{1}{\sqrt{1 - 2\mu h + h^2}} = \sum_{l=0}^{\infty} h^l P_l(\cos\theta)$$
 (Eq. 28)

is the generating function for the Legendre polynomials.

If a gravitating particle of mass m is moved from the origin a distance d along the *z*-axis, regarded as the pole of a coordinate system, then, using the cosine rule of trigonometry, the gravitational potential of the particle (in a region free of gravitating material) is

$$V(r,\theta) = \frac{Gm}{\sqrt{r^2 - 2r d \cos \theta + d^2}},$$
  

$$V(r,\theta) = \frac{Gm}{d} \sum_{l=0}^{\infty} \left(\frac{d}{r}\right)^{l+1} P_l(\cos \theta), \text{ when } r > d,$$
  

$$V(r,\theta) = \frac{Gm}{d} \sum_{l=0}^{\infty} \left(\frac{r}{d}\right)^l P_l(\cos \theta), \text{ when } r < d.$$
 (Eq. 29)

If the potential of a distribution of matter is independent of azimuth or east longitude, it is said to be zonal. In the case where the potential of the distribution in a source-free region along the z-axis is known to be

$$V(z) = \frac{G}{d} \sum_{l=0}^{\infty} \alpha_l \left(\frac{d}{z}\right)^{l+1} \quad \text{for } z > d,$$

and

$$V(z) = \frac{G}{d} \sum_{l=0}^{\infty} \alpha_l \left(\frac{z}{d}\right)^l \quad \text{for } z < d,$$
(Eq. 30)

then, from the continuity of the potential, the potential in regions away from the z-axis is

$$V(r,\theta) = \frac{G}{d} \sum_{l=0}^{\infty} \alpha_l \left(\frac{d}{r}\right)^{l+1} P_l(\cos \theta) \quad \text{for } r > d,$$

and

$$V(r,\theta) = \frac{G}{d} \sum_{l=0}^{\infty} \alpha_l \left(\frac{r}{d}\right)^l P_l(\cos\theta) \quad \text{for } r < d.$$
 (Eq. 31)

# **Recurrence relations**

Differentiation of the generating function (28) and the Rodrigues formula (21) can be used to derive the recurrence relations for Legendre polynomials. The more important ones are

Bonnet's formula 
$$(l+1)P_{l+1} - (2l+1)\mu P_l + lP_{l-1} = 0,$$
  
(Eq. 32)

$$\frac{dP_{l+1}}{d\mu} = \mu \frac{dP_l}{d\mu} + (l+1)P_l,$$
 (Eq. 33)

and

$$(2l+1)P_l = \frac{\mathrm{d}P_{l+1}}{\mathrm{d}\mu} - \frac{\mathrm{d}P_{l-1}}{\mathrm{d}\mu}.$$
 (Eq. 34)

# Multiple derivatives of inverse distance

Parameters  $\boldsymbol{\xi}$  and  $\boldsymbol{\eta}$  are required, and they are defined by

$$\xi = -\frac{1}{\sqrt{2}}(x + iy) = -\frac{1}{\sqrt{2}}r\sin\theta e^{i\phi},$$
  

$$\eta = \frac{1}{\sqrt{2}}(x - iy) = \frac{1}{\sqrt{2}}r\sin\theta e^{-i\phi}.$$
(Eq. 35)

Partial derivatives with respect to  $\xi$  and  $\eta$  are

$$\frac{\partial f}{\partial \xi} = -\frac{1}{\sqrt{2}} \left( \frac{\partial f}{\partial x} - i \frac{\partial f}{\partial y} \right), \quad \frac{\partial f}{\partial \eta} = \frac{1}{\sqrt{2}} \left( \frac{\partial f}{\partial x} + i \frac{\partial f}{\partial y} \right).$$
(Eq. 36)

The solid spherical harmonic, inverse distance, is

$$\frac{1}{r} = \frac{1}{\sqrt{x^2 + y^2 + z^2}} = \frac{1}{\sqrt{z^2 - 2\xi\eta}},$$
 (Eq. 37)

with multiple derivatives

$$\left(\frac{\partial}{\partial\xi}\right)^{m}\frac{1}{r} = 1 \cdot 3 \cdot 5 \dots (2m-1)\frac{\eta^{m}}{r^{2m+1}},$$
$$\left(\frac{\partial}{\partial\eta}\right)^{m}\frac{1}{r} = 1 \cdot 3 \cdot 5 \dots (2m-1)\frac{\xi^{m}}{r^{2m+1}}.$$
(Eq. 38)

The  $(l-m)^{\text{th}}$  derivative of  $1/r^{2m+1}$  with respect to z is

$$(-1)^{l-m} \left(\frac{\partial}{\partial z}\right)^{l-m} \frac{1}{r^{2m+1}} = (2m+1)(2m+3)\dots(2l-1)$$
$$\left[\frac{z^{l-m}}{r^{2l+1}} - \frac{(l-m)(l-m-1)z^{l-m-2}}{2(2l-1)} + \frac{(l-m)(l-m-1)(l-m-2)(l-m-3)z^{l-m-4}}{2\cdot 4(2l-1)(2l-3)} - \dots\right]$$
(Eq. 39)

The required 2l + 1 independent spherical harmonics of degree *l* are obtained by differentiating (38) partially with respect to *z* some l - m times, for  $m = -l, -l + 1, \ldots -1, 0, 1, \ldots, l - 1, l$ , when, with the substitutions  $z = r \cos \theta$  and  $\mu = \cos \theta$ ,

$$(-1)^{l-m} \left(\frac{\partial}{\partial \eta}\right)^{m} \left(\frac{\partial}{\partial z}\right)^{l-m} \frac{1}{r} = \frac{1}{r^{l+m+1}} \frac{(l-m)!}{2^{l}l!} \xi^{m} \\ \left[\frac{(2l)!}{(l-m)!} \mu^{l-m} - \frac{l(2l-2)!}{(l-m-2)!} \mu^{l-m-2} + \frac{l(l-1)(2l-4)!}{2(l-m-4)!} \mu^{l-m-4} - \dots\right].$$
(Eq. 40)

The series in (40) is the  $(l+m)^{\text{th}}$  derivative of a series which can be summed by the binomial theorem, and hence

$$(-1)^{l-m} \left(\frac{\partial}{\partial x} + i\frac{\partial}{\partial y}\right)^m \left(\frac{\partial}{\partial z}\right)^{l-m} \frac{1}{r}$$
  
=  $(-1)^m \frac{e^{im\phi}}{r^{l+1}} \frac{(l-m)!}{2^l l!} (1-\mu^2)^{m/2} \left(\frac{d}{d\mu}\right)^{l+m} (\mu^2-1)^l.$   
(Eq. 41)

## Ferrers normalized functions

Associated Legendre functions are solutions of Eq. (12), and are given in the first instance as the Ferrers normalized functions  $P_{l,m}(\mu)$ , (Ferrers, 1897), defined by

$$P_{l,m}(\mu) = (1 - \mu^2)^{m/2} \left(\frac{d}{d\mu}\right)^m P_l(\mu),$$
  
=  $\frac{1}{2^l l!} (1 - \mu^2)^{m/2} \left(\frac{d}{d\mu}\right)^{l+m} (\mu^2 - 1)^l, \text{ for } l \ge |m|$   
(Eq. 42)

See Table H1 for a list of these functions.

Applying Leibnitz's theorem for multiple derivatives of  $\left[(\mu-1)^l(\mu+1)^l\right]$  in the function  $P_l^{-m}(\mu)$  and then re-arranging terms, gives the expression in terms of  $P_l^m(\mu)$ ,

$$P_{l,-m}(\mu) = \frac{1}{2^{l}l!} (1-\mu^{2})^{-m/2} \left(\frac{d}{d\mu}\right)^{l-m} (\mu^{2}-1)^{l}$$
$$= (-1)^{m} \frac{(l-m)!}{(l+m)!} P_{l,m}(\mu).$$
(Eq. 43)

Both Eqs. (42) and (43) can be used with positive or negative values of m. Caution is needed with definitions based on |m|. Equations (42) and (43) can be used to derive the normalization integral for associated Legendre functions with Ferrers normalization,

$$\frac{1}{2} \int_{-1}^{1} P_{l,m}(\mu) P_{L,m}(\mu) d\mu = \frac{1}{2l+1} \frac{(l+m)!}{(l-m)!} \delta_l^L.$$
 (Eq. 44)

# Surface spherical harmonics

Surface spherical harmonics  $Y_l^m(\theta, \phi)$  are defined in terms of the Ferrers normalized functions  $P_{l,m}(\cos \theta)$ 

$$Y_{l}^{m}(\theta,\phi) = (-1)^{m} e^{im\phi} \sqrt{(2l+1)\frac{(l-m)!}{(l+m)!}} P_{l,m}(\cos\theta),$$
  
=  $(-1)^{m} e^{im\phi} \sqrt{(2l+1)\frac{(l-m)!}{(l+m)!}} \frac{1}{2^{l}l!} (1-\mu^{2})^{m/2} \left(\frac{d}{d\mu}\right)^{l+m} (\mu^{2}-1)^{l}.$   
(Eq. 45)

The initial factor  $(-1)^m$  is now used following the influential work of Condon and Shortley (1935). See Table H1 for a list of the functions  $Y_l^m(\theta, \phi)$ , and Figure H4 for tesseral, sectorial, and zonal harmonics.

Therefore, in terms of multiple derivatives of inverse distance, from Eqs. (41) and (45),

$$\frac{1}{r^{l+1}}Y_l^m(\theta,\phi)$$

$$= (-1)^{l-m}\sqrt{\frac{2l+1}{(l-m)!(l+m)!}} \left(\frac{\partial}{\partial x} + i\frac{\partial}{\partial y}\right)^m \left(\frac{\partial}{\partial z}\right)^{l-m}\frac{1}{r}$$
(Eq. 46)

The series expression for surface spherical harmonics is

$$Y_{l}^{m}(\theta,\phi) = \frac{(2l)!}{2^{l}l!} e^{im\phi} \sqrt{\frac{2l+1}{(l-m)!(l+m)!}} (1-\mu^{2})^{m/2} \\ \left[ \mu^{l-m} - \frac{(l-m)(l-m-1)}{2(2l-1)} \mu^{l-m-2} + \frac{(l-m)(l-m-1)(l-m-2)(l-m-3)}{2 \cdot 4(2l-1)(2l-3)} \mu^{n-m-4} - \dots \right].$$
(Eq. 47)

**Table H1** List of associated Legendre functions  $P_1^m(\cos\theta)$  in Ferrers normalization and Schmidt normalization to degree and order six, and the corresponding surface spherical harmonics  $Y_1^m(\theta, \phi)$ , normalized after Condon and Shortley

In the special case m = 0, from Eq. (45),

$$Y_{l}^{0}(\theta,\phi) = \sqrt{(2l+1)} \frac{1}{2^{l} l!} \left(\frac{\mathrm{d}}{\mathrm{d}\mu}\right)^{l} (\mu^{2}-1)^{l} = \sqrt{(2l+1)} P_{l}(\mu),$$
(Eq. 48)

Changing the sign of m in Eq. (45) and making use of Eq. (43), gives

$$\begin{split} Y_{l}^{-m}(\theta,\phi) &= (-1)^{m} \mathrm{e}^{-\mathrm{i}m\phi} \sqrt{(2l+1)\frac{(l+m)!}{(l-m)!}} P_{l,-m}(\cos\theta), \\ &= \mathrm{e}^{-\mathrm{i}m\phi} \sqrt{(2l+1)\frac{(l-m)!}{(l+m)!}} P_{l,m}(\cos\theta), \\ &= (-1)^{m} \overline{Y_{l}^{m}(\theta,\phi)}. \end{split}$$
 (Eq. 49)

Note that  $\xi, z, \eta$  are related to the surface spherical harmonics of the first degree by

$$Y_1^1(\theta,\phi) = -\frac{\sqrt{6}}{2}\sin\theta e^{i\phi} = \frac{\sqrt{3}}{r}\xi,$$
  

$$Y_1^0(\theta,\phi) = \sqrt{3}\cos\theta = \frac{\sqrt{3}}{r}z,$$
  

$$Y_1^{-1}(\theta,\phi) = \frac{\sqrt{6}}{2}\sin\theta e^{-i\phi} = \frac{\sqrt{3}}{r}\eta.$$
 (Eq. 50)

The normalization and orthogonality integral is

$$\frac{1}{4\pi} \int_0^{2\pi} \int_0^{\pi} Y_l^m(\theta, \phi) \overline{Y_L^M(\theta, \phi)} \sin \theta d\theta d\phi = \delta_l^L \delta_m^M.$$
 (Eq. 51)

In theoretical physics texts, it is common practice to replace the initial factor  $1/4\pi$  in Eq. (51) by applying a factor  $\sqrt{1/4\pi}$  to the surface spherical harmonic  $Y_l^m(\theta, \phi)$ . This factor is sometimes broken up into a factor  $\sqrt{1/2\pi}$  applied to the associated Legendre function and a factor  $\sqrt{1/2}$  applied to the complex exponential part.

 $P_6^0(\cos\theta)$ 

**Figure H4** Zonal surface spherical harmonics are of the form  $P_l^0(\cos \theta)$ ; sectorial surface spherical harmonics are of the form  $P_l^l(\cos \theta)\cos l\phi$  and  $P_l^l(\cos \theta)\sin l\phi$ . Tesseral surface spherical harmonics are those that are neither zonal nor sectorial.

The (2l + 1) independent solutions of degree *l* of Laplace's equation, with no logarithmic singularity at the poles, are the (2l + 1) solid spherical harmonics,

$$r^{l}Y_{l}^{m}(\theta,\phi)$$
, where  $m = -l, -l+1, \dots l-1, l.$  (Eq. 52)

Given a sufficiently differentiable function  $f(\theta, \phi)$  over the surface of a sphere, it can be written as a finite linear combination of surface spherical harmonics

$$f(\theta, \phi) = \sum_{l=0}^{L} \sum_{m=-n}^{n} f_{lm} Y_{l}^{m}(\theta, \phi),$$
 (Eq. 53)

where the complex constant coefficients  $f_{lm}$  are determined using

$$f_{lm} = \frac{1}{4\pi} \int_0^{2\pi} \int_0^{\pi} f(\theta, \phi) \overline{Y_l^m(\theta, \phi)} \sin \theta d\theta d\phi.$$
 (Eq. 54)

Vector spherical harmonics are required for the representation of vector fields over the surface of a sphere.

# Schmidt normalized functions

The Schmidt normalized associated Legendre functions  $P_l^m(\cos\theta)$  are defined by

$$P_l^0(\cos\theta) = P_{l,0}(\cos\theta),$$
  

$$P_l^m(\cos\theta) = \sqrt{2\frac{(l-m)!}{(l+m)!}} P_{l,m}(\cos\theta), \quad m \neq 0.$$
 (Eq. 55)

They are normalized to have the same value as the Legendre polynomials and they are widely used in geomagnetism in accordance with a resolution of the Association of Terrestrial Magnetism and Electricity of the International Union of Geodesy and Geophysics (Goldie and Joyce, 1940). Following Schmidt (1899), it is convenient to write the two formulae of Eq. (55) in the form

$$P_l^m(\cos\theta) = \sqrt{\varepsilon_m \frac{(l-m)!}{(l+m)!}} P_{l,m}(\cos\theta)$$
 (Eq. 56)

in which the parameter  $\varepsilon_m$  is defined by

$$\varepsilon_0 = 1, \quad \varepsilon_1 = \varepsilon_2 = \varepsilon_3 = \ldots = 2,$$
 (Eq. 57)

or alternatively, in terms of the Kronecker delta function

$$\varepsilon_m = 2 - \delta_m^0. \tag{Eq. 58}$$

For expressions  $f(\theta, \phi)$  involving real variables only, we may write it as a linear combination of Schmidt normalized functions,

$$f(\theta,\phi) = \sum_{l=0}^{N} \left( g_l^m \cos m\phi + h_l^m \sin m\phi \right) P_l^m(\cos\theta)$$
 (Eq. 59)

where the constant coefficient where the constants  $g_n^m$  and  $h_n^m$  are determined using

$$g_l^m = (2l+1)\frac{1}{4\pi}\int_0^{2\pi}\int_0^{\pi} f(\theta,\phi)P_l^m(\cos\theta)\cos m\phi\sin\theta d\theta d\phi$$
$$h_l^m = (2l+1)\frac{1}{4\pi}\int_0^{2\pi}\int_0^{\pi} f(\theta,\phi)P_l^m(\cos\theta)\sin m\phi\sin\theta d\theta d\phi.$$
(Eq. 60)

# **Recurrence relations**

Recurrence relations for spherical harmonics are derived using derivatives of Eq. (46) and derivatives of the recurrence relations for Legendre polynomials. The spherical polar components for the derivatives used in Eq. (46) defining  $Y_n^m(\theta, \phi)$ , are

$$\frac{\partial f}{\partial x} + i\frac{\partial f}{\partial y} = \left(\frac{\partial f}{\partial r}\sin\theta + \frac{1}{r}\frac{\partial f}{\partial\theta}\cos\theta + \frac{i}{r\sin\theta}\frac{\partial f}{\partial\phi}\right)e^{i\phi}, \quad (\text{Eq. 61})$$

$$\frac{\partial f}{\partial z} = \frac{\partial f}{\partial r} \cos \theta - \frac{1}{r} \frac{\partial f}{\partial \theta} \sin \theta, \qquad (\text{Eq. 62})$$

$$\frac{\partial f}{\partial x} - i\frac{\partial f}{\partial y} = \left(\frac{\partial f}{\partial r}\sin\theta + \frac{1}{r}\frac{\partial f}{\partial \theta}\cos\theta - \frac{i}{r\sin\theta}\frac{\partial f}{\partial \phi}\right)e^{-i\phi}.$$
 (Eq. 63)

The basic set of recurrence relations in which the degree n and order m on the left hand side are changed by -1, 0, or +1 on the right-hand side are

$$- (l+1)\sin\theta Y_{l}^{m} + \cos\theta \frac{\partial Y_{l}^{m}}{\partial \theta} - \frac{m}{\sin\theta} Y_{l}^{m}$$
  
=  $e^{-i\phi} \sqrt{\frac{2l+1}{2l+3}(l+m+1)(l+m+2)} Y_{l+1}^{m+1}$ , (Eq. 64)

$$- (l+1)\cos\theta Y_{l}^{m} - \sin\theta \frac{\partial Y_{l}^{m}}{\partial\theta} = -\sqrt{\frac{2l+1}{2l+3}(l-m+1)(l+m+1)}Y_{l+1}^{m},$$
(Eq. 65)

$$-(l+1)\sin\theta Y_l^m + \cos\theta \frac{\partial Y_l^m}{\partial \theta} + \frac{m}{\sin\theta} Y_l^m$$
$$= -e^{i\phi} \sqrt{\frac{2l+1}{2l+3}(l-m+1)(l-m+2)} Y_{l+1}^{m-1}, \qquad (Eq. 66)$$

$$\frac{\partial Y_l^m}{\partial \theta} - m \cot \theta Y_l^m = e^{-i\phi} \sqrt{(l-m)(l+m+1)} Y_l^{m+1}, \quad \text{(Eq. 67)}$$

$$\frac{\partial Y_l^m}{\partial \theta} + m \cot \theta Y_l^m = -e^{i\phi} \sqrt{(l+m)(l-m+1)} Y_l^{m-1}, \quad \text{(Eq. 68)}$$

$$l\sin\theta Y_l^m + \cos\theta \frac{\partial Y_l^m}{\partial \theta} - \frac{m}{\sin\theta} Y_l^m$$
  
=  $e^{-i\phi} \sqrt{\frac{2l+1}{2l-1}(l-m)(l-m-1)} Y_{l-1}^{m+1}$ , (Eq. 69)

$$l\cos\theta Y_l^m - \sin\theta \frac{\partial Y_l^m}{\partial \theta} = \sqrt{\frac{2l+1}{2l-1}(l+m)(l-m)}Y_{l-1}^m, \quad (\text{Eq. 70})$$

$$l\sin\theta Y_l^m + \cos\theta \frac{\partial Y_l^m}{\partial \theta} + \frac{m}{\sin\theta} Y_l^m$$
$$= -e^{i\phi} \sqrt{\frac{2l+1}{2l-1}(l+m)(l+m-1)} Y_{l-1}^{m-1}.$$
 (Eq. 71)

Most recurrence relations can be derived from this basic set. Schuster (1903) gives a list of recurrence relations useful in ionospheric dynamo theory. Chapman and Bartels (1940) also derive some recurrence relations.

# Transformation of spherical harmonics

. . . .

On using the spinor forms of derivatives (see Rotations; Eq. (45))

$$\frac{\partial}{\partial\xi} = \lambda_1^2, \qquad \frac{1}{\sqrt{2}}\frac{\partial}{\partial z} = \lambda_1\lambda_2, \qquad \frac{\partial f}{\partial\eta} = \lambda_2^2,$$

it follows that solid spherical harmonics can also be written using spinors, in the more symmetric form

$$\frac{1}{r^{l+1}}Y_l^m(\theta,\phi) = (-1)^{l-m} \sqrt{\frac{2l+1}{(l-m)!(l+m)!}} \lambda_1^{l-m} \lambda_2^{l+m} \frac{1}{r}.$$
(Eq. 72)

The transformation law for spherical harmonics under rotation of the reference frame follows from Eq. (72), using the transformation law (see Rotations; (190))

$$\Lambda_1 = u\lambda_1 + v\lambda_2,$$
  

$$\Lambda_2 = -\bar{v}\lambda_1 + \bar{u}\lambda_2.$$
(Eq. 73)

where the Cayley-Klein parameters u and v are given in terms of Euler angles  $(\alpha, \beta, \gamma)$ , by

$$u = \cos \frac{1}{2} \beta e^{i(\gamma + \alpha)/2},$$
  

$$v = \sin \frac{1}{2} \beta e^{i(\gamma - \alpha)/2}.$$
 (Eq. 74)

If a point *P* has spherical polar coordinates, colatitude and east longitude  $(\theta, \phi)$ , and if after a rotation through Euler angles  $(\alpha, \beta, \gamma)$  the coordinates are  $(\Theta, \Phi)$ , then from Eq. (72)

$$\frac{1}{r^{l+1}}Y_l^m(\Theta,\Phi) = (-1)^{l-m}\sqrt{\frac{2l+1}{(l-m)!(l+m)!}}\Lambda_1^{l-m}\Lambda_2^{l+m}\frac{1}{r}.$$
(Eq. 75)

From the transformation formula for spinors Eq. (73), it follows that

$$\Lambda_1^{l-m} \Lambda_2^{l+m} = \left( u\lambda_1 + v\lambda_2 \right)^{l-m} \left( -\bar{v}\lambda_1 + \bar{u}\lambda_2 \right)^{l+m}$$
(Eq. 76)

and after expanding by the binomial theorem

$$\Lambda_1^{l-m} \Lambda_2^{l+m} = \sum_{j=0}^{l+m} \sum_{k=0}^{l-m} \frac{(l-m)!(l+m)!}{(l-m-k)!k!(l+m-j)!j!} .$$
 (Eq. 77)  
  $\times u^k \bar{u}^{l+m-j} v^{l-m-k} \bar{v}^{2l-j-k}$ 

Replace the summing index k by M, where k = l - M - j, and with the substitutions

$$u = (\cos\frac{1}{2}\beta)e^{i(\gamma+\alpha)/2}, \qquad v = (\sin\frac{1}{2}\beta)e^{i(\gamma-\alpha)/2}, \quad (Eq. 78)$$

we find that

$$\begin{split} \Lambda_1^{l-m} \Lambda_2^{l+m} &= \sum_M \sum_j \frac{(-1)^j}{(M-m+j)!(l-M-j)!(l+m-j)!\,j!} \\ &\times (\cos\frac{1}{2}\beta)^{2l-M+m-2j} (\sin\frac{1}{2}\beta)^{M-m+2j} \mathrm{e}^{-\mathrm{i}(M\alpha+m\gamma)} \lambda_1^{l-M} \lambda_2^{l+M} \end{split}$$
(Eq. 79)

The range of summing indices M and j, is such that none of the factorial expressions or powers of trigonometrical functions become negative.

# **Rotation matrix elements**

It follows from Eq. (79) that

$$(-1)^{l-m} \frac{\Lambda_1^{l-m} \Lambda_2^{l+m}}{\sqrt{(l-m)!(l+m)!}} = \sum_{M=-l}^l D_{Mm}^l(\alpha, \beta, \gamma) \\ \left[ (-1)^{l-M} \frac{\lambda_1^{l-M} \lambda_2^{l+m}}{\sqrt{(L-m)!(L+m)!}} \right],$$

where the functions  $D^{\lambda}_{Mm}(\alpha,\beta,\gamma)$  are called "rotation matrix elements" and are written

$$D_{Mm}^{l}(\alpha,\beta,\gamma) = d_{Mm}^{l}(\beta) e^{-i(M\alpha+m\gamma)}, \qquad (Eq. 80)$$

and the purely real function  $d_{Mm}^l(\beta)$  is

$$\begin{split} d^{l}_{Mm}(\beta) &= (-1)^{M-m} \sum_{j} (-1)^{j} \frac{\sqrt{(l-M)!(l+M)!(l-m)!(l+m)!}}{(M-m+j)!(l-M-j)!(l+m-j)! \ j!} \\ &\times (\cos\frac{1}{2}\beta)^{2l-M+m-2j} (\sin\frac{1}{2}\beta)^{M-m+2j}. \end{split}$$
 (Eq. 81)

See Table H2 for a list of these functions. The form often given for the functions  $d_{Mm}^l(\beta)$  is obtained with the substitution j = m - M + t, when

$$d_{Mm}^{l}(\beta) = \sum_{t} (-1)^{t} \frac{\sqrt{(l-M)!(l+M)!(l-m)!(l+m)!}}{(m-M+t)!(l+M-t)!(l-m-t)!t!} \\ \times (\cos\frac{1}{2}\beta)^{2l-m+M-2t} (\sin\frac{1}{2}\beta)^{m-M+2t}, \\ = \sqrt{\frac{(l-M)!(l+M)!}{(l-m)!(l+m)!}} \sum_{t} (-1)^{t} \binom{l+m}{l+M-t} \binom{l-m}{t} \\ \times (\cos\frac{1}{2}\beta)^{2l-m+M-2t} (\sin\frac{1}{2}\beta)^{m-M+2t}, \quad \text{(Eq. 82)}$$

**Table H2** List of rotation matrix elements to degree and order 3. Symmetry properties are required to complete the  $(2l + 1) \times (2l + 1)$  table of rotation matrix elements for degree *l* 

The transformation law for spherical harmonics is therefore

$$Y_l^m(\Theta, \Phi) = \sum_{M=-l}^l D_{Mm}^l(\alpha, \beta, \gamma) Y_l^M(\theta, \phi).$$
 (Eq. 83)

Equation (82) is valid for half-odd integer values of the parameters l, M, and m. In particular,

$$D_{-\frac{1}{2},-\frac{1}{2}}^{\frac{1}{2}}(\alpha,\beta,\gamma) = \cos\frac{1}{2}\beta e^{i(\gamma+\alpha)/2} = u,$$
  
$$D_{\frac{1}{2},-\frac{1}{2}}^{\frac{1}{2}}(\alpha,\beta,\gamma) = \sin\frac{1}{2}\beta e^{i(\gamma-\alpha)/2} = v.$$
 (Eq. 84)

The transformation law for spinors, Eq. (73), becomes

$$\begin{pmatrix} \Lambda_1 \\ \Lambda_2 \end{pmatrix} = \begin{pmatrix} D_{-\frac{1}{2},-\frac{1}{2}}^{\frac{1}{2}}(\alpha,\beta,\gamma) & D_{\frac{1}{2},-\frac{1}{2}}^{\frac{1}{2}}(\alpha,\beta,\gamma) \\ -D_{-\frac{1}{2},\frac{1}{2}}^{\frac{1}{2}}(\alpha,\beta,\gamma) & D_{-\frac{1}{2},-\frac{1}{2}}^{\frac{1}{2}}(\alpha,\beta,\gamma) \end{pmatrix} \begin{pmatrix} \lambda_1 \\ \lambda_2 \end{pmatrix}.$$
(Eq. 85)

The transformation law for surface spherical harmonics of degree one, is

$$\begin{pmatrix} Y_{1}^{1}(\Theta, \Phi) \\ Y_{1}^{0}(\Theta, \Phi) \\ Y_{1}^{-1}(\Theta, \Phi) \end{pmatrix}$$

$$= \begin{pmatrix} \cos^{2}\frac{1}{2}\beta e^{i(\alpha+\gamma)} & \sqrt{2}\sin\frac{1}{2}\beta\cos\frac{1}{2}\beta e^{i\gamma} & \sin^{2}\frac{1}{2}\beta e^{i(-\alpha+\gamma)} \\ -\sqrt{2}\sin\frac{1}{2}\beta\cos\frac{1}{2}\beta e^{i\alpha} & \cos\beta & \sqrt{2}\sin\frac{1}{2}\beta\cos\frac{1}{2}\beta e^{-i\alpha} \\ \sin^{2}\frac{1}{2}\beta e^{i(\alpha-\gamma)} & -\sqrt{2}\sin\frac{1}{2}\beta\cos\frac{1}{2}\beta e^{-i\gamma} & \cos^{2}\frac{1}{2}\beta e^{-i(\alpha+\gamma)} \end{pmatrix} \\ \begin{pmatrix} Y_{1}^{1}(\theta, \phi) \\ Y_{1}^{0}(\theta, \phi) \\ Y_{1}^{-1}(\theta, \phi) \end{pmatrix}$$
(Eq. 86)

# Closure

When a rotation through Euler angles  $(\alpha_1, \beta_1, \gamma_1)$  is followed by a second rotation through Euler angles  $(\alpha_2, \beta_2, \alpha_2)$ , then

$$\begin{split} Y_l^{m'}(\Theta, \Phi) &= \sum_{M=-l}^l D_{Mm'}^l(\alpha_1, \beta_1, \gamma_1) \; Y_l^M(\theta, \phi), \\ Y_l^M(\Theta', \Phi') &= \sum_{m'=-l}^l D_{m'm}^l(\alpha_2, \beta_2, \gamma_2) \; Y_l^{m'}(\Theta, \Phi), \end{split}$$

and therefore,

$$Y_l^m(\Theta',\Phi') = \sum_{M=-l}^l \left[ \sum_{m'=-l}^l D_{Mm'}^l(\alpha_1,\beta_1,\gamma_1) D_{m'm}^l(\alpha_2,\beta_2,\gamma_2) \right] Y_l^M(\theta,\phi).$$

However, this is equivalent to a rotation through Euler angles  $(\alpha, \beta, \gamma)$  where

$$Y_l^m(\Theta', \Phi') = \sum_{M=-l}^l D_{Mm}^l(\alpha, \beta, \gamma) Y_l^M(\theta, \phi),$$

from which it follows that

$$D_{Mm}^{l}(\alpha,\beta,\gamma) = \sum_{m'=-l}^{l} D_{Mm'}^{l}(\alpha_{1},\beta_{1},\gamma_{1}) D_{m'm}^{l}(\alpha_{2},\beta_{2},\gamma_{2}). \quad (\text{Eq. 87})$$

Equation (87) is an important result, with special cases giving the sum rule, the addition theorems of trigonometry, and formulae of spherical trigonometry, including the analogies of Napier and Delambre, as well as the various haversine formulae. For example, in the special case that  $\alpha_1 = \alpha_2 = \alpha_3 = 0$  and  $\gamma_1 = \gamma_2 = \gamma_3 = 0$ , then  $\beta_3 = \beta_1 + \beta_2$ , and

$$d_{Mm}^{l}(\beta_{1}+\beta_{2}) = \sum_{m'=-l}^{l} d_{Mm'}^{l}(\beta_{1}) d_{m'm}^{l}(\beta_{2}),$$
(Eq. 88)

which is a generalization of all of the sum formulae of trigonometry.

# **Rodrigues formula**

The rotation matrix elements  $D_{Mm}^{l}(\beta)$  have two types of orthogonality. Firstly, they are orthogonal under integration over the range of the Euler angles,  $0 \le \alpha < 2\pi, 0 \le \beta \le \pi$ , and  $0 \le \gamma < 2\pi$ , and secondly, for a fixed value of *l*, regarded as a  $(2l+1) \times (2l+1)$  matrix array, they have matrix orthogonality properties. These properties are most easily derived using the Rodrigues formula, substituting  $z = \cos \beta$ , when

$$d_{Mm}^{l}(z) = \frac{(-1)^{l+M}}{2^{l}} \sqrt{\frac{(l-M)!}{(l+m)!(l-m)!(l+M)!}} \times (1-z)^{(M-m)/2} (1+z)^{(M+m)/2} \left(\frac{d}{dz}\right)^{l+M} [(1-z)^{l+m}(1+z)^{l-m}].$$
 (Eq. 89)

The "symmetry",  $d_{M,m}^l(\beta) = d_{-m,-M}^l(\beta)$ , indicates that there are two other equivalent formulae (Schendel, 1877).

Equation (89), in the case m = 0, using Eq. (43), gives

$$d_{M,0}^{l}(z) = \frac{(-1)^{M}}{2^{l}l!} \sqrt{\frac{(l-M)!}{(l+M)!}} (1-z^{2})^{M/2} \left(\frac{d}{dz}\right)^{l+M} (z^{2}-1)^{l},$$
  
$$= (-1)^{M} \sqrt{\frac{(l-M)!}{(l+M)!}} P_{l,M}(z),$$
  
$$= \sqrt{\frac{(l+M)!}{(l-M)!}} P_{l,-M}(z).$$
(Eq. 90)

A full description of the properties of the rotation matrix elements, including contour integral formulae is given in Vilenkin (1968).

# Orthogonality

The D-functions form unitary matrices, with orthonormal rows and columns for each fixed degree *l*. They also have orthogonality properties under integration over all three Eulerian angles. The derivation makes use of a second equivalent form for  $d'_{Mm}(z)$ , namely

$$d_{Mm}^{l}(z) = \frac{(-1)^{l-m}}{2^{l}} \sqrt{\frac{(L+M)!}{(l+m)!(l-m)!(L-M)!}} \times (1-z)^{(-M+m)/2} (1+z)^{(-M-m)/2}} \left(\frac{d}{dz}\right)^{l-M} \left[ (1-z)^{l-m} (1+z)^{l+m} \right].$$
(Eq. 91)

The required property is that

$$\frac{1}{8\pi^2} \int_0^{2\pi} \int_0^{\pi} \int_0^{2\pi} D_{Mm}^l(\alpha, \beta, \gamma) \overline{D_{M'm'}^l(\alpha, \beta, \gamma)} \sin\beta d\alpha d\beta d\gamma$$
$$= \frac{1}{2l+1} \delta_l^{l'} \delta_M^{M'} \delta_m^{m'}.$$
(Eq. 92)

#### Special values

At the particular values  $0, \pi, 2\pi$  of  $\beta$ , the rotation matrix elements are

$$\begin{aligned} d^{l}_{M,m}(0) &= \delta^{m}_{M}, \\ d^{l}_{M,m}(\pi) &= (-1)^{l+M} \ \delta^{-m}_{M} = (-1)^{l-m} \delta^{-m}_{M}, \\ d^{l}_{M,m}(2\pi) &= (-1)^{2l} \delta^{m}_{M}, \end{aligned}$$
(Eq. 93)

with symmetries for general values of  $\beta$ 

$$\begin{aligned} d^{l}_{M,m}(\beta) &= d^{l}_{-m,-M}(\beta), \\ d^{l}_{m,M}(\beta) &= (-1)^{m-M} d^{l}_{-m,-M}(\beta), \end{aligned} \tag{Eq. 94}$$

and

$$\begin{aligned} d_{M,m}^{l}(-\beta) &= (-1)^{m-M} d_{M,m}^{l}(\beta) = d_{m,M}^{l}(\beta), \\ d_{M,m}^{l}(\pi+\beta) &= (-1)^{l-m} d_{M,-m}^{l}(\beta), \\ d_{M,m}^{l}(\pi-\beta) &= (-1)^{l-M} d_{M,-m}^{\beta}(\beta) = (-1)^{l+m} d_{-M,m}^{l}(\beta). \end{aligned}$$
(Eq. 95)

## The sum rule

An important special case of Eq. (89) is that for which m = 0, when, from Eq. (75) defining  $Y_l^m(\theta, \phi)$ , and with  $\mu = \cos \beta$ , we obtain

$$D_{M,0}^{l}(\alpha,\beta,\gamma) = d_{M,0}^{l}(\beta)e^{-iM\alpha},$$
  
=  $(-1)^{M}\sqrt{\frac{(l-M)!}{(l+M)!}}P_{l,M}(\mu)e^{-iM\alpha},$   
=  $\frac{1}{\sqrt{2l+1}}\overline{Y_{l}^{M}(\beta,\alpha)}.$  (Eq. 96)

Therefore, in the special case m = 0, the transformation formula (83) becomes

$$Y_{l}^{0}(\Theta, \Phi) = \sum_{M=-l}^{l} D_{M0}^{l}(\alpha, \beta, \gamma) Y_{l}^{M}(\theta, \phi) .$$
 (Eq. 97)

From Eqs. (48) and (96), Eq. (97) becomes

$$P_l(\cos\Theta) = \frac{1}{2l+1} \sum_{M=-l}^{l} \overline{Y_l^M(\beta,\alpha)} Y_l^M(\theta,\phi) .$$
 (Eq. 98)

and the sum rule in the form Eq. (98) becomes

$$P_{l}(\cos \Theta) = \sum_{M=-l}^{l} \frac{(l-M)!}{(l+M)!} P_{l,M}(\cos \beta) P_{l,M}(\cos \theta) e^{iM(\phi-\alpha)}.$$
(Eq. 99)

In terms of Schmidt normalized functions, the sum rule takes the wellknown form,

$$P_l(\cos\Theta) = \sum_{M=0}^{l} P_l^M(\cos\beta) P_l^M(\cos\theta) \cos m(\phi - \alpha). \quad \text{(Eq. 100)}$$

The case l = 1 of Eq. (100) is the cosine rule of spherical trigonometry,

$$\cos \Theta = \cos \beta \cos \theta + \sin \beta \sin \theta \cos(\phi - \alpha), \qquad (Eq. 101)$$

and the case l = 2, is the basic rule in the theory of tides, with the longitudinal terms showing the dependence on M = 0 long-period terms, M = 1 lunar diurnal terms and M = 2 lunar semidiurnal terms,

$$P_2(\cos\theta) = P_2(\cos\beta)P_2(\cos\theta) + P_2^1(\cos\beta)P_2^1(\cos\theta)\cos(\phi - \alpha) + P_2^2(\cos\beta)P_2^2(\cos\theta)\cos 2(\phi - \alpha).$$
(Eq. 102)

In the case that  $\Theta = 0$ , and the spherical triangle collapses to a straight line so that  $\beta = \theta$  and  $\phi = \alpha$ , then since  $P_l(1) = 1$  for all values of *l*, then Eq. (98) becomes

$$\sum_{M=-l}^{l} \overline{Y_l^M(\theta,\phi)} \; Y_l^M(\theta,\phi) = 2l+1 \; . \tag{Eq. 103}$$

and Eq. (100) in terms of Schmidt normalized polynomials gives

$$\sum_{M=0}^{l} \left[ P_{l}^{M}(\cos\theta) \right]^{2} = 1,$$
 (Eq. 104)

which can be used to provide a useful check on numerical work.

The result of Eq. (103) is equivalent to the conservation of "lengths" under rotation, and therefore requires that the  $(2l + 1) \times (2l + 1)$  rotation matrices  $D_{Mm}^{l}(\alpha, \beta, \gamma)$  be unitary, i.e.,

$$\sum_{M=-l}^{l} \overline{D_{M'M}^{l}(\alpha,\beta,\gamma)} D_{M''M}^{l}(\alpha,\beta,\gamma) = \delta_{M'}^{M''}.$$
 (Eq. 105)

# Schmidt's analysis

Schmidt (1899) derived the transformation formula (83) for spherical harmonics well before the later derivations in the context of the theory of atomic spectra. Schmidt gave the result in terms Schmidt normalized functions, using real variables only, as

$$P_l^m(\cos\Theta)\cos m[\pi - (\Phi + \gamma)] = \frac{1}{2} \sum_{M=0}^l \sqrt{\varepsilon_m \varepsilon_M} \Big[ (-1)^M d_{M,m}^l(\beta) + d_{-M,m}^l(\beta) \Big] \\ \times P_l^M(\cos\theta)\cos M(\phi - \alpha).$$
(Eq. 106)

Because *m* and M = 1, 2, 3, ... only in the expression for imaginary component, therefore, in this case,  $\varepsilon_m = 2$  and  $\varepsilon_M = 2$ , and

$$P_l^m(\cos\Theta)\sin m[\pi - (\Phi + \gamma)]$$
  
=  $\sum_{M=1}^l \left[ (-1)^M d_{M,m}^l(\beta) - d_{-M,m}^l(\beta) \right] P_l^M(\cos\theta)\sin M(\phi - \alpha)$   
(Eq. 107)

The expression Schmidt developed for the rotation matrix elements was given in a slightly different, but nevertheless equivalent form to that of Eq. (89) where  $z = \cos \beta$ . In Schmidt's result,  $c = \cos \beta$  and  $s = \sin \beta$ , and

$$d_{Mm}^{l}(\beta) = (-1)^{M} \sqrt{\frac{(l-m)!(l-M)!}{(l+m)!(l+M)!}} (1+c)^{m} s^{M-m} \\ \left(\frac{d}{dc}\right)^{M} \left[ (1-c)^{m} \left(\frac{d}{dc}\right)^{m} P_{l}(c) \right].$$
 (Eq. 108)

Leibnitz's theorem is used to show the equivalence of Eqs. (108) and (89), where  $z = \cos \beta$ .

## Wigner 3-*j* coefficients

The Wigner 3-*j* coefficients (Wigner, 1931) are just generalizations of the factors that appear in recurrence relations for associated Legendre polynomials, and rotation matrix elements. They have an interesting structure, and are best defined as a sum of products of three combinatorial coefficients. Thus

$$\begin{aligned} & \stackrel{\prime a}{\alpha} & \stackrel{c}{\beta} & \stackrel{c}{\gamma} \\ & \stackrel{\alpha}{\alpha} & \stackrel{\beta}{\beta} & \stackrel{\gamma}{\gamma} \end{aligned} = (-1)^{a-b-\gamma} \sqrt{\frac{(a-\alpha)!(a+\alpha)!(b-\beta)!(b+\beta)!(c-\gamma)!(c+\gamma)!}{(-a+b+c)!(a-b+c)!(a-b+c)!(a+b-c)!}} \\ & \times \frac{1}{\sqrt{(a+b+c+1)!}} \sum_{t} (-1)^{t} \binom{a-b+c}{a-\alpha-t} \binom{-a+b+c}{b+\beta-t} \binom{a+b-c}{t} \end{aligned}$$
(Eq. 109)

Conditions on the values of the parameters require that the nine elements of the following  $3 \times 3$  array, called a Racah square, are all positive,

$$\begin{array}{ccc} -a+b+c & a-b+c & a+b-c \\ a-\alpha & b-\beta & c-\gamma \\ a+\alpha & b+\beta & c+\gamma \end{array}$$
(Eq. 110)

and that  $\alpha + \beta + \gamma = 0$ . The following special cases of the 3-*j* coefficients are determined from the series definition of Eq. (109),

$$\begin{pmatrix} l & l+1 & 1 \\ m & -m-1 & 1 \end{pmatrix} = (-1)^{l-m} \sqrt{\frac{(l+m+1)(l+m+2)}{(2l+1)(2l+2)(2l+3)}}, \\ \begin{pmatrix} l & l+1 & 1 \\ m & -m & 0 \end{pmatrix} = (-1)^{l-m-1} \sqrt{\frac{2(l-m+1)(l+m+1)}{(2l+1)(2l+2)(2l+3)}}, \\ \begin{pmatrix} l & l+1 & 1 \\ m & -m+1 & -1 \end{pmatrix} = (-1)^{l-m} \sqrt{\frac{(l-m+1)(l-m+2)}{(2l+1)(2l+2)(2l+3)}},$$
(Eq. 111)

$$\begin{pmatrix} l & l & 1 \\ m & -m-1 & 1 \end{pmatrix} = (-1)^{l-m} \sqrt{\frac{2(l-m)(l+m+1)}{2(2l+1)(2l+2)}}, \\ \begin{pmatrix} l & l & 1 \\ m & -m & 0 \end{pmatrix} = (-1)^{l-m} \frac{2m}{\sqrt{2l(2l+1)(2l+2)}}, \\ \begin{pmatrix} l & l & 1 \\ m & -m+1 & -1 \end{pmatrix} = (-1)^{l+m-1} \sqrt{\frac{2(l+m)(l-m+1)}{2l(2l+1)(l+2)}},$$
(Eq. 112)

$$\begin{pmatrix} l & l-1 & 1 \\ m & -m-1 & 1 \end{pmatrix} = (-1)^{l-m} \sqrt{\frac{(l-m-1)(l-m)}{(2l-1)2l(2l+1)}}, \\ \begin{pmatrix} l & l-1 & 1 \\ m & -m & 0 \end{pmatrix} = (-1)^{l-m} \sqrt{\frac{2(l-m)(l+m)}{(2l-1)2l(2l+1)}}, \\ \begin{pmatrix} l & l-1 & 1 \\ m & -m+1 & -1 \end{pmatrix} = (-1)^{l-m} \sqrt{\frac{(l+m-1)(l+m)}{(2l-1)2l(2l+1)}}$$
(Eq. 113)

#### An integration formula

The following integration formula can be used to derive the properties of 3-*j* coefficients directly from their definitions,

$$\begin{split} &\int_{-1}^{1} (\mu - 1)^{l_2 - m_2} (\mu + 1)^{l_2 + m_2} \left( \frac{\mathrm{d}}{\mathrm{d}\mu} \right)^{l_2 + l_2 - l_3} \left[ (\mu - 1)^{l_1 - m_1} (\mu + 1)^{l_1 + m_1} \right] \mathrm{d}\mu \\ &= (-1)^{2l_1} (l_1 + l_2 - l_3)! \begin{pmatrix} l_1 & l_2 & l_3 \\ m_1 & m_2 & m_3 \end{pmatrix} \\ &\times \left[ \frac{(l_1 - m_1)! (l_1 + m_1)! (l_2 - m_2)! (l_2 + m_2)! (l_3 - m_3)! (l_3 + m_3)!}{(l_1 + l_2 - l_3)! (l_1 - l_2 + l_3)! (-l_1 + l_2 + l_3)! (l_1 + l_2 + l_3)!} \right]. \end{split}$$
(Eq. 114)

The 3-j coefficients have two important orthogonality properties

$$\sum_{\substack{m_2,m_3\\m_1+m_2+m_3=0}} \binom{l_1 & l_2 & l_3}{m_1 & m_2 & m_3} \binom{l'_1 & l_2 & l_3}{m_1 & m_2 & m_3} = \frac{1}{2l_1+1} \delta_{l_1}^{l'_1},$$
(Eq. 115)

and Eq. (119) given below.

## Products of rotation matrix elements

The integral of a product of three rotation matrix elements is

$$\frac{1}{8\pi^2} \int_0^{2\pi} \int_0^{\pi} \int_0^{2\pi} D_{M_1m_1}^{l_1} D_{M_2m_2}^{l_2} D_{M_3m_3}^{l_3} \sin\beta d\alpha d\beta d\gamma$$
$$= \begin{pmatrix} l_1 & l_2 & l_3 \\ M_1 & M_2 & M_3 \end{pmatrix} \begin{pmatrix} l_1 & l_2 & l_3 \\ m_1 & m_2 & m_3 \end{pmatrix}$$
(Eq. 116)

and therefore, from the orthogonality of rotation matrix elements, it follows that the product of two rotation matrix elements can be written as a sum of rotation matrix elements,

$$D_{M_{1}m_{1}}^{l_{1}}(\alpha,\beta,\gamma)D_{M_{2}m_{2}}^{l_{2}}(\alpha,\beta,\gamma) = \sum_{l_{3}} (2l_{3}+1) \begin{pmatrix} l_{1} & l_{2} & l_{3} \\ M_{1} & M_{2} & M_{3} \end{pmatrix} \begin{pmatrix} l_{1} & l_{2} & l_{3} \\ m_{1} & m_{2} & m_{3} \end{pmatrix} \overline{D_{M_{3}m_{3}}^{l_{3}}(\alpha,\beta,\gamma)}$$
(Eq. 117)

Equation (117) is an important equation because it effectively contains all the recurrence relations for rotation matrix elements, and therefore for surface spherical harmonics. The first orthogonality property of 3-j coefficients applied to the product formula (117) gives

$$\sum_{M_1,M_2} \begin{pmatrix} l_1 & l_2 & l_3 \\ M_1 & M_2 & M_3 \end{pmatrix} D_{M_1,m_1}^{l_1} D_{M_2,m_2}^{l_2} = \begin{pmatrix} l_1 & l_2 & l_3 \\ m_1 & m_2 & m_3 \end{pmatrix} \overline{D_{M_3,m_3}^{l_3}}.$$
(Eq. 118)

Setting  $\alpha = \beta = \gamma = 0$  in Eq. (117) gives the second orthogonality property of the 3-*j* coefficients,

$$\sum_{l_3} (2l_3+1) \begin{pmatrix} l_1 & l_2 & l_3 \\ M_1 & M_2 & M_3 \end{pmatrix} \begin{pmatrix} l_1 & l_2 & l_3 \\ m_1 & m_2 & m_3 \end{pmatrix} = \delta_{M_1}^{m_1} \delta_{M_2}^{m_2}.$$
(Eq. 119)

#### Vector coupling coefficients

In applications, it is more convenient to use a coupling coefficient, (Varshalovich *et al.*, 1988),

$$C_{l_1m_1l_2m_2}^{l_3,-m_3} = (-1)^{l_1-l_2-m_3}\sqrt{2l_3+1} \begin{pmatrix} l_1 & l_2 & l_3 \\ m_1 & m_2 & m_3 \end{pmatrix}$$
, (Eq. 120)

when the orthogonality properties, Eqs. (115) and (119) are

$$\sum_{m_1+m_2=m_3} C_{l_1m_1l_2m_2}^{l_3m_3} C_{l_1m_1l_2m_2}^{l_3'm_3} = \delta_{l_3}^{l_3'}, \quad \text{with } m_1 + m_2 = m_3,$$
(Eq. 121)

$$\sum_{l_3} C_{l_1 m_1 l_2 m_2}^{l_3 m_3} C_{l_1 m_2' l_2 m_2'}^{l_3 m_3} = \delta_{m_1}^{m_1'} \delta_{m_2}^{m_2'}, \quad \text{with } m_1 + m_2 = m_3, m_1' + m_2' = m_3$$
(Eq. 122)

The product formulae (117) and (118), for rotation matrix elements become

$$D_{M_1,m_1}^{l_1} D_{M_2,m_2}^{l_2} = \sum_{l_3} C_{l_1 M_1 L_2 M_2}^{l_3 M_3} C_{l_1 m_1 l_2 m_2}^{l_3 m_3} D_{M_3,m_3}^{l_3}, \qquad (\text{Eq. 123})$$

$$\sum_{m_1,m_2} C_{l_1m_1l_2m_2}^{l_3m_3} D_{M_1,m_1}^{l_1} D_{M_2,m_2}^{l_2} = C_{l_1M_1l_2M_2}^{l_3M_3} D_{M_3,m_3}^{l_3},$$
(Eq. 124)

respectively, and in both of which

 $M_1 + M_2 = M_3$ , and  $m_1 + m_2 = m_3$ 

Note that the complex conjugate expressions required on the right-hand sides of Eqs. (117) and (118) are not required in the corresponding vector coupling coefficient formulae. This occurs because of the result that

$$D^{l}_{-M,-m}(\alpha,\beta,\gamma) = (-1)^{M-m} \overline{D^{l}_{M,m}(\alpha,\beta,\gamma)} .$$
 (Eq. 125)

We can now use vector-coupling coefficient to couple together two quantities that transform like spherical harmonics. Consider

$$Y_{l_1}^{m_1}(\Theta_1, \Phi_1) = \sum_{M_1=-l_1}^{l_1} D_{M_1, m_1}^{l_1}(\alpha, \beta, \gamma) Y_{l_1}^{M_1}(\theta_1, \phi_1),$$
  

$$Y_{l_2}^{m_2}(\Theta_2, \Phi_2) = \sum_{M_1=-l_1}^{l_1} D_{M_2, m_2}^{l_2}(\alpha, \beta, \gamma) Y_{l_2}^{M_2}(\theta_2, \phi_2).$$
 (Eq. 126)

When the coupled spherical harmonic expression is formed

$$\sum_{m_1,m_2} C_{l_1m_1l_2m_2}^{l_3m_3} Y_{l_1}^{m_1}(\Theta_1, \Phi_1) Y_{l_2}^{m_2}(\Theta_2, \Phi_2)$$

$$= \sum_{M_1=-l_1}^{l_1} \sum_{M_2=-l_2}^{l_2} \left[ \sum_{m_1,m_2} C_{l_1m_1l_2m_2}^{l_3m_3} D_{M_1m_1}^{l_1} D_{M_2m_2}^{l_2} \right]$$

$$\times Y_{l_1}^{l_1}(\theta_1, \phi_1) Y_{l_2}^{m_2}(\theta_2, \phi_2) . \quad \text{(Eq. 127)}$$

The sums on the right of Eq. (127) can be rearranged and the expressions in square brackets replaced by means of Eq. (124), giving the results that

$$\sum_{m_1,m_2} C_{l_1m_1l_2m_2}^{l_3m_3} Y_{l_1}^{m_1}(\Theta_1,\Phi_1) Y_{l_2}^{m_2}(\Theta_2,\Phi_2) = \sum_{M_3} D_{M_3m_3}^{l_3} \Biggl[ \sum_{M_1,M_2} C_{l_1M_1l_2M_2}^{l_3M_3} Y_{l_1}^{M_1}(\theta_1,\phi_1) Y_{l_2}^{M_2}(\theta_2,\phi_2) \Biggr],$$
(Eq. 128)

showing that the coupled expression in square brackets in Eq. (128) obeys the transformation law for spherical harmonics  $Y_{l_3}^{M_3}(\Theta, \Phi)$  under rotation of the reference frame; that is

$$Y_{l_3}^{M_3}(\Theta, \Phi) = \sum_{M_1, M_2} C_{l_1 M_1 l_2 M_2}^{l_3 M_3} Y_{l_1}^{M_1}(\theta_1, \phi_1) Y_{l_2}^{M_2}(\theta_2, \phi_2) \,, \quad \text{(Eq. 129)}$$

so that coupled spherical harmonics on the right of Eq. (129) will transform under rotation of the reference frame like a spherical harmonics.

## Vector spherical harmonics

If the unit vectors in the *x*-, *y*- and *z*-directions are denoted  $\mathbf{e}_x, \mathbf{e}_y, \mathbf{e}_z$ , respectively, the complex reference vectors  $\mathbf{e}_1, \mathbf{e}_0, \mathbf{e}_{-1}$ , are defined by

$$\mathbf{e}_{1} = -\frac{1}{\sqrt{2}}(\mathbf{e}_{x} + i\mathbf{e}_{y}) = \nabla\xi,$$
  

$$\mathbf{e}_{0} = \mathbf{e}_{z} = \nabla z,$$
  

$$\mathbf{e}_{-1} = \frac{1}{\sqrt{2}}(\mathbf{e}_{x} - i\mathbf{e}_{y}) = \nabla\eta.$$
(Eq. 130)

If  $\bar{\mathbf{e}}_{\mu}$  denotes the complex conjugate of  $\mathbf{e}_{\mu}$ ,  $\mu = -1, 0, 1$ , then the complex reference vectors satisfy

$$\mathbf{e}_{\mu} \cdot \bar{\mathbf{e}}_{\nu} = \delta^{\nu}_{\mu}, \text{and } \mathbf{e}_{\mu} \cdot \mathbf{e}_{\nu} = (-1)^{\mu-\nu} \delta^{-\nu}_{\mu}, \quad \text{for } \mu, \nu = 1, 0, -1.$$
(Eq. 131)

Therefore, a vector **B**, with Cartesian components  $B_x, B_y, B_z$ , will have complex reference components  $B_{-1}, B_0, B_1$ , such that  $\mathbf{B} = -B_1\mathbf{e}_{-1} + B_0\mathbf{e}_0 - B_{-1}\mathbf{e}_1$ , and

$$B_{1} = -\frac{1}{\sqrt{2}}(B_{x} + iB_{y}),$$
  

$$B_{0} = B_{z},$$
  

$$B_{-1} = \frac{1}{\sqrt{2}}(B_{x} - iB_{y}).$$
 (Eq. 132)

Complex reference components of the gradient operator  $\nabla$  and the angular momentum operator  $\mathbf{L} = -i\mathbf{r} \times \nabla$ , are obtained, and can be expressed in terms of spherical polar coordinates,  $r, \theta, \phi$ , as follows:

$$\nabla_{1} = -\frac{1}{\sqrt{2}} e^{i\phi} \left( \sin\theta \frac{\partial}{\partial r} + \frac{\cos\theta}{r} \frac{\partial}{\partial \theta} + \frac{i}{r \sin\theta} \frac{\partial}{\partial \phi} \right),$$
  

$$\nabla_{0} = \cos\theta \frac{\partial}{\partial r} - \frac{\sin\theta}{r} \frac{\partial}{\partial \theta},$$
  

$$\nabla_{-1} = \frac{1}{\sqrt{2}} e^{-i\phi} \left( \sin\theta \frac{\partial}{\partial r} + \frac{\cos\theta}{r} \frac{\partial}{\partial \theta} - \frac{i}{r \sin\theta} \frac{\partial}{\partial \phi} \right), \quad (\text{Eq. 133})$$

and

$$L_{1} = -\frac{1}{\sqrt{2}} e^{i\phi} \left( \frac{\partial}{\partial \theta} + i \cot \theta \frac{\partial}{\partial \phi} \right),$$
  

$$L_{0} = -i \frac{\partial}{\partial \phi},$$
  

$$L_{-1} = -\frac{1}{\sqrt{2}} e^{-i\phi} \left( \frac{\partial}{\partial \theta} - i \cot \theta \frac{\partial}{\partial \phi} \right).$$
 (Eq. 134)

We now define three vector spherical harmonics  $\mathbf{Y}_{l,l+1}^{m}(\theta,\phi), \mathbf{Y}_{l,l}^{m}(\theta,\phi), \mathbf{Y}_{l,l-1}^{m}(\theta,\phi)$ , in terms of complex reference vectors, and also present them in the better known and widely used forms in terms of spherical polars. Thus

$$\frac{1}{r^{l+2}}\sqrt{(l+1)(2l+1)}\mathbf{Y}_{l,l+1}^{m}(\theta,\phi) = \nabla \left[\frac{1}{r^{l+1}}Y_{l}^{m}(\theta,\phi)\right],$$
$$\sqrt{l(l+1)}\mathbf{Y}_{l,l}^{m}(\theta,\phi) = \mathbf{L}Y_{l}^{m}(\theta,\phi),$$
$$r^{l-1}\sqrt{l(2l+1)}\mathbf{Y}_{l,l-1}^{m}(\theta,\phi) = \nabla \left[r^{l}Y_{l}^{m}(\theta,\phi)\right].$$
(Eq. 135)

The spherical polar components of the vector spherical harmonics are

$$\begin{split} \sqrt{(l+1)(2l+1)}\mathbf{Y}_{l,l+1}^{m}(\theta,\phi) &= -(l+1)Y_{l}^{m}\mathbf{e}_{r} + \frac{\partial Y_{n}^{m}}{\partial \theta}\mathbf{e}_{\theta} + \frac{1}{\sin\theta}\frac{\partial Y_{n}^{m}}{\partial \phi}\mathbf{e}_{\phi},\\ \sqrt{l(l+1)}\mathbf{Y}_{l,l}^{m}(\theta,\phi) &= \frac{\mathrm{i}}{\sin\theta}\frac{\partial Y_{n}^{m}}{\partial \phi}\mathbf{e}_{\theta} - \mathrm{i}\frac{\partial Y_{n}^{m}}{\partial \theta}\mathbf{e}_{\phi},\\ \sqrt{l(2l+1)}\mathbf{Y}_{l,l-1}^{m}(\theta,\phi) &= l\,Y_{l}^{m}\mathbf{e}_{r} + \frac{\partial Y_{n}^{m}}{\partial \theta}\mathbf{e}_{\theta} + \frac{1}{\sin\theta}\frac{\partial Y_{n}^{m}}{\partial \phi}\mathbf{e}_{\phi},\\ (\mathrm{Eq.\ 136}) \end{split}$$

where  $\mathbf{e}_r, \mathbf{e}_{\theta}, \mathbf{e}_{\phi}$ , are unit vectors in the direction of  $r, \theta, \phi$ , increasing, respectively.

However, from the recurrence relations given in Eqs. (64)-(71), and from the spherical polar forms of the vector operators given in Eqs. (133) and (134), it follows immediately that

$$\begin{split} \sqrt{(l+1)(2l+1)}\mathbf{Y}_{l,l+1}^{m} &= \sqrt{\frac{2l+1}{2l+3}} \\ &\times \left(\frac{1}{\sqrt{2}}\sqrt{(l+m+1)(l+m+2)}Y_{l+1}^{m+1}\mathbf{e}_{-1}\right. \\ &-\sqrt{(l-m+1)(l+m+1)}Y_{l+1}^{m}\mathbf{e}_{0} \\ &+\frac{1}{\sqrt{2}}\sqrt{(l-m+1)(l-m+2)}Y_{l+1}^{m}\mathbf{e}_{1}\right), \end{split}$$
(Eq. 137)

$$\sqrt{l(l+1)}\mathbf{Y}_{l,l}^{m} = \frac{1}{\sqrt{2}}\sqrt{(l+m+1)(l-m)}Y_{l}^{m+1}\mathbf{e}_{-1} + mY_{l}^{m}\mathbf{e}_{0}$$
$$-\frac{1}{\sqrt{2}}\sqrt{(l+m)(l-m+1)}Y_{l}^{m-1}\mathbf{e}_{1},$$
(Eq. 138)

$$\begin{split} \sqrt{l(2l+1)}\mathbf{Y}_{l,l-1}^{m} &= \sqrt{\frac{2l+1}{2l-1}} \bigg( \frac{1}{\sqrt{2}} \sqrt{(l-m-1)(l-m)} Y_{l-1}^{m+1} \mathbf{e}_{-1} \\ &+ \sqrt{(l+m)(l-m)} Y_{l-1}^{m} \mathbf{e}_{0} \\ &+ \frac{1}{\sqrt{2}} \sqrt{(l+m-1)(l+m)} Y_{l-1}^{m-1} \mathbf{e}_{1} \bigg). \end{split}$$
(Eq. 139)

Using the 3-*j* coefficients listed in Eqs. (111)–(113), it follows that all three Eqs. (137)–(139) can be written as a single expression

$$\mathbf{Y}_{l,l+\nu}^{m}(\theta,\phi) = (-1)^{l+\nu-1+m} \sqrt{2l+1} \sum_{\mu=-1}^{l} \begin{pmatrix} l+\nu & 1 & l \\ m-\mu & \mu & -m \end{pmatrix} Y_{l+\nu}^{m-\mu} \mathbf{e}_{\mu}.$$
(Eq. 140)

In terms of the coupling coefficient of Eq. (120)

$$\mathbf{Y}_{l,l+\nu}^{m}(\theta,\phi) = \sum_{\mu=-1}^{1} C_{l+\nu,m-\mu,1,\mu}^{l,m} Y_{l+\nu}^{m-\mu} \mathbf{e}_{\mu}.$$
 (Eq. 141)

Because of the orthogonality properties of complex reference vectors and surface spherical harmonics, it follows that the vector spherical harmonics are orthogonal under integration over the surface of a sphere:

$$\frac{1}{4\pi} \int_{0}^{2\pi} \int_{0}^{\pi} \mathbf{Y}_{l_{1}, l_{1}+\mu}^{m_{1}}(\theta, \phi) \cdot \mathbf{Y}_{l_{2}, l_{2}+\nu}^{m_{2}}(\theta, \phi) \sin \theta d\theta d\phi = \delta_{l_{1}}^{l_{2}} \delta_{m_{1}}^{m_{2}} \delta_{\nu}^{\mu}.$$
(Eq. 142)

Rotations

#### Introduction

The word "rotation" has related, but nevertheless, different meanings in different disciplines, such as agriculture, medicine, psychology, and mechanics. This article is intended to deal with the theory of rotation about an axis, and to bring together the relationships between the different methods used to describe rotations, including the angle and axis of rotation, the Euler-Rodrigues parameters, quaternions, the Cayley-Klein parameters, spinors, and Euler angles.

#### Rotation about an axis

Consider a positive rotation of a system of particles without deformation, through an angle V about an axis **n**, in a reference frame that remains fixed. An origin O is chosen along the axis of rotation, and r is the position vector of a general particle that becomes the vector **R**. From Figures H5 and H6, it can be seen that

$$\mathbf{R} = \overrightarrow{OQ} = \overrightarrow{OP} + \overrightarrow{PN} + \overrightarrow{NQ},$$
  
=  $\mathbf{r} + [(\mathbf{n} \times \mathbf{r}) \times \mathbf{n}](\cos V - 1) + (\mathbf{n} \times \mathbf{r})\sin V.$  (Eq. 143)

where N is a point along PM, such that PN is perpendicular to NQ. Therefore,

$$\mathbf{R} = \mathbf{r}\cos V + \mathbf{n}(\mathbf{n}\cdot\mathbf{r})(1-\cos V) + (\mathbf{n}\times\mathbf{r})\sin V. \quad \text{(Eq. 144)}$$

**Figure H5** The point *P* with position vector  $\mathbf{r}$  relative to the origin *O*, is carried to the point *Q*, with the position vector  $\mathbf{R}$ , by rotation through an angle *V* about the axis  $\mathbf{n}$ .

**Figure H6** Showing the vector geometry of the rotation through an angle *V* about an axis of rotation **n**.

# Rotation of the reference frame

The equation for the transformation of the coordinates of P, under rotation of the reference frame, follows directly from Eq. (144) by changing the sign of the angle V. Thus

$$\mathbf{R} = \mathbf{r}\cos V + \mathbf{n}(\mathbf{n}\cdot\mathbf{r})(1-\cos V) - (\mathbf{n}\times\mathbf{r})\sin V. \quad (\text{Eq. 145})$$

Writing out the Cartesian components of Eq. (145) gives a matrix form

$$\mathbf{R} = \mathbf{A} \cdot \mathbf{r}$$
, where  $\mathbf{A} = \mathbf{A}(\mathbf{n}, V)$ , and (Eq. 146)

$$\mathbf{A}(\mathbf{n}, V) = \begin{pmatrix} \cos V & | & ab(1 - \cos V) & | & ac(1 - \cos V) \\ +a^2(1 - \cos V) & | & +c\sin V & | & -b\sin V \\ ----- & ---- & ---- & ---- \\ ab(1 - \cos V) & | & \cos V & | & bc(1 - \cos V) \\ -c\sin V & | & +b^2(1 - \cos V) & | & +a\sin V \\ ----- & ---- & ---- & ---- \\ ac(1 - \cos V) & | & bc(1 - \cos V) & | & \cos V \\ +b\sin V & | & -a\sin V & | & +c^2(1 - \cos V) \end{pmatrix}$$
(Eq. 147)

# The angle and axis of rotation

The angle of rotation and the axis of rotation can be determined from the trace and the antisymmetric components of the transformation matrix A. The trace can be expressed in a number of different ways,

trace 
$$\mathbf{A}(\mathbf{n}, V) = 3\cos V + (a^2 + b^2 + c^2)(1 - \cos V)$$
  
=  $1 + 2\cos V = 4\cos^2\frac{1}{2}V - 1 = \frac{\sin\frac{3}{2}V}{\sin\frac{1}{2}V}.$   
(Eq. 148)

The trace of  $\mathbf{A}(\mathbf{n}, V)$  is a single valued function of V in the range  $0 < V < \pi$ , and for rotations V in the range  $\pi < V < 2\pi$ , the axis of rotation  $\mathbf{n}$  is reversed. In the case of no rotation when V = 0, and  $\cos V = 1$ , the rotation matrix reduces to  $\mathbf{A}(\mathbf{n}, 0) = \mathbf{1}$ , and there is no axis of rotation. Having determined the angle of rotation, the Cartesian components (a, b, c) of the axis of rotation are given by

$$2a \sin V = \mathbf{A}_{23} - \mathbf{A}_{32} = 4a \sin \frac{1}{2} V \cos \frac{1}{2} V,$$
  

$$2b \sin V = \mathbf{A}_{31} - \mathbf{A}_{13} = 4b \sin \frac{1}{2} V \cos \frac{1}{2} V,$$
  

$$2c \sin V = \mathbf{A}_{12} - \mathbf{A}_{21} = 4c \sin \frac{1}{2} V \cos \frac{1}{2} V.$$
 (Eq. 149)

The eigenvalues of the rotation matrix A(n, V) depend only on the angle of rotation V,

$$\lambda_1 = e^{iV}, \quad \lambda_2 = e^{-iV}, \quad \lambda_3 = 1,$$
 (Eq. 150)

and their sum is equal to the trace of the rotation matrix,  $1 + 2 \cos V$ .

#### Infinitesimal rotations

When the angle of rotation V about the axis **n**, is written as a differential, or infinitesimal dV, then Eq. (144) for the new position vector **R** of a particle with original position vector  $d\mathbf{r}$ , of a system of particles, rotating as a rigid body, reduces to

$$\mathbf{R} = \mathbf{r} + (\mathbf{n} \times \mathbf{r}) \mathrm{d}V. \tag{Eq. 151}$$

The actual displacement during the rotation is  $d\mathbf{r} = \mathbf{R} - \mathbf{r}$ , and therefore,

$$\mathbf{lr} = (\mathbf{n} \times \mathbf{r})\mathbf{d}V. \tag{Eq. 152}$$

If the change takes place over an infinitesimal interval of time, dt, then

$$\frac{d\mathbf{r}}{dt} = (\mathbf{n} \times \mathbf{r}) \frac{dV}{dt},$$
  
=  $\mathbf{\Omega} \times \mathbf{r},$  (Eq. 153)

where  $\Omega$  is said to be the angular velocity of the particle.

The time rate of change of a scalar function of position  $f(\mathbf{r})$  relative to a position vector  $\mathbf{r}$  rotating with angle velocity  $\mathbf{\Omega}$  is therefore

$$\frac{\mathrm{d}f}{\mathrm{d}t} = \frac{\partial f}{\partial x}\frac{\mathrm{d}x}{\mathrm{d}t} + \frac{\partial f}{\partial y}\frac{\mathrm{d}y}{\mathrm{d}t} + \frac{\partial f}{\partial z}\frac{\mathrm{d}z}{\mathrm{d}t},$$

$$= \nabla f \cdot \frac{\mathrm{d}\mathbf{r}}{\mathrm{d}t},$$

$$= \nabla f \cdot (\mathbf{\Omega} \times \mathbf{r}),$$
(Eq. 154)

where it is assumed that there is no "local" time derivative, usually denoted  $\partial f / \partial t$ . By the rules for scalar triple products, we may write

$$\frac{\mathrm{d}f}{\mathrm{d}t} = \Omega \cdot (\mathbf{r} \times \nabla f). \tag{Eq. 155}$$

At this point it is convenient to introduce the operator **L**, known as the angular momentum operator in quantum physics, and

$$\mathbf{L}f = -\mathbf{i}\mathbf{r} \times \nabla f = \mathbf{i}\nabla \times (\mathbf{r}f), \qquad (\text{Eq. 156})$$

when the expression Eq. (154) for the time rate of change of  $f(\mathbf{r})$  becomes

$$\frac{\mathrm{d}f}{\mathrm{d}t} = \mathrm{i}\mathbf{\Omega} \cdot \mathbf{L}f, \text{ and } \left(\frac{\mathrm{d}}{\mathrm{d}t}\right)^n f = (\mathrm{i}\mathbf{\Omega} \cdot \nabla \mathbf{L})^n f.$$
 (Eq. 157)

The Cartesian components of the angular momentum operator are

$$L_{x}f = i\left(z\frac{\partial f}{\partial y} - y\frac{\partial f}{\partial z}\right),$$
  

$$L_{y}f = i\left(x\frac{\partial f}{\partial z} - z\frac{\partial f}{\partial x}\right),$$
  

$$L_{z}f = i\left(y\frac{\partial f}{\partial x} - x\frac{\partial f}{\partial y}\right).$$
 (Eq. 158)

In spherical polar coordinates, the Cartesian derivatives are

$$\frac{\partial f}{\partial x} = \sin\theta\cos\phi\frac{\partial f}{\partial r} + \frac{\cos\theta\cos\phi}{r}\frac{\partial f}{\partial\theta} - \frac{\sin\phi}{r}\frac{\partial f}{\partial\theta\phi},\\ \frac{\partial f}{\partial y} = \sin\theta\sin\phi\frac{\partial f}{\partial r} + \frac{\cos\theta\sin\phi}{r}\frac{\partial f}{\partial\theta} + \frac{\cos\phi}{r}\frac{\partial f}{\partial\theta\phi},\\ \frac{\partial f}{\partial z} = \cos\theta\frac{\partial f}{\partial r} - \frac{\sin\theta}{r}\frac{\partial f}{\partial\theta}.$$
(Eq. 159)

The spherical polar forms of the angular momentum operators are therefore

$$L_{x} = i \left( \sin \phi \frac{\partial}{\partial \theta} + \cot \theta \cos \phi \frac{\partial}{\partial \phi} \right),$$
  

$$L_{y} = i \left( -\cos \phi \frac{\partial}{\partial \theta} + \cot \theta \sin \phi \frac{\partial}{\partial \phi} \right),$$
  

$$L_{z} = -i \frac{\partial}{\partial \phi}.$$
(Eq. 160)

The Eq. (160) are used in determining recurrence relations for surface spherical harmonics. Note also that a finite rotation can be done by a

succession of a large number of small rotations, which can be used to show that the knowledge of the infinitesimal transformation amounts implicitly to a knowledge of the entire transformation.

#### *Euler Rodrigues parameters*

The Euler-Rodrigues parameters *p*,*q*,*r*,*s*, are defined by

$$p = a \sin \frac{1}{2}V,$$

$$q = b \sin \frac{1}{2}V,$$

$$r = c \sin \frac{1}{2}V,$$

$$s = \cos \frac{1}{2}V,$$
(Eq. 161)

and are spherical polar coordinates in a four-dimensional space. Greek symbols  $\xi$ ,  $\eta$ ,  $\zeta$ ,  $\chi$ , are also used (Whittaker, 1904), as well as  $\lambda$ ,  $\mu$ ,  $\nu$ ,  $\rho$  (Kendall and Moran, 1962).

Note that (a, b, c), regarded as (x, y, z), are spherical harmonics of the first degree, and those of higher degree being generated by multiple derivatives inverse distance. The Euler-Rodrigues parameters (p, q, r, s) are spin-weighted spherical harmonics, with terms of higher degree generated by derivatives of the inverse square of distance.

### Resultant of two rotations

When a reference frame is rotated through angle  $V_1$  about an axis  $\mathbf{n}_1$ , and then rotated through an angle  $V_2$  about an axis  $\mathbf{n}_2$ , the resulting configuration is equivalent to a single rotation through an angle  $V_3$ about an axis  $\mathbf{n}_3$ . In terms of rotation matrices

$$A(n_3, V_3) = A(n_2, V_2)A(n_1, V_1).$$
 (Eq. 162)

The trace of the product matrix is found to have the form

$$1 + 2\cos V_3 = (\mathbf{n}_1 \cdot \mathbf{n}_2)^2 (1 - \cos V_2)(1 - \cos V_2) - 2(\mathbf{n}_1 \cdot \mathbf{n}_2) \sin V_2 \sin V_1 + (1 + \cos V_2)(1 + \cos V_1)$$

leads to a perfect square for  $\cos \frac{1}{2}V_3$ , the positive square root of which gives

$$\cos\frac{1}{2}V_3 = \cos\frac{1}{2}V_2\cos\frac{1}{2}V_1 - (\mathbf{n}_1 \cdot \mathbf{n}_2)\sin\frac{1}{2}V_2\sin\frac{1}{2}V_1.$$
(Eq. 163)

Similarly, the antisymmetric parts of the product matrix, after some algebra, lead to

$$a_{3}\sin\frac{1}{2}V_{3} = (b_{1}c_{2} - c_{1}b_{2})\sin\frac{1}{2}V_{2}\sin\frac{1}{2}V_{1} + a_{1}\cos\frac{1}{2}V_{2}\sin\frac{1}{2}V_{1} + a_{2}\sin\frac{1}{2}V_{2}\cos\frac{1}{2}V_{1}, b_{3}\sin\frac{1}{2}V_{3} = (c_{1}a_{2} - a_{1}c_{2})\sin\frac{1}{2}V_{2}\sin\frac{1}{2}V_{1} + b_{1}\cos\frac{1}{2}V_{2}\sin\frac{1}{2}V_{1} + b_{2}\sin\frac{1}{2}V_{2}\cos\frac{1}{2}V_{1}, c_{3}\sin\frac{1}{2}V_{3} = (a_{1}b_{2} - b_{1}a_{2})\sin\frac{1}{2}V_{2}\sin\frac{1}{2}V_{1} + c_{1}\cos\frac{1}{2}V_{2}\sin\frac{1}{2}V_{1} + c_{2}\sin\frac{1}{2}V_{2}\cos\frac{1}{2}V_{1}.$$
(Eq. 164)

ć

Using p,q,r,s, as defined in Eq. (161), with suitable subscripts, Eq. (164) leads to the following formulae for the combination of rotations of the reference frame,

$$p_{3} = s_{2}p_{1} + r_{2}q_{1} - q_{2}r_{1} + p_{2}s_{1}$$

$$q_{3} = -r_{2}p_{1} + s_{2}q_{1} + p_{2}r_{1} + q_{2}s_{1}$$

$$r_{3} = q_{2}p_{1} - p_{2}q_{1} + s_{2}r_{1} + r_{2}s_{1},$$

$$s_{3} = -p_{2}p_{1} - q_{2}q_{1} - r_{2}r_{1} + s_{2}s_{1}.$$
(Eq. 165)

## The beginnings of vector algebra

The product formula of Eq. (165) contains within it as a special case, the vector product of the axes of rotation, namely  $\mathbf{n}_1$  and  $\mathbf{n}_2$ , and also their scalar product. By choosing the rotation angles  $V_1$  and  $V_2$  to be  $\pi$ radians, equivalent to 180°, then  $s_1 = s_2 = \cos \frac{1}{2}\pi = 0$ , and the remaining Euler-Rodrigues parameters reduce to the Cartesian components of the rotation axes,

$$(p_1, q_1, r_1)|_{V_1 = \pi} = (a_1, b_1, c_1) = \mathbf{n}_1$$

and

$$(p_2, q_2, r_2)|_{V_2=\pi} = (a_2, b_2, c_2) = \mathbf{n}_2$$
 (Eq. 166)

The product formula (165) reduces to

$$\begin{array}{l} a_3 = c_2 b_1 - b_2 c_1 \\ b_3 = a_2 c_1 - c_2 a_1 \\ c_3 = b_2 a_1 - a_2 b_1 \end{array} \right\} \text{so that } (a_3, b_3, c_3) \equiv \mathbf{n}_1 \times \mathbf{n}_2, \qquad \text{(Eq. 167)}$$

while the expression for  $s_3$  reduces to the scalar product times -1,

$$s_3|_{V_1,V_2=\pi} = -a_1a_2 - b_1b_2 - c_1c_2$$
 so that  $s_3|_{V_1,V_2=\pi} = -\mathbf{n}_1 \cdot \mathbf{n}_2.$   
(Eq. 168)

The results of Eqs. (167) and (168) would be written  $Vn_1n_2$  and  $Sn_1n_2$  respectively, where V and S refer to "vector" and "scalar," respectively. Maxwell's equations were given in Cartesian form (Maxwell, 1881), and also as equivalent "quaternion expressions" using V and S as in Eqs. (167) and (168). It was the fashion, when using Hamilton's quaternions, to write vectors, such as the electromagnetic momentum A and the magnetic induction B in Gothic upper case script,  $\mathfrak{A}$  and  $\mathfrak{B}$ , respectively.

# Hyperspherical trigonometry

If the rotation axes  $\mathbf{n}_1$  and  $\mathbf{n}_2$  subtend an angle  $\Theta$  between them, and

$$\mathbf{n}_{1} = (a_{1}, b_{1}, c_{1}) = (\sin \theta_{1} \cos \phi_{1}, \sin \theta_{1} \sin \phi_{1}, \cos \theta_{1}),$$
  

$$\mathbf{n}_{2} = (a_{2}, b_{2}, c_{2}) = (\sin \theta_{2} \cos \phi_{2}, \sin \theta_{2} \sin \phi_{2}, \cos \theta_{2}),$$
  
(Eq. 169)

then  $\mathbf{n}_1 \cdot \mathbf{n}_2 = \cos \Theta$ , and hence Eq. (163) for  $s_3$  becomes

$$\cos\frac{1}{2}V_3 = \cos\frac{1}{2}V_1\cos\frac{1}{2}V_2 - \sin\frac{1}{2}V_1\sin\frac{1}{2}V_2\cos\Theta, \quad \text{(Eq. 170)}$$

where  $\cos \Theta$  is the scalar product of  $\mathbf{n}_1$  and  $\mathbf{n}_2$ ,

$$\cos\Theta = \cos\theta_1 \cos\theta_2 + \sin\theta_1 \sin\theta_2 \cos(\phi_1 - \phi_2).$$
 (Eq. 171)

Thus Eq. (170) uses half-angles of rotation, and Eq. (171) uses polar coordinates of rotation axes.

# Without using half-angles

From Eqs. (163) and (164), the trace and the antisymmetric part of the resultant rotation matrix  $A(\mathbf{n}_3, V_3)$  can be expressed as the product of the Euler Rodrigues parameters,

$$2a_{3} \sin V_{3} = 4a_{3} \sin \frac{1}{2}V_{3} \cos \frac{1}{2}V_{3} = 4p_{3}s_{3},$$
  

$$2b_{3} \sin V_{3} = 4b_{3} \sin \frac{1}{2}V_{3} \cos \frac{1}{2}V_{3} = 4q_{3}s_{3},$$
  

$$2c_{3} \sin V_{3} = 4c_{3} \sin \frac{1}{2}V_{3} \cos \frac{1}{2}V_{3} = 4r_{3}s_{3},$$
  

$$2 + 2 \cos V_{3} = 4s_{3}^{2}.$$

Thus, starting with

$$s_3 = \frac{1}{2}\sqrt{\operatorname{trace}[\mathbf{A}(\mathbf{n}_3, V_3)] + 1},$$

then

$$p_3 = [\mathbf{A}(\mathbf{n}_3, V_3)_{23} - \mathbf{A}(\mathbf{n}_3, V_3)_{32}]/2s_3, q_3 = [\mathbf{A}(\mathbf{n}_3, V_3)_{31} - \mathbf{A}(\mathbf{n}_3, V_3)_{13}]/2s_3, r_3 = [\mathbf{A}(\mathbf{n}_3, V_3)_{12} - \mathbf{A}(\mathbf{n}_3, V_3)_{21}]/2s_3.$$

# Rigid body rotations

The formulae for rigid body rotations are obtained by replacing  $(V_1, V_2, V_3)$  by  $(-V_1, -V_2, -V_3)$ , when the required formulae are

$$p_{3} = s_{2}p_{1} - r_{2}q_{1} + q_{2}r_{1} + p_{2}s_{1},$$

$$q_{3} = r_{2}p_{1} + s_{2}q_{1} - p_{2}r_{1} + q_{2}s_{1},$$

$$r_{3} = -q_{2}p_{1} + p_{2}q_{1} + s_{2}r_{1} + r_{2}s_{1},$$

$$s_{3} = -p_{2}p_{1} - q_{2}q_{1} - r_{2}r_{1} + s_{2}s_{1}.$$
(Eq. 172)

It is important to distinguish carefully between Eq. (165) for rotation of the reference frame and Eq. (172) for a rigid-body rotation.

#### Quaternions

The product formula Eq. (172) for combining rigid-body rotations, corresponds exactly to the law for the product  $Q_2Q_1$  of quaternions  $Q_1$  and  $Q_2$ , where

$$\mathbf{Q}_{1} = 1s_{1} + ip_{1} + jq_{1} + kr_{1},$$
  

$$\mathbf{Q}_{2} = 1s_{2} + ip_{2} + jq_{2} + kr_{2},$$
(Eq. 173)

subject to the rules that 1 is the identity and

$$i^{2} = j^{2} = k^{2} = -1,$$
  
 $jk = i, \quad kj = -i,$   
 $ki = j, \quad ik = -j,$   
 $ij = k, \quad ji = -k,$   
 $ijk = -1.$  (Eq. 174)

It is difficult to see why such a fuss is made over the "rule" that ijk = -1, when it is an immediate consequence of the rules ij = k and  $k^2 = -1$ . Quaternions are useful for the occasional calculation, but if any quantity of such rigid-body rotation calculations has to be done, then clearly the matrix form of Eq. (172) is easier to deal with.

# Cayley-Klein parameters

The Cayley-Klein parameters u and v are defined by

$$u = s + ir = \cos \frac{1}{2}V + ic \sin \frac{1}{2}V,$$
  

$$v = q + ip = (b + ia) \sin \frac{1}{2}V.$$
 (Eq. 175)

With this substitution, the quaternion product formula (165) for the combining of reference frame rotations can be written

$$s_3 + ir_3 = (s_2 + ir_2)(s_1 + ir_1) - (q_2 + ip_2)(q_1 - ip_1),$$
  
-q\_3 + ip\_3 = -(q\_2 - ip\_2)(s\_1 + ir\_1) - (s\_2 - ir\_2)(q\_1 - ip\_1),  
(Eq. 176)

which becomes

\_

$$u_3 = u_2 u_1 - v_2 \bar{v}_1,$$
  
$$-\bar{v}_3 = -\bar{v}_2 u_1 - \bar{u}_2 \bar{v}_1,$$
 (Eq. 177)

and, in matrix form, Eq. (177) becomes

$$\begin{pmatrix} u_3 \\ -\bar{v}_3 \end{pmatrix} = \begin{pmatrix} u_2 & v_2 \\ -\bar{v}_2 & \bar{u}_2 \end{pmatrix} \begin{pmatrix} u_1 \\ -\bar{v}_1 \end{pmatrix}.$$
 (Eq. 178)

Equation (178) can be regarded as the transformation law for the Cayley-Klein parameters u and v, and, more importantly, can be used to derive the transformation law for homogeneous polynomials of u and v of degree n.

## Spinors

Using the elementary results that

$$ax + by = \frac{1}{2}[(a + ib)(x - iy) + (a - ib)(x + iy)],$$
  

$$\cos V + ic \sin V + \frac{1}{2}(a^2 + b^2)(1 - \cos V) = (\cos \frac{1}{2}V + ic \sin \frac{1}{2}V)^2,$$
  
(Eq. 179)

and the vector relationships

$$\begin{pmatrix} X + iY \\ Z \\ X - iY \end{pmatrix} = \begin{pmatrix} 1 & i & 0 \\ 0 & 0 & 1 \\ 1 & -i & 0 \end{pmatrix} \begin{pmatrix} X \\ Y \\ Z \end{pmatrix}, \text{ and}$$

$$\begin{pmatrix} x \\ y \\ z \end{pmatrix} = \begin{pmatrix} \frac{1}{2} & 0 & \frac{1}{2} \\ -\frac{1}{2}i & 0 & \frac{1}{2}i \\ 0 & 1 & 0 \end{pmatrix} \begin{pmatrix} x + iy \\ z \\ x - iy \end{pmatrix},$$
(Eq. 180)

one obtains from the basic Eq. (147) for reference frame rotation, that

$$\begin{split} X + \mathrm{i}Y &= (x + \mathrm{i}y)(\cos\frac{1}{2}V - \mathrm{i}c\sin\frac{1}{2}V)^2 \\ &- 2z(b - \mathrm{i}a)\sin\frac{1}{2}V(\cos\frac{1}{2}V - \mathrm{i}c\sin\frac{1}{2}V) \\ &- (x - \mathrm{i}y)\left[(b - \mathrm{i}a)\sin\frac{1}{2}V\right]^2, \\ Z &= (x + \mathrm{i}y)(b + \mathrm{i}a)\sin\frac{1}{2}V(\cos\frac{1}{2}V - \mathrm{i}c\sin\frac{1}{2}V) \\ &+ z\left[\cos^2\frac{1}{2}V + c^2\sin^2\frac{1}{2}V - (1 - c^2)\sin^2\frac{1}{2}V\right] \\ &+ (x - \mathrm{i}y)(b - \mathrm{i}a)\sin\frac{1}{2}V(\cos\frac{1}{2}V + \mathrm{i}c\sin\frac{1}{2}V), \end{split}$$

.

$$X - iY = (x + iy) \left[ (a - ib) \sin \frac{1}{2}V \right]^2$$
  
- 2z(b + ia) sin  $\frac{1}{2}V(\cos \frac{1}{2}V + ic \sin \frac{1}{2}V)$   
+ (x - iy)(cos  $\frac{1}{2}V + ic \sin \frac{1}{2}V)^2$ . (Eq. 181)

Using the Cayley-Klein parameters u and v defined in Eq. (175), the Eq. (181) become

$$-(X + iY) = -(x + iy)\bar{u}^{2} + 2z\bar{u}\,\bar{v} + (x - iy)\bar{v}^{2},$$
  

$$Z = (x + iy)\bar{u}v + z(u\bar{u} - v\bar{v}) + (x - iy)u\bar{v},$$
  

$$(X - iY) = -(x + iy)v^{2} - 2zuv + (x - iy)u^{2}.$$
 (Eq. 182)

Introducing the parameters  $\xi$  and  $\eta$ , defined by

$$\begin{split} \xi &= -\frac{1}{\sqrt{2}}(x + \mathrm{i}y), \quad \xi' = -\frac{1}{\sqrt{2}}(X + \mathrm{i}Y), \\ \eta &= \frac{1}{\sqrt{2}}(x - \mathrm{i}y), \quad \eta' = \frac{1}{\sqrt{2}}(X - \mathrm{i}Y), \end{split} \tag{Eq. 183}$$

the Eq. (182) become

$$\begin{split} \xi' &= \xi \, \bar{u}^2 + \sqrt{2} \, z \bar{u} \, \bar{v} + \eta \, \bar{v}^2, \\ Z &= -\sqrt{2} \, \xi \, \bar{u} v + z (u \bar{u} - v \bar{v}) + \sqrt{2} \, \eta \, u \bar{v}, \\ \eta' &= \xi \, v^2 - \sqrt{2} \, z u v + \eta \, u^2 \end{split} \tag{Eq. 184}$$

These equations are easily solved with  $V \rightarrow -V$ , when by Eq. (175),  $u \rightarrow \bar{u}$  and  $v \rightarrow -v$  giving

$$\begin{aligned} \xi &= \xi' u^2 - \sqrt{2} Z \, u \bar{v} + \eta' \bar{v}^2, \\ z &= \sqrt{2} \, \xi' u v + Z (u \bar{u} - v \bar{v}) - \sqrt{2} \, \eta' \bar{u} \, \bar{v}, \\ \eta &= \xi' v^2 + \sqrt{2} Z \, \bar{u} v + \eta' \, \bar{u}^2. \end{aligned}$$
(Eq. 185)

The required partial derivatives then follow from Eq. (185) and the chain rule of partial differentiation,

$$\begin{pmatrix} \frac{\partial f}{\partial \xi'} \\ \frac{1}{\sqrt{2}} \frac{\partial f}{\partial Z} \\ \frac{\partial f}{\partial \eta'} \end{pmatrix} = \begin{pmatrix} u^2 & 2uv & v^2 \\ -u\bar{v} & u\bar{u} - v\bar{v} & \bar{u}v \\ \bar{v}^2 & -2\bar{u}\bar{v} & \bar{u}^2 \end{pmatrix} \begin{pmatrix} \frac{\partial f}{\partial \xi} \\ \frac{1}{\sqrt{2}} \frac{\partial f}{\partial z} \\ \frac{\partial f}{\partial \eta} \end{pmatrix}.$$
 (Eq. 186)

The substitutions

$$\frac{\partial f}{\partial \xi'} = \Lambda_1^2, \qquad \frac{\partial f}{\partial \xi} = \lambda_1^2,$$
$$\frac{1}{\sqrt{2}} \frac{\partial f}{\partial Z} = \Lambda_1 \Lambda_2, \qquad \frac{1}{\sqrt{2}} \frac{\partial f}{\partial z} = \lambda_1 \lambda_2,$$
$$\frac{\partial f}{\partial \eta'} = \Lambda_2^2, \qquad \frac{\partial f}{\partial \eta} = \lambda_2^2, \qquad (Eq. 187)$$

are valid only for spherical harmonic functions, since

$$\nabla^2 f = \frac{\partial^2 f}{\partial x^2} + \frac{\partial^2 f}{\partial y^2} + \frac{\partial^2 f}{\partial z^2},$$
  
$$= -2\frac{\partial}{\partial\xi}\frac{\partial f}{\partial\eta} + \frac{\partial^2 f}{\partial z^2},$$
  
$$= -2\lambda_1^2\lambda_2^2 + 2\lambda_1^2\lambda_2^2,$$
  
$$= 0.$$
 (Eq. 188)

With the substitutions of Eqs. (187), the Eq. (186) becomes

$$\begin{split} \Lambda_1^2 &= (u\lambda_1 + v\lambda_2)^2, \\ \Lambda_1\Lambda_2 &= (u\lambda_1 + v\lambda_2)(-\bar{v}\lambda_1 + \bar{u}\lambda_2), \\ \Lambda_2^2 &= (-\bar{v}\lambda_1 + \bar{u}\lambda_2)^2, \end{split} \tag{Eq. 189}$$

and are equivalent to the  $2 \times 2$  form

$$\begin{split} \Lambda_1 &= u\lambda_1 + v\lambda_2, \\ \Lambda_2 &= -\bar{v}\lambda_1 + \bar{u}\lambda_2, \end{split} \tag{Eq. 190}$$

where the positive square roots are required. In the case when there is no rotation and the angle V = 0, for which u = 1 and v = 0, the Eq. (190) reduce correctly to  $\Lambda_1 = \lambda_1$  and  $\Lambda_2 = \lambda_2$ . In matrix form, Eq. (190) can be written

$$\begin{pmatrix} \Lambda_1 \\ \Lambda_2 \end{pmatrix} = \begin{pmatrix} u & v \\ -\bar{v} & \bar{u} \end{pmatrix} \begin{pmatrix} \lambda_1 \\ \lambda_2 \end{pmatrix}.$$
 (Eq. 191)

The parameters  $\Lambda_1, \Lambda_2$ , and  $\lambda_1, \lambda_2$  are called spinors, and although from their basic definition given in Eq. (187), they appear to be the square roots of differential operators, they are in fact, apart from the transformation formula Eq. (191) (and representations of "spin weighted" spherical harmonics), used only in combinations of integer powers of differential operators.

The 2 × 2 matrix in Eq. (191) has already been derived in Eq. (178) from the product formula for the Euler-Rodrigues parameters p,q,r,s, based on the complex forms (the Cayley-Klein parameters) u and v, arising solely from the need for a formula for the resultant of two successive rotations.

# *Euler angles* $(\alpha, \beta, \gamma)$

In this system the (x, y, z) reference frame is rotated through an angle  $\alpha$  about the *z*-axis to form the (x', y', z') reference frame, which is rotated though an angle  $\beta$  about the *y'*-axis to form the (x'', y'', z'') reference frame, which is rotated through an angle  $\gamma$  about the *z''*-axis to form the final (X, Y, Z) frame (see Figure H7). The point with coordinates of *r* becomes a point with coordinates **R** in the rotated reference frame, and the relationship can be written

$$\mathbf{R} = \mathbf{A}(\alpha, \beta, \gamma)\mathbf{r}, \tag{Eq. 192}$$

**Figure H7** The *Oxyz* reference frame is rotated through Euler angles  $(\alpha, \beta, \gamma)$  to become the *OXYZ* reference frame.

where the matrix  $\mathbf{A}(\alpha, \beta, \gamma)$  has the form

$$\mathbf{A}(\alpha,\beta,\gamma) = \begin{pmatrix} \cos\alpha\cos\beta\cos\gamma & \sin\alpha\cos\beta\cos\gamma & -\sin\beta\cos\gamma \\ -\sin\alpha\sin\gamma & +\cos\alpha\sin\gamma & \\ -\cos\alpha\cos\beta\sin\gamma & -\sin\alpha\cos\beta\sin\gamma & \sin\beta\sin\gamma \\ -\sin\alpha\cos\gamma & +\cos\alpha\cos\gamma & \\ \cos\alpha\sin\beta & \sin\alpha\sin\beta & \cos\beta \end{pmatrix}$$
(Eq. 193)

For the reverse rotation, the Euler angles  $(\alpha, \beta, \gamma)$  are replaced by  $(-\gamma, -\beta, -\gamma)$ ,

$$\mathbf{r} = \mathbf{A}(-\gamma, -\beta, -\alpha)\mathbf{R}.$$
 (Eq. 194)

The matrix can be written in terms of its factors, which derive from the three rotations:

$$\begin{pmatrix} X \\ Y \\ Z \end{pmatrix} = \begin{pmatrix} \cos \gamma & \sin \gamma & 0 \\ -\sin \gamma & \cos \gamma & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} \cos \beta & 0 & -\sin \beta \\ 0 & 1 & 0 \\ \sin \beta & 0 & \cos \beta \end{pmatrix} \times \begin{pmatrix} \cos \alpha & \sin \alpha & 0 \\ -\sin \alpha & \cos \alpha & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ y \\ z \end{pmatrix}.$$
(Eq. 195)

Comparing the off-diagonal terms of  $A(\mathbf{n}, V)$  of Eq. (147), and  $A(\alpha, \beta, \gamma)$  of Eq. (193), gives

$$\sin \alpha \sin \beta = cb(1 - \cos V) - a \sin V,$$
  

$$\sin \beta \sin \gamma = cb(1 - \cos V) + a \sin V,$$
  

$$-\sin \beta \cos \gamma = ca(1 - \cos V) - b \sin V,$$
  

$$\cos \alpha \sin \beta = ac(1 - \cos V) + b \sin V,$$
  

$$-\cos \alpha \cos \beta \sin \gamma - \sin \alpha \cos \gamma = ab(1 - \cos V) - c \sin V,$$
  

$$\sin \alpha \cos \beta \cos \gamma + \cos \alpha \sin \gamma = ba(1 - \cos V) + c \sin V,$$
  
(Eq. 196)

and from Eq. (196) it follows that

$$a \sin V = \frac{1}{2} \sin \beta (\sin \gamma - \sin \alpha),$$
  

$$b \sin V = \frac{1}{2} \sin \beta (\cos \gamma + \cos \alpha),$$
  

$$c \sin V = \frac{1}{2} (1 + \cos \beta) \sin(\gamma + \alpha).$$
 (Eq. 197)

The right-hand sides of Eq. (197) can be written as a product of two terms,

$$a \sin V = 2 \sin \frac{1}{2} \beta \sin \frac{1}{2} (\gamma - \alpha) \cdot \cos \frac{1}{2} \beta \cos \frac{1}{2} (\gamma + \alpha),$$
  

$$b \sin V = 2 \sin \frac{1}{2} \beta \cos \frac{1}{2} (\gamma - \alpha) \cdot \cos \frac{1}{2} \beta \cos \frac{1}{2} (\gamma + \alpha),$$
  

$$c \sin V = 2 \cos \frac{1}{2} \beta \sin \frac{1}{2} (\gamma + \alpha) \cdot \cos \frac{1}{2} \beta \cos \frac{1}{2} (\gamma + \alpha),$$
 (Eq. 198)

from which we obtain

$$(a^{2} + b^{2})\sin^{2} V = 4\sin^{2}\frac{1}{2}\beta\cos^{2}\frac{1}{2}\beta\cos^{2}\frac{1}{2}(\gamma + \alpha).$$
 (Eq. 199)

Comparing the diagonal terms of  $\mathbf{A}(\mathbf{n}, V)$  of Eq. (147), and  $\mathbf{A}(\alpha, \beta, \gamma)$  of Eq. (193), gives

(Eq. 200)

from the third of Eq. (200) we obtain

$$\sin^2 \frac{1}{2}\beta = \sin^2 \frac{1}{2}V - c^2 \sin^2 \frac{1}{2}V = (a^2 + b^2) \sin^2 \frac{1}{2}V \quad \text{(Eq. 201)}$$

From Eqs. (199) and (201)

$$\cos^2 \frac{1}{2}V = \cos^2 \frac{1}{2}\beta \cos^2 \frac{1}{2}(\gamma + \alpha),$$

and the positive square root is required, because in the case in which  $\alpha = \gamma = 0$ , the angle of rotation  $V = \beta$ . Therefore

$$\cos\frac{1}{2}V = \cos\frac{1}{2}\beta\cos\frac{1}{2}(\alpha + \gamma).$$
 (Eq. 202)

## Euler-Rodrigues parameters and Euler angles

Combining the results of Eq. (161) for rotation about **n** axis, with Eqs. (198) and (202),

$$p = a \sin \frac{1}{2}V = \sin \frac{1}{2}\beta \sin \frac{1}{2}(\gamma - \alpha),$$
  

$$q = b \sin \frac{1}{2}V = \sin \frac{1}{2}\beta \cos \frac{1}{2}(\gamma - \alpha),$$
  

$$r = c \sin \frac{1}{2}V = \cos \frac{1}{2}\beta \sin \frac{1}{2}(\gamma + \alpha),$$
  

$$s = \cos \frac{1}{2}V = \cos \frac{1}{2}\beta \cos \frac{1}{2}(\gamma + \alpha),$$
 (Eq. 203)

and these important equations relate the axis and angle of rotation with the Euler angle formulation of the same rotation.

## Cayley-Klein parameters and Euler angles

Using the Cayley-Klein parameters, u, v, defined in Eq. (175), and the results of Eq. (203),

$$u = s + ir = \cos\frac{1}{2}V + ic\sin\frac{1}{2}V = \cos\frac{1}{2}\beta e^{i(\gamma + \alpha)/2},$$
  

$$v = q + ip = (b + ia)\sin\frac{1}{2}V = \sin\frac{1}{2}\beta e^{i(\gamma - \alpha)/2}.$$
 (Eq. 204)

In terms of the rotation matrix elements  $D_{Mm}^{l}(\alpha, \beta, \gamma)$ , (see *Spherical harmonics*), and the generalized Legendre functions  $d_{M,m}^{l}(\beta)$ , the parameters u and v are

$$u = D_{-\frac{1}{2},-\frac{1}{2}}^{\frac{1}{2}}(\alpha,\beta,\gamma) = d_{-\frac{1}{2},-\frac{1}{2}}^{\frac{1}{2}}(\beta)e^{i(\alpha+\gamma)/2},$$
  

$$v = D_{\frac{1}{2},-\frac{1}{2}}^{\frac{1}{2}}(\alpha,\beta,\gamma) = d_{\frac{1}{2},-\frac{1}{2}}^{\frac{1}{2}}(\beta)e^{i(-\alpha+\gamma)/2}.$$
 (Eq. 205)

# Spherical harmonics

Briefly, spherical harmonics are multiple derivatives of inverse distance,

$$(-1)^{l-m} \left(\frac{\partial}{\partial \eta}\right)^m \left(\frac{\partial}{\partial z}\right)^{l-m} \frac{1}{r} = \frac{1}{r^{l+1}} \sqrt{\frac{(l+m)!(l-m)!}{2l+1}} Y_l^m(\theta,\phi).$$
(Eq. 206)

and on using the spinor forms of derivatives given in Eqs. (187)–(206), it follows that solid spherical harmonics can also be written in a more symmetric, spinor form,

$$\frac{1}{r^{l+1}}Y_l^m(\theta,\phi) = (-1)^{l-m} \sqrt{\frac{2l+1}{(l-m)!(l+m)!}} \lambda_1^{l-m} \lambda_2^{l+m} \frac{1}{r}.$$
(Eq. 207)

Using the transformation law (191) for spinors, under rotation of the reference frame, the transformation law for spherical harmonics is easily derived. This leads, for example, to formulae in spherical (and hyperspherical) trigonometry, and to the identification of vector and tensor quantities, which are formed into "irreducible" parts, with profound physical implications, on account of their identification as spherical harmonics in their own right.

# HARMONICS, SPHERICAL CAP

Spherical cap harmonics are used to model data over a small region of the Earth, either because data are only available over this region or because interest is confined to this region. The three-dimensional region considered in this article is that of a spherical cap (Figure H8), although one can also consider only the two-dimensional surface of a spherical cap. A three-dimensional model is used where the data are vector data that represent a field with zero curl and divergence, whereas a two-dimensional model is used for general fields with no such constraints.

In a source free region of the Earth, the vector magnetic field **B** can be expressed as the gradient of a scalar harmonic potential V. (This scalar potential is "harmonic" since its Laplacian is zero.) The potential, and therefore the field, can then be expressed mathematically as a series of basis functions, each term of the series being harmonic by design. This harmonic solution is usually identified by the coordinate system used. For example, when the coordinates chosen are rectangular coordinates, we say the field is expressed in terms of rectangular harmonics. These would be useful when dealing with a local or very small portion of the Earth's surface, such as in mineral exploration. When the coordinate system is the whole sphere, we speak of spherical harmonics (see Harmonics, spherical). These are used for investigating global features of the field. This article will discuss the harmonic solution for the case of a spherical cap coordinate system, which involves wavelengths intermediate between the local and the global solutions.

# **Basis functions**

The basis functions for the series expansion of the potential over a spherical cap region are found in the usual way by separating the variables in the given differential equations (that the curl and divergence of the field are zero) and solving the individual eigenvalue problems subject to the appropriate boundary conditions (e.g., Smythe, 1950; Sections 5.12 and 5.14). The boundary conditions include continuity in longitude, regularity at the spherical cap pole, and the appropriate Sturm-Liouville conditions on the basis functions and their derivatives at the boundary of the cap (e.g., Davis, 1963, Section 2.4). The details have been given by Haines (1985a), and computer programs in Fortran by Haines (1988).

Let *r* denote the radius,  $\theta$  the colatitude, and  $\lambda$  the east longitude of a given spherical cap coordinate. This coordinate system is, of course, identical to the usual spherical or polar coordinate system, except that the colatitude  $\theta$  must be less than  $\theta_0$ , the half angle of the spherical cap (Figure H8). Also, the spherical cap pole is not usually the geographic

**Figure H8** Three-dimensional spherical cap region: colatitude  $\theta \le \theta_0$ . Thickness of cap indicates radial coverage of data.

North Pole, in which case the geographic coordinate system is rotated to the new spherical cap pole giving new spherical cap colatitudes and longitudes. In both spherical and spherical cap systems, the radius rmust lie between the outer radius of any current sources within the Earth and the inner radius of any current sources within the ionosphere, and the longitude  $\lambda$  takes on the full 360° range. The harmonic solution of the potential  $V(r, \theta, \lambda)$  applicable to this three-dimensional spherical cap region is then given by:

$$V(r, \theta, \lambda) = a \sum_{k=0}^{K_{i}} \sum_{m=0}^{k} (a/r)^{n_{k}(m)+1} P_{n_{k}(m)}^{m}(\cos \theta) \\ \times [g_{k}^{m,i} \cos(m\lambda) + h_{k}^{m,i} \sin(m\lambda)] \\ + a \sum_{k=1}^{K_{c}} \sum_{m=0}^{k} (r/a)^{n_{k}(m)} P_{n_{k}(m)}^{m}(\cos \theta) \\ \times [g_{k}^{m,e} \cos(m\lambda) + h_{k}^{m,e} \sin(m\lambda)]$$
(Eq. 1)

where *a* is some reference radius, usually taken as the radius of the Earth, and  $P_{n_k(m)}^m(\cos \theta)$  is the associated Legendre function of the first kind. It is usual in geomagnetism for the Legendre functions *P* to be Schmidt-normalized (Chapman and Bartels, 1940; Sections 17.3 and 17.4). The subscript of *P* is known as the degree of the Legendre function and the superscript is known as the order; *k* is referred to as the index and simply orders the real (usually nonintegral) degrees  $n_k(m)$ . The  $g_k^m$  and  $h_k^m$  are the coefficients, which are each further identified with the superscript i or e to denote internal or external sources, respectively. The internal source terms involve powers of (n/a). If one intended to fit only internal (or external) sources, only the internal (or external) terms of the expansion would be used. The truncation indices  $K_i$  and  $K_e$  are the maximum indices for the internal and external series, respectively.

The potential can easily be transformed into a function of time *t* as well as space,  $V(r, \theta, \lambda, t)$ , by simply making the coefficients functions of time,  $g_k^m(t)$  and  $h_k^m(t)$ , and expanding these coefficients in terms of some temporal basis functions, such as cosine functions or Fourier functions or whatever is appropriate.

The degree  $n_k(m)$  is chosen so that

$$\frac{\mathrm{d}P_{n_k(m)}^m(\cos\theta_0)}{\mathrm{d}\theta} = 0 \quad \text{when } k - m = \text{even}$$
(Eq. 2)

and

$$P_{n_k(m)}^m(\cos\theta_0) = 0 \quad \text{when } k - m = \text{odd}$$
 (Eq. 3)

where the Legendre functions  $P_n^m(\cos \theta_0)$  are here considered to be functions of *n*, given the order *m* and the cap half-angle  $\theta_0$ . The index *k* simply starts at *m* and is incremented by 1 each time a root is found to one of the Eqs. (2) or (3). This choice of *k* is analogous to the case of ordinary spherical harmonics ( $\theta_0 = 180^\circ$ ), and in fact for that case the degree  $n_k(m)$  is simply the integer *k*. Table H3 gives the roots  $n_k(m)$  for  $\theta_0 = 30^\circ$ , up to k = 8. Figure H9 shows how  $P_{n_k(m)}^m(\cos \theta)$ varies over a  $30^\circ$  cap, up to index 4, both for k - m = even and for k - m = odd.

We can see how the  $P_{n_k(m)}^m(\cos\theta)$ ,  $0 \le \theta \le \theta_0$ , for k - m = even, are analogous to the cosine functions  $\cos(n\theta)$ ,  $0 \le \theta \le \pi$ , in that each has zero slope at the upper boundary  $(\theta_0 \text{ or } \pi, \text{respectively})$ . In fact, we can think of  $P_{n_k(m)}^m$  as being defined on the interval  $[-\theta_0, +\theta_0]$ , just as  $\cos(n\theta)$  is defined on  $[-\pi, +\pi]$ , so that an expansion over the spherical cap using  $P_{n_k(m)}^m(\cos\theta)$ , k - m = even, as basis functions is analogous to an expansion in Cartesian coordinates over  $[-\pi, +\pi]$  using  $\cos(n\theta)$  as basis functions. The extension of  $P_{n_k(m)}^m$  to the  $[-\theta_0, 0]$  interval of course, takes place on the meridian 180° away from the meridian on which the  $[0, +\theta_0]$  interval lies, which is why the  $P_{n_k(m)}^m(\cos\theta)$  must be zero at  $\theta = 0$  when  $m \neq 0$  (Figure H9a).

**Figure H9** Legendre functions  $P_{n_k(m)}^m(\cos \theta)$  of nonintegral degree  $n_k(m)$  (given in Table H3) and integral order *m*, up to index k = 4: (a) those that have zero slope at the cap boundary  $\theta_0 = 30^\circ$ , and (b) those that are zero at the cap boundary.

Similarly, the  $P_{n_k(m)}^m(\cos\theta)$ , for k - m = odd, are analogous to the sine functions  $\sin(n\theta)$ ,  $0 \le \theta \le \pi$ , in that each is zero at the upper boundary. Here, of course,  $P_{n_k(m)}^m(\cos\theta)$  must be nonzero at  $\theta = 0$  when m = 0 (Figure H9b). So an expansion over the spherical cap using  $P_{n_k(m)}^m(\cos\theta)$ , k - m = odd, as basis functions is analogous to an expansion in Cartesian coordinates using  $\sin(n\theta)$  as basis functions.

Finding the Legendre functions with zero slope (Eq. (2)) or zero value (Eq. (3)) at the boundary of the expansion region is therefore analogous to finding the Fourier cosine and sine basis functions (on the interval  $[0, \pi]$ ) applicable to a given expansion region in Cartesian coordinates. Those with zero slope at the boundary are able to fit non-zero functions there, while those that are zero at the boundary are only able to fit functions that go to zero there. Of course, we are considering Eq. (1) to be uniformly convergent, not merely convergent in mean

square (or "in the mean"). So to fit an arbitrary function over the region, one only needs to include the basis functions with zero slope at the boundary (like the cosine functions). On the other hand, if one wishes to fit the derivative of the arbitrary function, these basis functions would not do (unless that arbitrary function has zero slope at the boundary). However, the basis functions that are zero (and whose derivatives are therefore not zero) at the boundary, will be able to fit uniformly the derivative of that arbitrary function. Including basis functions both with zero slope and zero function at the boundary thus permits the uniform expansion of functions with both arbitrary values and arbitrary derivatives at the boundary of the expansion region.

The Legendre functions thus defined comprise two sets of separately orthogonal functions, with respect to the weight function  $\sin\theta$ . That is,  $P_{n_j(m)}^m(\cos\theta)$  and  $P_{n_k(m)}^m(\cos\theta)$  are orthogonal when  $j \neq k$  and when j - m and k - m are either both odd or both even. However, they are not orthogonal when j - m even and k - m = odd (or *vice versa*).

# The vector magnetic field B

The vector magnetic field **B** is given by the negative gradient of Eq. (1). That is, we compute the vertical and the horizontal spherical cap north and east components of **B** by differentiating Eq. (1) with respect to the spherical cap coordinates r,  $\theta$ , and  $\lambda$ , respectively (with appropriate signs and of course including the metrical coefficients 1, r, and  $r\sin\theta$ ). Note that only when the spherical cap pole is the geographic North Pole, are these components the usual geographic components.

We can see now why we need the spherical cap basis functions with k - m = odd. It is because the north component of the field involves a differentiation with respect to  $\theta$ . If the north component of the data happened to be nonzero at  $\theta = \theta_0$ , the north component of the model would not be uniformly convergent if only basis functions with  $dP(\cos\theta_0)/d\theta = 0$  were included in the model. Of course, if the north component is not being modeled, the second set of basis functions are not strictly required (the vertical anomaly field from Magsat data, e.g., was modeled by Haines, 1985b). In this case, the constraint on the derivative of *P* results in the field having zero slope, with respect to  $\theta$ , at the cap boundary.

Even if one did not need to fit a derivative, it can still be an advantage to include basis functions that allow for a nonzero derivative at the boundary of the analysis region. That advantage is in faster convergence (a smaller number of coefficients for a given truncation error), as discussed by Haines (1990).

Mean square and cross product values for the internal and external harmonics of the vector field **B** have been derived by Lowes (1999), in terms of the harmonics of the potential, as well as for their horizontal and radial components. Power spectra have been defined and expressed by Haines (1991), and the relationship of spherical cap harmonics to ordinary spherical harmonics has been described by De Santis *et al.* (1999).

# Subtraction of a reference field

The price paid for having uniform convergence over a spherical cap by including both sets of basis functions is that some of these functions are mutually nonorthogonal. Although most are mutually orthogonal (those within each of the two sets and all those of different order by virtue of the orthogonality of the longitude functions), even this sparse nonorthogonality can have an adverse effect on the coefficient solution, particularly at high truncation levels. This is because the nonorthogonality results in an ill-conditioned least-squares matrix, which will have some nondiagonal terms. The smaller the computer word size and the larger the field values being fitted, the more serious is this problem. It is therefore advantageous to subtract a spherical harmonic reference field from the data, do the spherical cap harmonic fit on the resulting residuals, and simply add the reference field back on when the full field is required. Which particular harmonic reference field is used for this purpose is unimportant; the idea is simply to have smaller numbers in the modeling process so as not to lose too much numerical accuracy for the given computer word size.

A second difficulty with spherical cap and other regional models, is the accumulation of errors in upward or downward continuation of the field (see *Upward and downward continuation*). The field at the continuation point, of course depends on field values outside the cap, as well as inside, and so unless the effect of these outside values could somehow be compensated for by more complicated boundary conditions, there will be an error in continuing a model based only on field values inside the cap. Here again, we can get considerable relief from subtraction of global reference fields, which are models of data from the whole Earth. Haines (1985a, Figures 3–6) shows the kinds of errors to expect in upward continuing fields to 300 and 600 km, and the lower errors when subtracting an *International Geomagnetic Reference Field (IGRF)* (*q.v.*) prior to analysis.

#### General fields over a cap surface

Previously, we have discussed fitting a harmonic function in a threedimensional region of space over a spherical cap, as portrayed in Figure H8. However, the spherical cap basis functions can also be used to expand a general function over a (two-dimensional) spherical cap surface ( $\theta \le \theta_0, r = r_0$ ). That is, there is no constraint for this surface field to be harmonic since the radial field is not being defined; it can represent, on the surface, fields that are very complex in three-dimensional space. This is analogous to the expansion theorem for the whole sphere (e.g., Courant and Hilbert, 1953, Chapter VII, Section 5.3).

The vertical field is able to play the role of the general function by considering only the internal field (i.e., putting  $K_e = 0$ ), and setting r = a. The factor  $-[n_k(m) + 1]$  arising from the differentiation with respect to r can also be set to unity. Similarly, the north and east components can be made to play the role of north and east derivatives of a general function by similar modifications (see Haines, 1988, p. 422 for details). This latter aspect can be used to model electric fields (horizontal derivatives of an electric potential) over a surface in the ionosphere. Although an electric potential satisfies Poisson's equation in three-dimensional space, it can be treated as a general function on the spherical surface.

This surface expansion is in fact the solution of the two-dimensional eigenvalue problem in the two variables (colatitude and longitude) whose functions (Legendre and trigonometric) were orthogonalized in the solution of the three-dimensional differential equation. This is a common technique in expansion methods. In Cartesian coordinates, for example, the solution to Laplace's equation in three-dimensional space ("Rectangular Harmonics") gives rise to a surface expansion (two-dimensional "Fourier Series") simply by finding the eigensolutions in the coordinates whose (trigonometric) functions were orthogonalized there. Again, these Fourier series allow the expansion of a very large class of functions, certainly functions that are in no way constrained as are the rectangular harmonic functions of three-dimensional space. Of course, we can go down another dimension and expand onedimensional functions in either of the surface variables. This gives an expansion, on the spherical cap, in trigonometric functions for longitude and in Legendre functions for colatitude, analogously to the one-dimensional trigonometric Fourier series in Cartesian coordinates.

## Example application

Regional magnetic field models over Canada have been produced every 5 years since 1985 using spherical cap harmonics. For each model, the IGRF at an appropriate epoch is subtracted from the data, and a spherical cap harmonic model of the residuals is then determined. (This also provides an estimate of the "error" or wavelength limitations of the IGRF that was subtracted.) The final model, obtained by adding the IGRF back on to the spherical cap model, is referred to as the Canadian Geomagnetic Reference Field (CGRF). Details of the data and processing methods used for the 1995 CGRF have been given by Haines and Newitt (1997).

# HARTMANN, GEORG (1489–1564)

Hartmann was born on February 9, 1489, at Eggolsheim, Germany. After studying theology and mathematics at Cologne around 1510, he spent some time in Rome, where he ranked Andreas, the brother of Nicholas Copernicus, amongst his friends. Hartmann belonged to that class of Renaissance scholar who, while the recipient of a learned education, also had a fascination with mechanics, horology, instrumentation, and natural phenomena. His principal claim to fame as a student of magnetism lay in his discovery that in addition to the compass needle pointing north, it also had a dip, or inclination, out of the horizontal. He claims to have noticed, for instance, that in Rome, the needle of a magnetic compass dipped by  $6^{\circ}$  towards the north. Although his numerical quantification of this phenomenon was wrong, the compass does, indeed, dip in Rome, as it does in most nonequatorial locations.

Although Hartmann never published his discovery, he did communicate it in a letter of 4 March 1544 to Duke Albert of Prussia. Unfortunately, this remained unknown to the wider world for almost the next three centuries, until it was finally printed in 1831. Hence, Hartmann's discovery had no influence on other early magnetical researchers, and credit for the discovery of the "dip" went to the Englishman *Robert*  398

Norman (q.v.), who published his own independent discovery in A Newe Attractive (London, 1581).

Hartmann was a priest by vocation, and held several important benefices. He settled in Nuremberg in 1518, where he was no doubt in his element, as that city was one of Europe's great centers for the manufacture of clocks, watches, instruments, ingenious firearms, and other precision metal objects. He collected astronomical and scientific manuscripts and was associated with the Nuremberg observational astronomer Johann Schöner, as well as Joachim Rheticus, who saw Copernicus' *De Revolutionibus* through the press at Nuremberg in 1543. Hartmann died in Nuremberg on April 9, 1564.

# HELIOSEISMOLOGY

Helioseismology is the study of the interior of the Sun using observations of waves on the Sun's surface. It was discovered in the 1960s by Leighton, Noyes, and Simon that patches of the Sun's surface were oscillating with a period of about 5 min. Initially these were thought to be a manifestation of convective motions, but by the 1970s it was understood from theoretical works by Ulrich and Leibacher and Stein and from further observational work by Deubner that the observed motions are the superposition of many global resonant modes of oscillation of the Sun (e.g., Deubner and Gough, 1984, Christensen-Dalsgaard, 2002). The Sun is a gaseous sphere, generating heat through nuclear fusion reactions in its central region (the core) and held together by self-gravity. It can support various wave motions, notably acoustic waves and gravitational waves; these set up global resonant modes. The modes in which the Sun is observed to oscillate are predominantly acoustic modes, though the acoustic wave propagation is modified by gravity and the Sun's internal stratification, and by bulk motions and magnetic fields. The observed properties of the oscillations, especially their frequencies, can be used to make inferences about the physical state of the solar interior. The excitation mechanism is generally believed to be turbulent convective motions in subsurface layers of the Sun, which generate acoustic noise. This is a broadband source, but only those waves that satisfy the appropriate resonance conditions constructively interfere to give rise to resonant modes.

There are many reasons to study the Sun. It is our closest star and the only one that can be observed in great detail, so it provides an important input to our understanding of stellar structure and evolution. The Sun greatly influences the Earth and near-Earth environment, particularly through its outputs of radiation and particles, so studying it is important for understanding solar-terrestrial relations. And the Sun also provides a unique laboratory for studying some fundamental physical processes in conditions that cannot be realized on Earth.

From the 1980s up to the present day, much progress has been made in helioseismology through analysis of the Sun's global modes of oscillation. Some of the results, on the Sun's internal structure and its rotation, are given below. Though not discussed here, similar studies are now also beginning to be made in more limited fashion for some other stars, in a field known as asteroseismology. In the past decade, global mode studies of the Sun have been complemented by socalled local helioseismology, techniques such as tomography which have been used to study flows in the near-surface layers and flows and structures under sunspots and active regions of sunspot complexes. Local helioseismology is also discussed below.

# Solar oscillations

The Sun's oscillations are observed in line-of-sight Doppler velocity measurements of the visible solar disk, and in measurements of variations of the continuum intensity of radiation from the surface. The latter are caused by compression of the radiating gas by the waves. Spatially resolved measurements are obtained by observing separately different portions of the visible solar disk; but the motions with the largest horizontal scales are also detectable in observations of the Sun as a star, in which light from the whole disk is collected and analyzed as a single time series. To measure the frequencies very precisely, long, uninterrupted series of observations are desirable. Hence, observations are made from networks of dedicated small solar telescopes distributed in longitude around the Earth (networks such as the Global Oscillation Network Group [GONG] making 1024 × 1024-pixel resolved observations and the Birmingham Solar Oscillation Network [BiSON] making Sun-as-a-star observations) or from space (for instance, the Solar and Heliospheric Orbiter [SOHO] satellite has three dedicated helioseismology instruments onboard, in decreasing order of resolution MDI, VIRGO and GOLF). In Doppler velocity, the amplitudes of individual modes are of order 10 cm s<sup>-1</sup> or smaller, their superposition giving a total oscillatory signal of the order of a few kilometers per second. The highest amplitude modes have frequencies v of around 3mHz

The outer 30% of the Sun comprises a convectively unstable region called the convection zone (e.g., Christensen-Dalsgaard *et al.*, 1996). The solar oscillations are stochastically excited by turbulent convection in the upper part of the convection zone. The modes are both excited and damped by their interactions with the convection. Although large excitation events such as solar flares may occasionally contribute, the dominant excitation is probably much smaller-scale and probably takes place in downward plumes where material previously brought to the surface by convection has cooled and flows back into the solar interior. These form a very frequent and widespread set of small-scale excitation sources.

The fluid dynamics of the solar interior is described by the fluid dynamical momentum equation and continuity equation, an energy equation and Poisson's equation for the gravitational potential. On the timescales of the solar oscillations of interest here, the bulk of the solar interior can be considered to be in thermal equilibrium and providing a static large-scale equilibrium background state in which the waves propagate. Treating the departures from the timeindependent equilibrium state as small perturbations with harmonic time dependence  $\exp(i\omega t)$ , where  $\omega \equiv 2\pi v$  is an (as yet) unknown resonant angular frequency, t is time and  $i = \sqrt{-1}$ , the above mentioned equations can be linearized in perturbation quantities and constitute a coupled set of linear equations describing the waves. The timescales of the solar oscillations are sufficiently short that the energy equation can be replaced by the condition that the perturbations of pressure (p) and density  $(\rho)$  are related by an adiabatic relation. At high frequencies, pressure forces provide the dominant restoring force for the perturbed motions, giving rise to acoustic waves. A key quantity for such acoustic waves is the adiabatic sound speed c, which varies with position inside the Sun:  $c^2 = \Gamma_1 p / \rho$ , where  $\Gamma_1$  is the first adiabatic exponent ( $\Gamma_1 = 5/3$  for a perfect monatomic gas). To an excellent approximation,  $p \propto \rho T/\mu$ , where T is temperature and  $\mu$  is the mean molecular weight of the gas, so

 $c \propto T^{1/2}$  inside the Sun. Except for wave propagating exactly vertically, inward-propagating waves get refracted back to the surface at some depth, because the temperature and hence sound speed increase with depth. Near the surface, outward-propagating waves also get deflected, by the sharply changing stratification in the near-surface layers. Hence the acoustic waves get trapped in a resonant cavity and form modes, with discrete frequencies  $\omega$ . To a good approximation, the Sun's structure is spherically symmetric, hence, the horizontal structure of the eigenfunctions of the modes is given by spherical harmonics  $Y_l^m$ , where integers  $l(l \ge 0)$  and  $m(-l \le m \le l)$  are respectively called the *degree* and *azimuthal* order of the mode. The structure of the eigenfunction in the radial direction into the Sun is described by a third quantum number n, called the *order* of the mode: the absolute value of n is essentially the number of nodes in the (say) pressure perturbation eigenfunction between the center and the surface of the Sun. Hence, each resonant frequency can be labeled with three quantum numbers thus:  $\omega_{nlm}$ . The labeling is such that at fixed l and m, the frequency  $\omega_{nlm}$  is a monotonic increasing function of *n*.

In a wholly spherically symmetrical situation the frequencies would be independent of *m*. However, the Sun's rotation, as well as any other large-scale motions, thermal asphericities, and magnetic fields break this degeneracy and introduce a dependence on *m* in the eigenfrequencies. The modes of different *m* but with the same values of *n* and *l* are called a multiplet: it is convenient also to introduce the mean multiplet frequency  $\omega_{nl}$ .

High-frequency modes, with positive values of the order n, are essentially acoustic modes (p modes): for them, the dominant restoring force is pressure. Low-frequency modes, with negative values of *n*, are essentially gravity modes (g modes) set up by gravity waves, which can propagate where there is a stable stratification. There is an intermediate mode with n = 0: this is the so-called fundamental or f mode. For large values of *l*, the f mode has the physical character of a surface gravity mode. The observed global modes of the Sun are p modes and f modes. Modes of low degree (mostly l = 0, 1, 2, 3) are detectable in observations of the Sun as a star: low-degree p modes are sensitive to conditions throughout the Sun, including the energy-generating core. Spatially resolved observations have detected p and f modes up to degrees of several thousand: such modes are no longer global in character, but nonetheless measuring their properties conveys information about the Sun's outer subsurface layers. Internal g modes have not unambiguously been observed to date, and they are expected to have small amplitudes at the surface: this is because their region of propagation is the stably stratified radiative interior and they are evanescent through the intervening convection zone.

The computed mean multiplet frequencies for modes of a current model of the Sun are shown in Figure H10. Points on each branch of the dispersion relation (each corresponding to a single value of n) have been joined with continuous curves.

## Results from global-mode helioseismology

The frequencies of the Sun's global modes are estimated by making suitable spatial projections and temporal Fourier transformations of the observed Doppler or intensity fluctuations. From these, using a variety of fitting or inversion techniques (similar to those used in other areas of, e.g., geophysics and astrophysics), properties of the solar interior can be deduced. Indeed, helioseismology has borrowed and adapted various approaches and ideas on inversion from geophysics, notably those of G. Backus and F. Gilbert (Backus and Gilbert, 1968, 1970). One of the principal deductions from helioseismology has been the sound speed as a function of position in the Sun (e.g., Gough *et al.*, 1996). The value of this deduction lies not in the precise value of the sound speed but in the inferences that follow concerning the physics that determines the sound speed. The sound speed in a solar model that is closely in agreement with the helioseismic data is illustrated in Figure H11. As discussed above, the adiabatic sound

**Figure H10** Mean multiplet cyclic frequencies  $v_{nl}(=\omega_{nl}/2\pi)$  of p, f, and g modes of a solar model, as a function of the mode degree *l*. The low-order p modes are labelled according to the value of the mode order *n*. The g modes are only illustrated up to l = 7 and for  $|n| \le 20$ .

**Figure H11** Square of the adiabatic sound speed *c* inside a model of the present Sun, as a function of fractional radius (center at 0, photospheric surface at 1.0).

speed *c* is related to temperature *T*, mean molecular weight  $\mu$ , and adiabatic exponent  $\Gamma_1$  by  $c^2 \propto \Gamma_1 T/\mu$ , where the constant of proportionality is the gas constant. The general increase in sound speed with depth reflects the increase in temperature from the surface to the center of the

Sun. The gradient of the temperature, and hence of the sound speed, is related to the physics by which heat is transported from the center to the surface. In the bulk of the Sun, that transport is by radiation; but in the outer envelope the transport is by convection. A break in the second derivative of the sound speed near a fractional radius of 0.7 indicates the transition between the two regimes and has enabled helioseismology to determine the location of the base of the convection zone: this is important because it delineates the region in which chemical elements observed at the surface are mixed and homogenized by convective motions. Beneath the convection zone, the gradients of temperature and sound speed are influenced by the opacity of the material to radiation: it has thus been possible to use the seismically determined sound speed to find errors in the theoretical estimates of the opacity, which is one of the main microphysical inputs for modeling the interiors of stars. Not readily apparent on the scale of Figure H11 is the spatial variation of  $\Gamma_1$  and hence of sound speed in the regions of partial ionization of helium and hydrogen in the outer 2% of the Sun. This variation depends on the equation of state of the material and on the abundances of the elements: it has been used to determine that the fractional helium abundance by mass in the convection zone, which is poorly determined from surface spectroscopic observations, is about 0.25. This is significantly lower than the value of 0.28 believed from stellar evolutionary models to have been the initial helium abundance of the Sun when it formed. The deficiency of helium in the present Sun's convection zone is now understood to arise from gravitational settling of helium and heavier elements out of the convection zone and into the radiative interior over the 4.7 Ba that the Sun has existed as a star. This inference is confirmed by an associated slight modification to the sound speed profile beneath the convection zone.

The dip in the sound speed at the center of the Sun is the signature of the fusion of hydrogen to helium that has taken place over the Sun's lifetime: the presence of helium increases the mean molecular weight  $\mu$ , decreasing the sound speed. Thus the amount of build-up of helium in the core is an indicator of the Sun's age. Apart from inversions, a sensitive indicator of the sound speed in the core is the difference  $v_{nl} - v_{n-1,l+2}$  between frequencies of p modes of low degree (l = 0, 1, 2, 3) differing by two in their degree. Such pairs of modes penetrate into the core and have similar frequencies and hence very similar sensitivity to radial structure in the outer part of the Sun, but have different sensitivities in the core.

Another major deduction of global-mode helioseismology has been the rotation as a function of position through much of the solar interior (Figure H12) (e.g., Thompson et al., 1996, 2003). In the convection zone, it has been discovered that the rotation varies principally with latitude and rather little with depth: at low solar latitudes the rotation is fastest, with a rotation period of about 25 days; while at high latitudes the rotation periods in the convection zone are in excess of 30 days. These rates are consistent with deductions of the surface rotation from spectroscopic observations and from measurements of motions of magnetic features such as sunspots. The finding was at variance with some theoretical expectations that the rotation in the convection zone would be constant on Taylor columns. At low- and mid-latitudes there is a near-surface layer of rotational shear, which may account for the different rotational speeds at which small and large magnetic features are observed to move. Near the base of the convection zone, the latitudinally differential rotation makes a transition to latitudinally independent rotation. This gives rise to a layer of rotational shear at low and high latitudes, which is called the tachocline. It is widely believed that the tachocline is where the Sun's large-scale magnetic field is generated by dynamo action, leading to the 11-year solar cycle of sunspots and the large-scale dipole field. Deeper still the rotation appears to be consistent with solid-body rotation, presumably caused by the presence of a magnetic field. In the core, there is some hint of a slower rotation, but the uncertainties on the deductions are quite large: nonetheless, some earlier theoretical predictions that the core would rotate much faster than the surface, a relic of the Sun's faster rotation as a

**Figure H12** (a) Contour plot of the rotation rate inside the Sun inferred from MDI data. The rotation axis is up the *y*-axis, the solar equator is along the *x*-axis. Contour spacings are 10 nHz; contours at 450, 400, and 350 nHz are thicker. The shaded region indicates where a localized solution has not been possible with these data. (b) The rotation rate deeper in the interior, on three radial cuts at solar latitudes  $0^{\circ}$ ,  $30^{\circ}$ , and  $60^{\circ}$ , using data from Sun-as-a-star observations by BiSON and spatially resolved observations by the LOWL instrument.

young star, are strongly ruled out by the seismic observations. Superimposed on the rotation of the convection zone are weak but coherent migrating bands of faster and slower rotation (of amplitude only a few meters per second, compared with the surface equatorial rotation rate of about 2 km s<sup>-1</sup>), which have been called torsional oscillations: the causal connection between the migrating zonal flows and the sunspot active latitudes, which also migrate during the solar cycle, is as yet uncertain. There have also been reported weak variations, with periodicities around 1.3 years, in the rotation rate in the deep convection zone and in the vicinity of the tachocline. To date there has been no direct helioseismic detection of magnetic field in the region of the tachocline: indeed, because the pressure increases rapidly with depth, a field there would have to have a strength of order 10<sup>6</sup> Gauss to have a significant direct influence on the mode frequencies. Thus detecting the effect of a temporally varying magnetic field on the angular momentum may be the most likely way to infer seismically the presence of such a field in the deep interior. On the other hand, nearsurface magnetic fields can influence mode frequencies in a detectable way, because the pressure is much lower there; and there is strong evidence that mode frequencies vary over the solar cycle in a manner that is highly correlated with the temporal and spatial variation of photospheric magnetic field.

# Local helioseismology

Analysis of the Sun's global mode frequencies has provided an unprecedented look at the interior of a star, but such an approach has limitations. In particular, the frequencies sense only a longitudinal average of the internal structure. To make more localized inferences, the complementary approaches of local helioseismology are used. One such technique is to analyze the power spectrum of oscillations as a function of frequency and the two horizontal components of the wavenumber in localized patches. To obtain good wavenumber resolution, the patches are usually quite large: square tiles of up to about  $2 \times 10^5$  km on the side. The technique is known as ring analysis, because at fixed frequency the p-mode power lies on near-circular rings in the horizontal wavenumber plane. By performing inversions for the depth dependence under each tile, maps with horizontal resolution similar to the size of the tiles can be obtained of structures and particularly of flows in the outer few per cent of the solar interior (e.g., Toomre, 2003). As well as the zonal flows, the meridional (i.e., northward and southward) flow components have also been measured. Beneath the surface, these are generally found to be poleward in both hemispheres down to the depth at which the ring analyzes lose resolution: this depth is of order  $10^4$  km. However, the analyses indicate that the flow patterns in the northern but not the southern hemispheres changed markedly in 1998-2000 as the Sun approached the maximum of its 11-year magnetic activity cycle.

Other local techniques include time-distance helioseismology and acoustic holography. So for example, in time-distance helioseismology, the travel-time of waves between different points on the surface of the Sun are used to infer wavespeed and flows under the surface (e. g., Kosovichev, 2003). This can be achieved on much smaller horizontal scales than have yet been achieved by ring analysis, down to just a few thousand kilometers. Since individual excitation events are rarely if ever seen, the travel-times are isolated from the measured Doppler velocities across the solar disk by cross-correlating pairs of points, or sets of points. Using high-resolution observations such as those from the MDI instrument onboard SOHO, travel-times can be measured between many different locations on the solar surface, and with different spatial separations which in turn provide different depth sensitivities to subsurface conditions. By comparing the measured traveltimes with those of a solar model, inversion techniques similar to those used in global mode helioseismology have been used to map conditions in the convection zone using travel-time data. In particular, wavespeed anomalies and flows under sunspots and active regions of strong magnetic fields on the surface have been mapped. An unexpected finding has been that the wavespeed beneath sunspots (which in such regions is not just the sound speed but is modified by the magnetic field) is increased relative to the spot's surroundings, except in a shallow layer of up to 5000km depth where the wavespeed is decreased. Such studies are providing much-needed constraints on models of sunspot structure and theories of their origin, and on models of the emergence of magnetic flux from the solar interior.

# **HIGGINS-KENNEDY PARADOX**

For the student learning about properties of the Earth's core it may be surprising that the core is solid at its center where its temperature is highest, while it becomes liquid at a distance of about 1220 km from the center where the temperature is lower. This property is caused by the dependence of the melting temperature  $T_m$  on the pressure p. That the melting temperature  $T_m$  of nearly all materials increases with pressure has been a well-known property for a long time and finds its most simple expression in Lindemann's law

$$\frac{1}{T_{\rm m}}\frac{\mathrm{d}T_{\rm m}}{\mathrm{d}p} = 2\left(\gamma - \frac{1}{3}\right)/k \tag{Eq. 1}$$

where k is the compressibility along the melting curve  $T_{\rm m}(p)$  and  $\gamma$  is the Grüneisen parameter which, in thermodynamics, is defined by

$$\gamma = \frac{\alpha k_T}{\rho c_v} = \frac{\alpha k_S}{\rho c_p}.$$
 (Eq. 2)

Here,  $\rho$  denotes the density,  $\alpha$  is the coefficient of thermal expansion, and  $k_T$  and  $k_S$  are the isothermal and adiabatic compressibilities, while  $c_v$  and  $c_p$  are the specific heats at constant volume and constant pressure, respectively. The Grüneisen parameter  $\gamma$  plays a prominent role in studies of the thermal state of planetary interiors since it assumes a value of the order unity for all condensed materials and does not vary much with pressure or temperature in contrast to the material properties on the right hand sides of Eq. (2). Using thermodynamic relationships one finds (see *Grüneisen's parameter for iron and Earth's core*)

$$\gamma = -\frac{T}{V} \frac{\partial V}{\partial T} \Big|_{S} = -\frac{\partial \ln V}{\partial \ln T} \Big|_{S}$$
(Eq. 3)

which indicates that  $\gamma$  describes the negative slope in logarithmic plots of volume versus temperature under adiabatic compression. The  $\gamma$  used in relationship (1) is not necessarily the thermodynamic one, since the melting temperature may be influenced by electronic contributions and other effects which are not taken into account in Eqs. (2) and (3). The simple approximate relationship (1) called Lindemann's law is far from a rigorous law in any mathematical sense and is mentioned here only as an example of many similar "laws" that have been derived in the literature. For a review and a recent paper, see Jacobs (1987) and Anderson *et al.* (2003).

The adiabatic temperature gradient is defined by (see *Core, adiabatic gradient*)

$$\left. \frac{\partial T}{\partial p} \right|_{S} = \frac{\alpha T}{\rho c_{p}} = \frac{\gamma T}{k_{S}} \tag{Eq. 4}$$

Here, the isentropic compressibility  $k_S$  is well determined in the Earth's core by seismic data, since the relationship  $k_S =$  $\rho(V_{\rm p}^2 - \frac{4}{3}V_{\rm s}^2)$  holds where  $V_{\rm p}$  and  $V_{\rm s}$  are the velocities of propagation of p (compressional)- and s (shear)-waves. The adiabatic temperature gradient defines a state where the exchange of fluid parcels from different radii can be accomplished without gain or loss of energy when dissipative effects such as those connected with viscous friction can be neglected. When the increase of temperature with pressure is less than the adiabatic gradient, a stably stratified state is obtained which requires an input of energy for the exchange of fluid parcels from different radii. When the temperature increases more strongly by a finite amount  $\varepsilon$  than the adiabatic gradient, the static state becomes unstable and convection sets in. In fact, for dimensions as large as those of the core, the amount  $\varepsilon$  is minute, such that a state of convection corresponds essentially to an adiabatic temperature distribution. Since convection flows of sufficient strength are needed to generate the geomagnetic field (Busse, 1975) it has always been assumed that the temperature field of the liquid outer core must be close to an adiabatic one except, perhaps, close to the core-mantle boundary.

In their paper of 1971, Higgins and Kennedy shattered this confidence in the adiabatic temperature distribution. On the basis of the extrapolation of numerous experimental results measured at relatively low pressures, they suggested that the melting temperature  $T_m$  in the core depends only weakly on the pressure and that the adiabatic temperature would exhibit a much steeper dependence. Accordingly they claimed that the latter temperature distribution could only be compatible with a frozen outer core in contradiction to all seismic evidence, while any temperature distribution at the melting temperature or above would imply a stably stratified core in contradiction to the dynamo hypothesis of the origin of geomagnetism. This is the Higgins-Kennedy core paradox.

The publication of the paper by Higgins and Kennedy (1971) stimulated numerous attempts to circumvent the paradoxial situation. It turns out that the melting temperature  $T_m(p)$  can coincide with an isentropic temperature distribution if a suspension is assumed of small solid particles; the melting and freezing of which contributes the correct energies for a neutral exchange of fluid parcels from different radii (Busse, 1972; Malkus, 1973). Stacey (1972) pointed out that the adiabat corresponding to the temperature at the inner core-outer core boundary may well lie above the melting temperature of the outer core since the latter corresponds to that of iron alloyed with a significant amount of light elements. It is thus considerably lower than the temperature at the boundary of the inner core, which corresponds to the melting of nearly pure iron or an iron-nickel alloy. In later years rather convincing arguments have been put forward which cast doubts on the validity of the extrapolation of experimental data carried out by Higgins and Kennedy. Their proposed melting temperature together with their assumed value of  $\gamma$  is far removed from Lindemann's law (1). On the other hand, modern theoretical studies support relationships similar to Eq. (1). Stevenson (1980) and others argued that a weak pressure dependence of  $T_{\rm m}(p)$  is compatible only with an unphysically low value of the Grüneisen parameter  $\gamma$ . Indeed, comparing Eqs. (1) and (4) one finds that

$$\left. \frac{\mathrm{d}T_m}{\mathrm{d}p} < \frac{\mathrm{d}T}{\mathrm{d}p} \right|_S \tag{Eq. 5}$$

can be satisfied only for  $\gamma < \frac{2}{3}$ , which contrasts with the value of about 1.5 of  $\gamma$  found for most liquid metals at high pressures. For details on the various theoretical arguments we refer to the comprehensive review given by Jacobs (1987). For a recent review of experimental measurements see Boehler (2000). Although it is unlikely today that a situation as imagined by Higgins and Kennedy exists in the Earth's core, this possibility cannot be excluded entirely. In view of our ignorance about properties of the core, it seems advisable to keep the core paradox in the back of one's mind in thinking about problems of planetary interiors (see *Dynamos, planetary and satellites*).

# HUMBOLDT, ALEXANDER VON (1759–1859)

Alexander von Humboldt (Figure H13) was born in Berlin in 1769 as the son of a nobleman and former officer of the Prussian Army. He studied at the universities of Frankfurt/Oder and Göttingen, at the trade academy of Hamburg and at the mining academy of Freiberg in Saxonia. In his studies he was interested in all aspects of nature from botany and zoology to geography and astronomy. His friendship with Georg Forster who had participated in Cook's second voyage and whom he met in Göttingen had a strong influence on him and

motivated him to see his vocation as a scientific explorer. First he entered, however, the career as a mining inspector in the service of the Prussian state. But when his mother died in 1796-he had lost his father already when he was only nine years old-and he became the heir of a considerable fortune, he declined the offer of the directorship of the Silesian mines and started the realization of his long held plan for a scientific expedition. In 1798, he embarked on his six years voyage to South and North America from which he returned in 1804 with huge collections of scientific data and materials. It was in the preparation for this expedition that he was instructed by the French mathematician and nautical officer Jean-Charles de Borda in the measurements of the components of the Earth's magnetic field and throughout the years of his voyage he collected magnetic data in addition to geodetic, meteorological, and other ones. One of his findings was the decrease of magnetic intensity with latitude which, apparently, had not been clearly recognized until that time since measurements had been focused on the direction of the field.

A. von Humboldt continued his magnetic measurements on his voyage with his friend Gay-Lussac to Italy in 1805 and back to Berlin. Here he was offered a wooden cabin, which allowed him to take readings of the declination each night for several months, a task he shared with the astronomer Oltmann. In December 1805 he was lucky in observing strong fluctuations of the magnetic field while an aurora borealis occurred. Humboldt coined the term "Magnetischer Sturm" for the period of strong oscillations of the magnetometer needle. Nowadays the term "magnetic storm" is generally accepted for this phenomenon. Because of the defeat of Prussia by Napoleon's army von Humboldt had to stay longer in Berlin than he had planned and returned to Paris only in late 1807. Here he was occupied with the edition of the scientific results of his American voyage until 1827. It is worth noting that during a shorter journey to Berlin in 1826, he stopped in Göttingen to meet Carl Friedrich Gauss (see Gauss, Carl Friedrich) for the first time in person.

A. von Humboldt and Gauss were the most prominent German scientists of their time and they had been in contact by letters for quite a while. They had high regards for each other even though they were opposites in their styles of research. A. von Humboldt was one of the last universally educated scientists interested in the descriptive comprehension of all natural phenomena, while the mathematician and physicist Gauss used primarily deductive analysis in his research. The study of the Earth's magnetic field was one of their common interests. Their interaction intensified after von Humboldt had invited Gauss to participate in the 7th Assembly of the Society of German Scientists and Physicians, which took place in the fall of 1828 in Berlin. During that time Gauss stayed at von Humboldt's house. The latter had left Paris reluctantly in 1827 to follow a call from the Prussian King Friedrich Wilhelm III to assume the position of a chamberlain at the Berlin court. In his free time, von Humboldt continued his scientific work among which magnetic measurements had a high priority. For this purpose his friend A. Mendelson-Bartholdy (father of the famous composer) had provided a place in his garden where von Humboldt built an iron free wooden cabin for his magnetometers.

Gauss pursued his studies of the Earth's magnetic field quite independently from those of von Humboldt, which caused the latter some irritation. Von Humboldt had thought that he had motivated Gauss to do magnetic measurements when the latter visited him in Berlin in 1828. But Gauss' interests in geomagnetism went back to a time 40 years earlier, as he mentions in a letter of 1833, and in 1806 he had already contemplated a description of the field in terms of spherical harmonics. At the Berlin Assembly, Gauss had met the promising physicist Wilhelm Weber and had arranged that this young man got a professorship in Göttingen in 1831. In the following six years, an intense and highly productive collaboration between Gauss and Weber ensued on all kinds of electromagnetic problems. In the course of this research Gauss developed his method of the absolute determination of magnetic intensity (see Gauss' determination of absolute intensity) and built together with Weber appropriate instruments. It now became possible to calibrate instruments locally independently from any other. For the purpose of absolute measurements of the magnetic field and its variations in time at different places on the Earth, Gauss and Weber initiated the "Göttinger Magnetischer Verein."

Alexander von Humboldt was also interested in simultaneous measurements of the geomagnetic field at different geographic locations in order to determine, for instance, whether magnetic storms are of terrestrial origin or depended on the position of the Sun. Already in 1828 he had arranged for coincident measurements in Paris and inside a mine in Freiberg (Saxonia). When he received a glorious reception at the Russian court at St. Petersburg in 1829 at the end of his expedition to Siberia, von Humboldt used the opportunity to suggest the creation of a network of stations throughout the Russian empire for the collection of magnetic and meteorological data. In the following years such stations were indeed installed including one in Sitka, Alaska, which at that time belonged to Russia. Von Humboldt realized that he had to persuade British authorities in order to achieve his goal of a nearly worldwide distribution of stations. In 1836 he wrote to the Duke of Sussex whom he had gotten to know during his student days at the University of Göttingen and who was now the president of the Royal Society. For an English translation of this letter see the paper by Malin and Barraclough (1991). Von Humboldt's recommendations for the establishment of permanent magnetic observatories in Canada, St. Helena, Cape of Good Hope, Ceylon, Jamaica, and Australia were well received. Besides realizing these proposals, the British Government went a step further and organized an expedition to Antarctica under the direction of Sir James Clark Ross with magnetic measurements as one of its main tasks. Based on the observatory data, Sir Edward Sabine (see Sabine, Edward) who supervised the network of stations could later establish a connection between magnetic storms and sunspots and demonstrate in particular the correlation between the 11-year sunspot cycle and a corresponding periodicity of magnetic storms

In the course of his continuing research on geomagnetism, von Humboldt realized the superiority of Gauss' method of measurement and he also often expressed his admiration for Gauss' theoretical work on the representation of the geomagnetic field in terms of potentials and the separation of internal and external sources in particular. From today's point of view it is obvious that Gauss made the more fundamental contributions to the field of geomagnetism. But Alexander 404

von Humboldt's lasting legacy has been the organization of a worldwide cooperation in the gathering of geophysical data with simultaneous measurements at prearranged dates; the influence of which can still be felt today. A. von Humboldt died in 1859 at the age of nearly 90 years. For further details on von Humboldt's scientific endeavours the reader is referred to the book by Botting (1973).

Baron Alexander von Humboldt (September 14, 1769–May 6, 1859) was a great German naturalist and explorer, universal genius and cosmopolitan, scientist, and patron. Application of his experience and knowledge gained through his travels and experiments transformed contemporary western science. He is widely acknowledged as the founder of modern geography, climatology, ecology, and oceanography. This article focuses on Alexander von Humboldt's contribution to the science of geomagnetism (Busse, 2004), which is not so widely known.

#### Historical background on geomagnetism

With the publication of *De Magnete* by William Gilbert in A.D. 1600, the Earth itself was seen as a great magnet, and a new branch of physics, geomagnetism, was born. The first map of magnetic field declination was made by Edmund Halley in the beginning of 18th century.

Alexander von Humboldt prepared a chart of "isodynamic zones" in 1804, based on his measurements made during his voyages through the Americas (1799–1805). He swung a dip needle in the magnetic meridian plane, and observed the number of oscillations during 10 min. He noticed that the number of oscillations were at maximum near the magnetic equator, and decreased to the north and to the south. This indicated a regular decrease of the total magnetic intensity from the poles to the equator. The publication of this result stimulated further investigations on the Earth's magnetic field (Chapman and Bartels, 1940). Von Humboldt, together with Guy Lussac, improvised the method to measure the horizontal intensity by observing the time of oscillation of a compass needle in the horizontal plane. They took the first measurements of the relative horizontal intensity of the Earth's magnetic field on a journey to Italy in 1807.

From May 1806 to June 1807 in Berlin, Humboldt and a colleague observed the local magnetic declination every half hour from midnight to morning. On December 21, 1806, for six consecutive hours, von Humboldt observed strong magnetic deflections and noted the presence of correlated northern lights (aurora) overhead. When the aurora disappeared at dawn, the magnetic perturbations disappeared as well. Von Humboldt concluded that the magnetic disturbances on the ground and the auroras in the polar sky were two manifestation of the same phenomenon (Schröder, 1997). He gave this phenomenon involving large-scale magnetic disturbances (possibly already observed by George Graham) the name "Magnetische Ungewitter," or magnetic storms (von Humboldt, 1808). The worldwide net of magnetic observatories later confirmed that such "storms" were indeed worldwide phenomena.

Alexander von Humboldt organized the first simultaneous observations of the geomagnetic field at various locations throughout the world after his return from his South American journey. Wilhelm Weber, Karl F. Gauss, and he organized the Göttingen Magnetische Verein (Magnetic Union); and from 1836-1841, simultaneous observations of the Earth's magnetic field were made in nonmagnetic huts at up to 50 different locations, marking the beginning of the magnetic observatory system. Through his diplomatic contacts, Alexander von Humboldt was instrumental in the establishment of a number of magnetic observatories around the world, especially in Britain, Russia, and in countries then under the British and Russian rule, e.g., cities such as Toronto, Sitka, and Bombay, etc. He constructed his own iron-free magnetic observatory in Berlin in 1832. These observatories have played an important role in the development of the science of geomagnetism. With the beginning of the space age, our knowledge about the near-Earth space environment, the magnetosphere-ionosphere system in general, and geomagnetic storms in particular, has improved dramatically.

#### Intense geomagnetic storms and their causes

A geomagnetic storm is characterized by a main phase during which the horizontal component of the Earth's low-latitude magnetic fields are significantly depressed over a time span of one to a few hours. This is followed by a recovery phase, which may extend for  $\sim 10$  h or more (Rostoker, 1997). The intensity of a geomagnetic storm is measured in terms of the disturbance storm-time index (Dst). Magnetic storms with Dst < -100 nT are called intense and those with Dst < -500 nT are called superintense. Geomagnetic storms occur when solar wind-magnetosphere coupling becomes intensified during the arrival of fast moving solar ejecta like interplanetary coronal mass ejections (ICMEs) and fast streams from the coronal holes (Gonzalez et al., 1994) accompanied by long intervals of southward interplanetary magnetic field (IMF) as in a "magnetic cloud" (Klein and Burlaga, 1982). It is now well established that the major mechanism of energy transfer from the solar wind to the Earth's magnetosphere is magnetic reconnection (Dungey, 1961). The efficiency of the reconnection process is considerably enhanced during southward IMF intervals (Tsurutani and Gonzalez, 1997), leading to strong plasma injection from the magnetotail towards the inner magnetosphere causing intense auroras at highlatitude nightside regions. Further, as the magnetotail plasma gets injected into the nightside magnetosphere, the energetic protons drift to the west and electrons to the east, forming a ring of current around the Earth. This current, called the "ring current," causes a diamagnetic decrease in the Earth's magnetic field measured at near-equatorial magnetic stations (see Figure H14 for the results from one such station). The decrease in the equatorial magnetic field strength, measured by the Dst index, is directly related to the total kinetic energy of the ring current particles (Dessler and Parker, 1959; Sckopke, 1966); thus the Dst index is a good measure of the energetics of the magnetic storm. The Dst index itself is influenced by the interplanetary parameters (Burton et al., 1975).

One obviously cannot directly determine the solar/interplanetary causes of storm events prior to the space age. However, based on the recently gained knowledge on solar, interplanetary, and magneto-spheric physics, one can make these determinations by a process of elimination. For example, by examining the profile of magnetic storms using ground magnetic field data, storm generation mechanisms can be identified (Tsurutani *et al.*, 1999). From the ground magnetometer data shown in Figure H14, reports on the related solar flare event (Carrington, 1859; Hodgson, 1859), and reports on the concomitant aurora (taken from newspapers and private correspondence, Kimball,

**Figure H14** The Colaba (Bombay) magnetogram for the September 1–2, 1859 geomagnetic storm. The peak near 0400 UT September 2, is due to the storm sudden commencement (SSC) caused probably by the shock ahead of the magnetic cloud. This was followed by the storm "main phase" which lasted for about one hour and a half. Taken from Tsurutani *et al.* (2003).

1960), Tsurutani et al. (2003) were able to deduce that an exceptionally fast (and intense) magnetic cloud was the interplanetary cause of the superintense geomagnetic storm of September 1-2, 1859 with a Dst  $\sim$ -1760 nT. This large value of Dst is consistent with the decrease of  $\Delta H = 1600 \pm 10$  nT recorded at Colaba (Bombay), India (Figure H14). The supposition that the intense southward IMF was due to a magnetic cloud was surmised by the simplicity and short duration of the storm in the ground magnetic field data. Main phase compound events or "double storms" (Kamide et al., 1998) can be ruled out by the (simple) storm profile. Compound stream events (Burlaga et al., 1987) can also be eliminated by the storm profile. The only other possibility that might be the cause of the storm is sheath fields associated with an ICME. This can be ruled out because the compression factor of magnetic fields following fast shocks is only approximately four times (Kennel et al., 1985). Thus with quiet interplanetary fields being typically ~3 to 10 nT, the compressed fields would be too low to generate the inferred interplanetary and magnetospheric electric fields for the storm. Thus by a process of elimination the interplanetary fields that caused this superintense storm have been determined to be part of a fast, intense magnetic cloud.

Geomagnetic storms produce severe disturbances in Earth's magnetosphere and ionosphere, creating so-called adverse space weather conditions. They pose major threats to space- and ground-based technological systems on which modern society is becoming increasingly dependent. The intense magnetic storms during October 29–31, 2003, the so-called "Halloween storms", associated with the largest x-ray solar flare of the solar cycle 23, caused damage to 28 satellites, ending the operational life of two, disturbed flight routes of some airlines, telecommunications problems, and power outage in Sweden. These Halloween storms with Dst  $\sim$ -400 nT were about four times less intense than the superintense storm of 1859. One can imagine the loss to society if a magnetic storm similar to the superintense storm of 1859 were to occur today!

# IAGA, INTERNATIONAL ASSOCIATION OF GEOMAGNETISM AND AERONOMY

#### History

The origin of the International Association of Geomagnetism and Aeronomy (IAGA) can be traced to the Commission for Terrestrial Magnetism and Atmospheric Electricity, part of the International Meteorological Organization, which was established in 1873. The Commission planned the geomagnetic observation campaign for the First International Polar Year, 1882-1883. Following the end of World War I, the International Research Council (IRC) was established to promote science through international cooperation. At a meeting of the IRC in July 1919, the International Geodetic and Geophysical Union was formed, with Terrestrial Magnetism and Electricity as Section D, and with its leadership provided by the International Meteorological Organization. In 1930, the International Geodetic and Geophysical Union agreed to cooperate with the International Meteorological Organization to organize a Second International Polar Year, 50 years after the first. The Union changed its name to the International Union of Geodesy and Geophysics (IUGG), its Sections were renamed Associations, and the International Association of Terrestrial Magnetism and Electricity (IATME) came into existence.

At the Brussels IUGG General Assembly in 1951, upper atmosphere scientists lobbied to have their interests recognized within IATME. Following the Brussels Assembly, *Sydney Chapman (q.v.)*, who had previously suggested replacing the term "Terrestrial Magnetism" by "Geomagnetism" coined the term "Aeronomy" and suggested adoption of the name International Association of Geomagnetism and Aeronomy. The expansion of the scope of IATME was ratified at the General Assembly in Rome in 1954, the new title IAGA was agreed, and aeronomy was defined as "the science of the upper atmospheric regions where dissociation and ionization are important."

In 1950, Lloyd Berkner proposed a Third International Polar Year to provide motivation to re-equip geophysical observatories, many of which had been damaged or destroyed during World War II. The International Council of Scientific Unions adopted and broadened the scope of the idea, and designated July 1957 to December 1958 the International Geophysical Year (IGY). Observations were made in a number of IUGG discipline areas, including geomagnetism. The IGY resulted in a leap forward in geophysics through coordinated observational campaigns and through the establishment of new observatories and the World Data Center system. It was the beginning of the space age, and marked the start of the modern era for IAGA science, which has expanded to include solar-terrestrial interactions and studies of the Sun and the planets.

# Present structure and organization

In 2005, IAGA is one of seven scientific associations of the IUGG. It is an international nongovernmental organization deriving the majority of its funding from the IUGG member nations. An Executive Committee, elected by member countries, runs the Association, and the scientific work is organized through a structure defined in the Association's Statutes and By-Laws:

Division I: Internal Magnetic Fields; Division II: Aeronomic Phenomena; Division III: Magnetospheric Phenomena; Division IV: Solar Wind and Interplanetary Field; Division V: Geomagnetic Observatories, Surveys, and Analyses. Interdivisional Commission on History Interdivisional Commission on Developing Countries

Several of the Divisions have Working Groups in specialist topic areas and establish Task Groups to deal with specific issues.

# IAGA's purpose and linkages

IAGA's "mission" is defined by the Association's first Statute, which states that IAGA should promote scientific studies of international interest and facilitate international coordination and discussion of research. An important defining characteristic of IAGA is, therefore, to encourage inclusiveness in the scientific community, making excellent science accessible to scientists worldwide. There is a particular commitment to the less developed countries, and to the free exchange of scientific data and information.

One way in which IAGA achieves its objectives is through the organization of meetings. IAGA Scientific Assemblies are held every 2 years, and in conjunction with IUGG General Assemblies every 4 years. Smaller scale meetings and specialized workshops make IAGA science accessible to a wider audience and help younger scientists and scientists from developing countries to accelerate their learning. IAGA sponsors several such meetings each year. They are held in all parts of the world, an important factor in enabling attendance by scientists with limited resources.

Meetings enable scientific results to be presented and debated, new ideas generated, and collaborations to be established. The major Assemblies are also used to conduct divisional and working group business meetings, and matters of interest to IAGA are presented at open meetings convened for discussions between the IAGA Executive, the official delegates from member countries, and individual scientists. Resolutions are adopted as a formal means for IAGA to express views on scientific
matters. Support is often given to scientific initiatives under consideration by national or international agencies that will benefit IAGA science. For example, a series of IAGA Resolutions supported the initiation of and extensions to the International Equatorial Electrojet Year (IEEY) project (1991–1994). The project not only produced good science, but also resulted in investment in observational facilities at low-latitudes, benefiting scientists in the less developed world. Although the IEEY has finished, the impetus it gave to research in the equatorial regions continues. Similarly, IAGA has supported the Decade of Geopotential Research, which appears likely to achieve its goal of securing uninterrupted geomagnetic field satellite survey measurements spanning a decade (including the Ørsted and CHAMP missions).

IAGA science is also promoted through collaboration with other bodies with similar interests. There are links with the other IUGG Associations and with Inter-Association bodies including *Studies of the Earth's Deep Interior* (SEDI) (q.v.) and the Working Group on Electric and Magnetic Studies on Earthquakes and Volcanoes (EMSEV). There are formal contacts for liaison with the International Lithosphere Program (ILP), the Scientific Committee on Antarctic Research (SCAR), the Committee on Space Research (COSPAR), and the Scientific Committee on Solar Terrestrial Physics (SCOSTEP).

IAGA cooperates with the World Data Center system on the definition of geomagnetic data exchange formats and management and preservation of analog and digital databases. The Association has provided strong support to INTERMAGNET (q.v.), the international program promoting the modernization of magnetic observatory practice and the distribution of data in near real time. IAGA advises bodies such as the International Organization for Standardization (ISO).

#### IAGA science in the 21st century

IAGA science, because of the pervasiveness of the geomagnetic field and its interactions with charged particles and electrically conducting materials, is useful for studies of properties and processes in practically all parts of the solid Earth, the atmosphere, and the surrounding space environment. As well as covering a vast range of length scales, IAGA science covers timescales from seconds to billions of years. Modern-day observatories record rapid variations during magnetic storms caused by the interaction of the solar wind with the magnetosphere; the imprinting of the paleomagnetic field in rocks provides records of geodynamic changes on geological timescales.

While IAGA provides an international focus for fundamental research resulting in advances in understanding in specialist areas, national and international funding for research often focuses on issues of societal concern. IAGA science is providing answers to many important questions, and through its links to other bodies and projects the Association is able to foster the building of the interdisciplinary teams required to address complex problems of interest to society.

For instance, a natural goal for IAGA scientists is to be able to understand and model the whole Sun-Earth system including the complex interactions and feedbacks controlling the transfer of energy momentum and matter between parts of the system. Research in this area is proving relevant to the problem of how to disentangle natural from anthropogenic causes of climate change. This area of science also underpins the understanding of how "space weather" conditions affect the risk to technological systems and human activities on the ground and in space. For example, during magnetic storms, electrical power distribution grids, radio communications, GPS accuracy, and satellite operations can be adversely affected. Also in the geohazards area, EMSEV is charged with establishing firm scientific understanding of the generation mechanisms of any signals that may help to mitigate the effects of earthquakes and volcanoes.

IAGA is responsible for the production of the International Geomagnetic Reference Field, used in a variety of scientific and "real world" applications, including navigation, and hydrocarbons exploration and production. The Association is responsible for the definition of the most widely used magnetic activity indices, and works closely with the International Service for Geomagnetic Indices, the body responsible for their production and distribution.

IAGA has a long history, and its science remains vigorous and relevant. Rapid advances in scientific understanding are resulting from improved instruments, better observations and data analysis techniques, the wealth of satellite data now routinely available, and the power of modern computer technology. As the 50th anniversary of the IGY approaches, IAGA is promoting the concept of an "Electronic Geophysical Year" (eGY), for 2007–2008, taking advantage of the modern capability to link distributed computing resources to multiple remote sources of data and modeling codes to address scientific problems. This initiative is in line with the Association's mission to promote international scientific cooperation and collaboration, and has the potential to advance the ability of scientists in developing countries to participate in leading-edge research.

(The principal point of contact with the Association is the IAGA Secretary General, and IAGA communicates with its members and the public through its Web site and through issues of *IAGA News*.)

## **IDEAL SOLUTION THEORY**

Consider two different substances; mix them together and in general they will form a *solution*, like sugar and coffee, for example. We call *solvent* the substance present in the largest quantity (coffee), and *solute* the other (sugar). In general solutions may have more than one solute, and/or more than one solvent, but for simplicity we will focus here only on binary mixtures.

The *behavior* of solutions can be understood in terms of the *chemical potential*  $\mu_i$ , which represents the constant of proportionality between the energy of the system and the amount of the specie *i* (Wannier, 1966):

$$\mu_i = \left(\frac{\partial E}{\partial N_i}\right)_{S,V} \tag{Eq. 1}$$

where *E* is the internal energy of the system, *S* is the entropy, *V* is the volume, and  $N_i$  is the number of particles of the specie *i*. Alternative equivalent definitions of the chemical potential are (Wannier, 1966; Mandl, 1997):

$$\mu_{i} = \left(\frac{\partial F}{\partial N_{i}}\right)_{T,V} = \left(\frac{\partial G}{\partial N_{i}}\right)_{T,p} = -T\left(\frac{\partial S}{\partial N_{i}}\right)_{E,V}$$
(Eq. 2)

where F and G are the Helmholtz and Gibbs free energies of the system, T is the temperature, and p is the pressure.

We recall the statistical mechanics definition of the Helmholtz free energy for a classical system (Frenkel, 1996):

$$F = -k_{\rm B}T\ln\frac{1}{\Lambda^{3N}N!}\int_{V} d\mathbf{R}_1 \dots \int_{V} d\mathbf{R}_N e^{-U(\mathbf{R}_1,\dots,\mathbf{R}_N;T)/k_{\rm B}T}, \quad ({\rm Eq.\,3})$$

where  $U(\mathbf{R}_1, \ldots, \mathbf{R}_N; T)$  is the potential energy which depends on the positions  $(\mathbf{R}_1, \ldots, \mathbf{R}_N)$  of all the particles in the system and on T,  $k_B$  is the Boltzmann constant and  $\Lambda = h/(2\pi M k_B T)^{1/2}$  is the thermal wavelength, with M being the nuclear mass and h the Plank's constant.

Consider now a solution with  $N_A$  particles of solvent A and  $N_X$  particles of solute X, with  $N = N_A + N_X$ . The Helmholtz free energy of this system is:

$$F = -k_{\rm B}T\ln\frac{1}{\Lambda_{\rm A}^{3N_{\rm A}}\Lambda_{\rm X}^{3N_{\rm X}}\mu_{\rm A}!N_{\rm X}!}\int_{V}\mathrm{d}\mathbf{R}_{1}\dots\int_{V}\mathrm{d}\mathbf{R}_{N}\mathrm{e}^{-U(\mathbf{R}_{1},\dots,\mathbf{R}_{N};T)/k_{\rm B}T}.$$
(Eq. 4)

According to (Eq. 2), we have:

$$\mu_{\rm X} = \left(\frac{\partial F}{\partial N_{\rm X}}\right)_{T, V} = F(N_{\rm A}, N_{\rm X} + 1) - F(N_{\rm A}, N_{\rm X}), \qquad (\text{Eq. 5})$$

which can be evaluated using (Eq. 4)

$$\mu_{\rm X} = -k_{\rm B}T \ln \frac{1}{\Lambda_{\rm X}^3(N_{\rm X}+1)}$$
$$\frac{\int_V d\mathbf{R}_1 \dots \int_V d\mathbf{R}_N \int_V d\mathbf{R}_{N+1} e^{-U(\mathbf{R}_1,\dots,\mathbf{R}_N,\mathbf{R}_{N+1};T)/k_{\rm B}T}}{\int_V d\mathbf{R}_1 \dots \int_V d\mathbf{R}_N e^{-U(\mathbf{R}_1,\dots,\mathbf{R}_N;T)/k_{\rm B}T}}.$$
(Eq. 6)

The ratio of the two integrals is an extensive quantity, but  $\mu_X$  is an intensive quantity; therefore it is useful to rewrite the expression as follows:

$$\mu_{\rm X} = -k_{\rm B}T \ln \frac{N}{(N_{\rm X}+1)} \left\{ \frac{1}{N\Lambda_{\rm X}^3} \frac{\int_V d\mathbf{R}_1 \dots \int_V d\mathbf{R}_N \int_V d\mathbf{R}_{N+1} e^{-U(\mathbf{R}_1,\dots,\mathbf{R}_N,\mathbf{R}_{N+1};T)/k_{\rm B}T}}{\int_V d\mathbf{R}_1 \dots \int_V d\mathbf{R}_N e^{-U(\mathbf{R}_1,\dots,\mathbf{R}_N;T)/k_{\rm B}T}} \right\}$$
(Eq. 7)

so that the value in curly brackets is now independent on system size. By setting  $c_X = N_X/N$  (which in the limit of large N and  $N_X$  is the same as  $(N_X + 1)/N$ ) and

$$\tilde{\mu}_{\rm X} = -k_{\rm B} T \ln \left\{ \frac{1}{N\Lambda_E^3} \frac{\int_V d\mathbf{R}_1 \dots \int_V d\mathbf{R}_N \int_V d\mathbf{R}_{N+1} e^{-U(\mathbf{R}_1,\dots,\mathbf{R}_N,\mathbf{R}_{N+1};T)/k_{\rm B}T}}{\int_V d\mathbf{R}_1 \dots \int_V d\mathbf{R}_N e^{-U(\mathbf{R}_1,\dots,\mathbf{R}_N;T)/k_{\rm B}T}} \right\}$$
(Eq. 8)

we can rewrite the chemical potential in our final expression:

$$\mu_{\mathrm{X}}(p,T,c_{\mathrm{X}}) = k_{\mathrm{B}}T\ln c_{\mathrm{X}} + \tilde{\mu}_{\mathrm{X}}(p,T,c_{\mathrm{X}}). \tag{Eq. 9}$$

The first term of (Eq. 9) depends only on the number of particles of solute present in the solution, while the second term is also responsible for all possible chemical interactions. For small concentration of solute we can make a Taylor expansion of  $\tilde{\mu}_{x}$ :

$$\tilde{\mu}_{\mathrm{X}} = \mu_{\mathrm{X}}^{0} + \lambda c_{\mathrm{X}} + o(c_{\mathrm{X}}^{2}), \qquad (\mathrm{Eq. 10})$$

where  $\lambda = (\partial \tilde{\mu}_X / \partial c_X)_{p,T}$ . If the solution is so dilute that the particles of the solute do not interact with each other, we can stop the expansion to the first term:

$$\mu_{\rm X}(p, T, c_{\rm X}) = k_{\rm B} T \ln c_{\rm X} + \mu_{\rm X}^0(p, T).$$
 (Eq. 11)

We define *ideal solution* a system in which (Eq. 11) is strictly satisfied.

To find an expression for the chemical potential of the solvent we employ the Gibbs-Duhem equation, which for a system at constant pressure and constant temperature reads (Wannier, 1966):

$$\sum_{i} N_i \mathrm{d}\mu_i = 0. \tag{Eq. 12}$$

In particular, in our two-components system the Gibbs-Duhem equation implies:

$$c_{\rm A}\mathrm{d}\mu_{\rm A} + c_{\rm X}\mathrm{d}\mu_{\rm X} = 0, \tag{Eq. 13}$$

which gives (Alfè et al., 2002a):

$$\mu_{\rm A}(p,T,c_{\rm X}) = \mu_{\rm A}^0(p,T) + (k_{\rm B}T + \lambda_{\rm X}(p,T))\ln(1-c_{\rm X}) + \lambda_{\rm X}(p,T)c_{\rm X} + O(c_{\rm X}^2), \qquad ({\rm Eq.~14})$$

where  $\mu_A^0$  is the chemical potential of the pure solvent. To linear order in  $c_x$ , this gives:

$$\mu_{\rm A}(p,T,c_{\rm X}) = \mu_{\rm A}^0(p,T) - k_{\rm B}Tc_{\rm X} + O(c_{\rm X}^2). \tag{Eq. 15}$$

Notice that this expression for  $\mu_A$  is not restricted to *ideal solutions*. Though  $\mu_A^0$  is the chemical potential of the pure solvent, observe that  $\mu_X^0$  is *not* the chemical potential of the pure solute, unless the validity of (Eq. 11) extends all the way up to  $c_X = 1$ .

## Volume of mixing

It is often interesting to study the change of volume of a solution as a function of the concentration of the solute. To this end, it is useful to express the volume of the system as the partial derivative of the Gibbs free energy with respect to pressure, taken at constant temperature and number of particles:

$$V = (\partial G/\partial p)_{T,N_{\rm X},N_{\rm A}}.$$
 (Eq. 16)

If we now add to the system one particle of solvent at constant pressure, the total volume changes by  $v_A$ , and becomes  $V + v_A$ . We call  $v_A$  the *partial molar volume* of the solvent. The total Gibbs free energy is  $G + \mu_A$ , so that according to (Eq. 16)  $v_A = (\partial \mu_A / \partial p)_{T,N_X,N_A} = (\partial \mu_A / \partial p)_{T,c_X}$ , where the last equality stems from the fact that  $\mu_A$  only depends on  $N_X$  and  $N_A$ through the molar fraction  $c_X$  (we assume here that  $c_X$  does not change when we add one particle of solvent to the system, this is obviously true if the number of atoms of solvent  $N_A$  is already very large). The partial volume in general depends on  $c_X$ , p, and T, but under the assumption of ideality  $v_A = (\partial \mu_A^0 / \partial p)_{T,c_X}$ , and it depends only on p and T. In an ideal solution  $v_A$  is the same as in the pure solvent.

Similarly, the partial molar volume of the solute is:  $v_X = (\partial \mu_X / \partial p)_{T,c_X}$ , which becomes independent on  $c_X$  under the *assumption* of ideality. Notice that this is *not* in general equal to the partial volume of the pure solute.

As an illustration of the applicability of the *ideal solution* approximation, I mention the recent first-principles calculations of the density of the Earth's liquid outer core as a function of the concentration of light impurities like sulfur, silicon, and oxygen in liquid iron. As reported in (Gubbins *et al.*, 2004), explicit first-principles calculations of the density of the core were not able to resolve any departure from the prediction of *ideal solution theory*. However, we shall see below that for other properties *ideal solution theory* is not necessarily a good working hypothesis.

## Solid-liquid equilibrium

We want to study now the conditions that determine the equilibrium between solid and liquid, and in particular how the solute partitions between the two phases. Thermodynamic equilibrium is reached when the Gibbs free energy of the system is at its minimum (Wannier, 1966; Mandl, 1997), and therefore,  $0 = dG = d(G^{l} + G^{s})$ , where

superscripts s and l indicate quantities in the solid and in the liquid, respectively. In a multicomponent system, the Gibbs free energy can be expressed in terms of the chemical potentials of the species present in the system (Wannier, 1966; Mandl, 1997):

$$G = \sum_{i} N_{i} \mu_{i}.$$
 (Eq. 17)

Using (Eq. 17) and the Gibbs-Duhem equation (12), we obtain:

$$\mathrm{d}G = \sum_{i} \mu_i \mathrm{d}N_i. \tag{Eq. 18}$$

If the system is isolated, particles can only flow between the solid and the liquid, and we have  $dN_i^s = -dN_i^l$ , which implies:

$$\mathrm{d}G = \sum_{i} \mathrm{d}N_i(\mu_i^{\mathrm{l}} - \mu_i^{\mathrm{s}}). \tag{Eq. 19}$$

If  $\mu_i^l < \mu_i^s$  there will be a flow of particles from the solid to the liquid region  $(dN_i > 0)$ , so that the Gibbs free energy of the system is lowered. The opposite will happen if  $\mu_i^l > \mu_i^s$ . The flow stops at equilibrium, which is therefore reached when  $\mu_i^l = \mu_i^s$ . In particular, in our two-components system, the equilibrium between solid and liquid implies that the chemical potentials of both solvent and solute are equal in the solid and liquid phases:

where  $T_{\rm m}$  is the melting temperature of the solution at pressure *p*. Using (Eq. 9), we can rewrite the first of the two equations above as:

$$\tilde{\mu}_{\mathbf{X}}^{\mathbf{s}}(p, T_{\mathbf{m}}) + kT_{\mathbf{m}} \mathbf{ln} c_{\mathbf{X}}^{\mathbf{s}} = \tilde{\mu}_{\mathbf{X}}^{\mathbf{l}}(p, T_{\mathbf{m}}) + kT_{\mathbf{m}} \mathbf{ln} c_{\mathbf{X}}^{\mathbf{l}};$$
(Eq. 21)

from which we obtain an expression for the ratio of concentrations of solute between the solid and the liquid:

$$c_{\rm X}^{\rm s}/c_{\rm X}^{\rm l} = \exp\{[\tilde{\mu}_{\rm X}^{\rm l}(p, T_{\rm m}) - \tilde{\mu}_{\rm X}^{\rm s}(p, T_{\rm m})]/kT_{\rm m}\}.$$
 (Eq. 22)

In general  $\tilde{\mu}_X^l < \tilde{\mu}_X^s$ , because the greater mobility of the liquid can usually better accommodate particles of solute, and therefore their energy (chemical potential) is lower. This means that the concentration of the solute is usually smaller in the solid.

Equation (22) was used by Alfè et al. (2000, 2002a,b) to put constraints on the composition of the Earth's core. The constraints came from a comparison of the calculated density contrast at inner core boundary, and that obtained from seismology, which is between  $4.5\% \pm 0.5\%$  (Shearer and Masters, 1990) and  $6.7\% \pm 1.5\%$  (Masters and Gubbins, 2003). This density contrast is significantly higher than that due to the crystallization of pure iron, and therefore must be due to the partitioning of light elements between solid and liquid. This partitioning for some candidate impurities can be obtained by calculating  $\tilde{\mu}_{\rm X}^{\rm l}$  and  $\tilde{\mu}_{\rm X}^{\rm s}$ . Alfè *et al.* (2000, 2002a,b) considered sulfur, silicon, and oxygen as possible impurities, and using first-principles simulations, in which the interactions between particles were treated using quantum mechanics, obtained the partitions for each impurity. The calculations showed that for both sulfur and silicon  $\tilde{\mu}_X^l$  and  $\tilde{\mu}_X^s$  are very similar, which means that  $c_X^s$  and  $c_X^l$  are also very similar, according to (Eq. 22). As a result, the density contrast of a Fe/S or a Fe/Si system is not much different from that of pure Fe, and still too low when compared with the seismological data. By contrast, for oxygen  $\tilde{\mu}_{e}^{l}$  and  $\tilde{\mu}_{x}^{s}$ are very different, and the partitioning between solid and liquid is very large. This results in a much too large density contrast, which also does not agree with the seismological data. The conclusion from these calculations was that none of these binary mixtures can be viable for

the core. The density contrast can of course be explained by ternary or quaternary mixtures. Assuming no cross-correlated effects between the chemical potentials of different impurities, Alfè *et al.* (2002a,b) proposed an inner core containing about 8.5% of sulfur and/or silicon and almost no oxygen, and an outer core containing about 10% of sulfur and/or Si, and an additional 8% of oxygen.

It is worth noting that these calculations (Alfè *et al.*, 2000, 2002a,b) also showed that the dependence of  $\tilde{\mu}_{X}^{s}$  and  $\tilde{\mu}_{X}^{l}$  on  $c_{X}^{s}$  and  $c_{X}^{l}$  was significant, and therefore departure from *ideal solution* behavior. If nonideal effects were ignored, the calculations would result in an outer core containing about 12% of sulfur and/or silicon, and about 6% of oxygen.

## Shift of freezing point

The partitioning of the solute between the solid and the liquid is generally responsible for a change in the melting temperature of the mixture with respect to that of the pure solvent. To evaluate this, we expand the chemical potential of the solvent around the melting temperature of the pure system,  $T_m^0$ :

$$\mu_{\rm A}(p, T_{\rm m}, c_{\rm X}) = \mu_{\rm A}(p, T_{\rm m}^0, c_{\rm X}) - s_{\rm A}^0 \delta T + \cdots$$
(Eq. 23)

where  $\delta T = (T_{\rm m} - T_{\rm m}^0)$ , and  $s_{\rm A}^0 = -(\partial \mu_{\rm A}/\partial T)_{T=T_{\rm m}^0}$  is the entropy of the pure solvent at  $T_{\rm m}^0$ . We now impose continuity across the solid-liquid boundary:

$$\mu_{\rm A}^{\rm 0s}(p,T_{\rm m}^{\rm 0}) - s_{\rm A}^{\rm 0s}\delta T - kT_{\rm m}c_{\rm X}^{\rm s} = \mu_{\rm A}^{\rm 0l}(p,T_{\rm m}^{\rm 0}) - s_{\rm A}^{\rm 0l}\delta T - kT_{\rm m}c_{\rm X}^{\rm l},$$
(Eq. 24)

where we have considered only the linear dependence of  $\mu_A$  on  $c_X$  (See Eq. 15). Noting that  $\mu_A^{OS}(p, T_m^0) = \mu_A^{OI}(p, T_m^0)$  we have

$$\delta T = \frac{kT_{\rm m}}{s_{\rm A}^{01} - s_{\rm A}^{0\rm s}} (c_{\rm X}^{\rm s} - c_{\rm X}^{\rm l}).$$
(Eq. 25)

Since usually  $c_X^s < c_X^l$ , there is generally a *depression* of the freezing point of the solution.

Using (Eq. 25), Alfè *et al.* (2002a,b) estimated a depression of about 600–700 K of the melting temperature of the core mixture with respect to the melting temperature of pure Fe, and they suggested an inner core boundary temperature of about 5600 K.

# IGRF, INTERNATIONAL GEOMAGNETIC REFERENCE FIELD

### History of the IGRF

The IGRF is an internationally agreed global spherical harmonic model of the Earth's magnetic field whose sources are in the Earth's core (see *Harmonics, spherical* and *Main field modeling*). It is revised every 5 years under the auspices of the International Association of Geomagnetism and Aeronomy (see *IAGA, International Association of Geomagnetism and Aeronomy*).

The concept of an IGRF grew out of discussions concerning the presentation of the results of the World Magnetic Survey (WMS). The WMS was a deferred element in the program of the International Geophysical Year, which, during 1957–1969, encouraged magnetic surveys on land, at sea, in the air, and from satellites and organized the collection and analysis of the results. At a meeting in 1960, the Committee on World Magnetic Survey and Magnetic Charts of IAGA recommended that, as part of the WMS program, a spherical harmonic analysis be made using the results of the WMS, and this proposal was accepted. Another 8 years of argument and discussion followed this decision and a summary of this, together with a detailed description of the WMS program, is given by Zmuda (1971). The first IGRF was ratified by IAGA in 1969.

The original idea of an IGRF had come from global modelers, including those who produced such models in association with the production of navigational charts. However, the IGRF as it was first formulated was not considered to be accurate or detailed enough for navigational purposes.

The majority of potential users of the IGRF at this time consisted of geophysicists interested in the geological interpretation of regional magnetic surveys. An initial stage in such work is the removal of a background field from the observations that approximates the field whose sources are in the Earth's core. With different background fields being used for different surveys, difficulties arose when adjacent surveys had to be combined. An internationally agreed global model, accurately representing the field from the core, eased this problem considerably. Another group of researchers who were becoming increasingly interested in descriptions of the geomagnetic field at this time were those studying the ionosphere and magnetosphere and behavior of cosmic rays in the vicinity of the Earth. This remains an important user community today.

#### Development of the IGRF

The IGRF has been revised and updated many times since 1969 and a summary of the revision history is given in Table II (see also Barton, 1997, and references therein).

Each generation of the IGRF comprises several constituent models at 5-year intervals, some of which are designated definitive. Once a constituent model is designated definitive it is called a Definitive Geomagnetic Reference Field (DGRF) and it is not revised in subsequent generations of the IGRF.

New constituent models are carefully produced and widely documented. The IAGA Working Group charged with the production of the IGRF invites submissions of candidate models several months in advance of decision dates. Detailed evaluations are then made of all submitted models, and the final decision is usually made at an IAGA Assembly if it occurs in the appropriate year, otherwise by the IAGA Working Group. The evaluations are also widely documented. The coefficients of the new constituent models are derived by taking means (sometimes weighted) of the coefficients of selected candidate models. This method of combining several candidate models has been used in almost all generations as, not only are different selections of available data made by the teams submitting models, there are many different methods for dealing with the fields which are not modeled by the IGRF, for example the ionospheric and magnetospheric fields and crustal fields. The constituent main field models of the most recent generation of the IGRF (IAGA, 2005) extend to spherical harmonic degree 10 up to and including epoch 1995.0, thereafter they extend to degree 13 to take advantage of the excellent coverage and quality of satellite data provided by Ørsted and CHAMP (see Ørsted and CHAMP). The predictive secular variation model extends to degree 8.

## Future of the IGRF

Firstly, no model of the geomagnetic field can be better than the data on which it is based. An assured supply of high-quality data distributed evenly over the Earth's surface is therefore a fundamental prerequisite for a continuing and acceptably accurate IGRF. Data from magnetic observatories (see *Observatories, overview*) continue to be the most important source of information about time-varying fields. However their spatial distribution is poor and although data from other sources such as repeat stations (see *Repeat stations*), Project MAGNET (see *Project MAGNET*), and marine magnetic surveys (see *Magnetic surveys, marine*) have all helped to fill in the gaps,

the best spatial coverage is provided by near-polar satellites. Measurements made by the POGO satellites (1965–1971) (see *POGO (OGO-2, -4, and -6 spacecraft*)), *Magsat* (1979–1980), POGS (1990–1993), Ørsted (1999–), and CHAMP (2000–) have all been utilized in the production of the IGRF.

Secondly, the future of the IGRF depends on the continuing ability of the groups who have contributed candidate models to the IGRF revision process to produce global geomagnetic field models. This ability is dependent on the willingness of the relevant funding authorities to continue to support this type of work.

Thirdly, the continued interest of IAGA is a necessary requirement for the future of the IGRF. This is assured as long as there is, as at present, a large and diverse group of IGRF-users worldwide. One reason why the IGRF has gained the reputation it has is because it is endorsed and recommended by IAGA, the recognized international organization for geomagnetism.

A topic still under discussion is how best to extend the IGRF backward in time. The current generation includes non-definitive models at 5-year intervals covering the interval 1900.0–1940.0, and, more importantly, some of the earlier DGRFs are of questionable quality. Constructing an internationally acceptable model that describes the time variation better than the IGRF using splines is one way forward (see *Time-dependent models of the geomagnetic field*).

## **INDUCTION ARROWS**

#### Introduction

The history of continuous magnetic field observations in Germany dates back to the 19th century (see *Observatories in Germany*). Modern observatory work began in 1930, with the foundation of the geomagnetic observatory in Niemegk, south of Potsdam. When a second observatory started operation in the late 1940s in Wingst, northern Germany, scientists soon noticed reversed signal amplitudes in the vertical field components between the two locations.

This observation was unexpected because magnetic field disturbances were known to be generated by large-scale processes in the Earth's atmosphere, far away from the surface of the Earth (see *Natural sources for EM induction studies*). Hence, for external sources, the magnetic field variations should have been very similar, given the relatively short distance between the two observatories. However, it was soon speculated that this peculiar behavior may be caused by electromagnetic induction of currents into an electrically conducting region deep in the earth's interior. When portable magnetometers became available, this phenomenon was investigated more systematically. With measurements following a N-S oriented profile at selected field sites, Schmucker (1959) could not only confirm the observatory results but could also confine the width of this North German anomaly to approximately 100 km.

Northern Germany was not the only place where magnetic field variations were studied; similar conductivity anomalies were reported from many other parts of the world. Over the years, some of the largest conductivity anomalies on Earth were identified with studies relating vertical magnetic fields to horizontal magnetic fields (see *Geomagnetic deep sounding*).

#### The induction arrow

Wiese (1962) and Parkinson (1962) independently developed graphical methods to locate the observed "induction effect," thereby inventing the induction arrow (IA). Both original definitions of the IA are based on a time-domain approach which is not in use any more. However, we still draw our IAs in either the Wiese or the *Parkinson* (q, v)convention according to their original designs (see Hobbs, 1992).

Functions that interrelate vertical or horizontal magnetic fields are known as transfer functions (see *Transfer functions*). If lateral conductivity variations exist within the subsurface on length scales equal to or greater than the penetration depth of the induced horizontal magnetic fields, a vertical magnetic field component is generated.

The frequency-domain, geomagnetic transfer functions  $T_x(\omega), T_y(\omega)$  are defined as (dependence on frequency assumed):

$$B_z = T_x B_x + T_y B_y \tag{Eq. 1}$$

*x*, *y*, and *z* denote north, east, and vertical directions, respectively. *B* is the magnetic field component in [*T*]. The IA is a graphical representation of the complex vertical magnetic field transfer function **T**. The real and imaginary parts of  $T_x$  and  $T_y$  can be combined to form  $\pm(T_{xr}, T_{yr})$  and  $(T_{xi}, T_{yi})$ . The visual display of the IAs in maps is a comprehensive presentation of changes in vertical magnetic field anomalies, both, as a function of frequency and location. In Parkinson convention the  $(-T_{xr}, -T_{yr})$  is plotted, which tends to point toward regions of higher conductivity. The IA in the Wiese convention  $(T_{xr}, T_{yr})$  tends to point away from areas of higher conductivity. Table 12 gives the definitions of the IAs in the Wiese and Parkinson conventions.

Figure I1 shows an example. The conductivity contrast associated with a fault zone can be either due to a juxtaposition of different lithologies (upper panel of Figure I1) or the damaged rocks within a fault zone can become conductive to form a conductive channel (*bottom panel* of Figure I1). If the conductivity contrast is assumed to extend indefinitely, both cases resemble a two-dimensional (2D) problem.

INDUCTION FROM SATELLITE DATA

**Figure 11** Expected and observed behavior of induction arrows (IA) for two different fault structures. In Wiese convention real (black) arrows point away from good conductors; imaginary (gray) arrows are parallel or antiparallel to the real arrows, given 2D Earth structure. Across a conductivity contrast (*top panel*) real IAs point away from the more conductive side and are largest over the less conductive side. Measurements from the Dead Sea Transform, locally known as the Arava Fault, are representative of this type of fault structure. A conductive fault zone sandwiched between more resistive units is characterized by IAs pointing away from the fault on both sides and small IAs over the fault zone conductor. The West Fault in Chile is representative of this type of fault structure. (Figure after Ritter *et al.*, 2005.)

The expected behavior for the real IA is indicated on the left-hand side of the figure. In 2D, the real and imaginary IAs point parallel or antiparallel to each other, and perpendicular to the strike of the structure. The largest real IAs are observed close to a conductivity contrast, they become smaller with increasing distance from that boundary. A larger conductivity contrast will also cause a longer arrow. Although vertical magnetic field response functions do not contain direct information about the underlying conductivity structure, they are extremely valuable in detecting the lateral extension and the strike of conductivity anomalies.

In the absence of lateral resistivity gradients IAs vanish. Real and imaginary IAs pointing obliquely indicate the influence of off-profile features of a more complicated three-dimensional Earth. The observed IAs on the right-hand side of Figure I1 show this influence to some extend but overall, they are still in good agreement with the simple 2D scenarios on the left. If IAs show great variation, both between sites and between real and imaginary arrows then a simple interpretation in terms of geoelectric strike direction is not possible.

Many scientists, including the author, prefer the term induction vector over IA because we construct and treat IAs like vectors, i.e., their length and the direction have a physical meaning. They are however, not vectors in a strict mathematical sense. IAs caused by a superposition of two different lateral conductivity contrasts which are linked by inductive coupling will generally not be the same as the vector constructed by adding the individual IAs. Furthermore, IAs are very sensitive to *electrical anisotropy* (*q.v.*) (Pek and Verner, 1997).

# **INDUCTION FROM SATELLITE DATA**

In addition to sources of internal origin, magnetic satellites record the variations in Earth's external magnetic field caused by interaction of the ionosphere and magnetosphere with the solar wind and radiation, along with the secondary magnetic fields induced in Earth. The ratio of the internal to external field may be used to probe the electrical conductivity structure of the planet. Satellite induction studies date from Didwall's (1984) early work with the POGO satellite data. Olsen (1999a) and Constable and Constable (2004a) provide reviews of satellite induction methods. Table 13 presents a list of past, present, and future magnetic satellite missions that are relevant to induction studies (*see MAGSAT, Ørsted, POGO*).

Table 13 Satellite missions relevant to magnetic induction studies, as of July, 2005

Longer period EM variations penetrate deeper into Earth, because EM fields decay exponentially with a characteristic length given by the skin depth, or

$$z_s \approx 500 \sqrt{T/\sigma}$$
 m

where  $\sigma$  is electrical conductivity (S m<sup>-1</sup>) and T is the period of the field variations (s). Traditionally, studies of deep Earth conductivity have relied on either the magnetotelluric (MT) method (q.v.) or the geomagnetic depth sounding (GDS) method (q.v.). For MT studies, time series measurements of horizontal magnetic and electric fields are transformed into frequency domain Earth impedance (see Transfer functions for EM). In GDS, observatory records of three-component magnetic fields (or data from portable arrays of instruments), along with an assumption about the geometry of the inducing field, are transformed into a similar impedance. MT studies have the advantage that they are largely independent of the geometry of the external fields, but because induced electric fields decay with increasing period, MT studies are limited to periods of less than a few days. GDS studies, on the other hand, have been extended out to the period of the 11-year sunspot cycle, the longest wherein field variations are external to Earth's core.

The usual assumption about the geometry of the external field variations is that it is dominated by the fundamental *spherical harmonic* (q.v.) aligned with Earth's internal dipole field called  $P_1^0$ . This is based both on observations of field geometry (e.g., Banks, 1969) and the morphology of the equatorial *ring current* (q.v.), which is composed mainly of oxygen ions circulating at a distance of 2–9 Earth radii (a review of the ring current is given by Daglis *et al.*, 1999). Within the satellite orbit, the magnetic field **B** can be expressed as the gradient of a scalar potential  $\Phi$ 

$$\mathbf{B} = -\mu_0 \nabla \Phi \tag{Eq. 1}$$

 $(\mu_0 \text{ is the magnetic permeability of space})$  where for  $P_1^0$  geometry  $\Phi$  is described by a spherical harmonic representation in radial distance from Earth's center *r*, Earth radius  $a_0$ , and geomagnetic colatitude  $\theta$ :

$$\Phi_1^0(r,\theta) = a_0 \left\{ i_1^0(t) \left(\frac{a_0}{r}\right)^2 + e_1^0(t) \left(\frac{r}{a_0}\right) \right\} P_1^0(\cos\theta).$$
 (Eq. 2)

In GDS studies, knowledge of the field geometry allows observatory time series measurements of vertical and horizontal components of the magnetic field to be separated into the internal  $(i_1^0)$  and external  $(e_1^0)$  coefficients, which may be Fourier transformed into the frequency domain to derive a complex geomagnetic response function of period:

$$Q_1^0(T) = i_1^0(T)/e_1^0(T).$$
 (Eq. 3)

**Figure 12** The equatorial ring current generates an external magnetic field of uniform  $P_1^0$  geometry (grey arrows). The external field variations induce an internal field (black arrows) which is also described by  $P_1^0$  geometry but that decays with altitude. The different altitude dependence and different directional behavior with latitude allows a separation of the internal and external fields using satellite measurements made during pole to pole passes.

**Figure 13** Amplitude spectrum taken from 13 years of the hourly Dst geomagnetic index. A broad peak in energy is seen around the 27-day solar rotation period, and narrow peaks at periods of 1 day and harmonics. The daily variations are generated mainly in the ionosphere, and are not  $P_1^0$  geometry. Power at frequencies lower than  $10^{-7}$  Hz is probably dominated by secular variation in the internal magnetic field.

The more familiar MT apparent resistivity and phase can be derived from the real and imaginary components of  $Q_1^0(T)$ , as can the inductive scale length C-response (see *transfer functions for EM*).

Magnetic satellites, collecting either scalar (total field magnitude only) or vector (three component) data, offer an opportunity to take GDS induction studies beyond the global observatory network. There are numerous advantages to using satellites for these types of studies:

- Global coverage can be achieved using satellites, while the magnetic observatory network is sparse, nonuniform, and restricted to land.
- 2. During each mission magnetic measurements are made using a single, high-quality instrument having a single calibration and which is removed from the distorting effects of crustal magnetic anomalies. Satellite magnetic sensors include scalar proton precession magnetometers, which are often augmented by vector fluxgate magnetometers oriented by star cameras (see *Magnetometers*).
- 3. Extensive spatial coverage means that the geometry of the inducing magnetic fields can be estimated, instead of being assumed.

Point (3) is illustrated in Figure I2. As a satellite makes a pass across the equator from pole to pole, the geometry of the magnetic field variations is different for the internal and external components. Variations in satellite altitude provide additional discrimination to fit the separate geometries of the internal and external fields.

Induction is powered by variations in the ring current intensity caused by interactions with the solar wind. During magnetic *storms* (q.v.), these may amount to a few hundred nanoteslas. A proxy for ring current intensity is provided by the Dst (disturbed storm time) magnetic index, a weighted average of horizontal fields at four low latitude magnetic observatories. Ring current variations are observed at periods of a few hours to many months or years, but are strongest at about 1 month because the solar wind is modulated by solar rotation.

Figure 13 shows an amplitude spectrum of the Dst index; power at the daily harmonics is caused by contamination from the daily variation in the magnetic field, generated in the ionosphere and by the Chapman-Ferraro currents outside the magnetosphere, and is more complicated than simple  $P_1^0$  geometry. Power at periods greater than 1 month is contaminated by secular variation of the main *magnetic field* (*q.v.*), of internal origin and unsuitable for induction studies. For GDS observatory studies, it is difficult to reject these contaminations and these periods have to be avoided, but satellite data have some power to reject non- $P_1^0$  geometries.

The above discussion ignores the contributions to the magnetic field that come from the main (internal) field and the *crustal field* (q.v.). These parts of the field must be removed before an induction analysis can be carried out, and therein lies one of the great difficulties of satellite induction. Without additional information, it is impossible to

**Figure 14** Without additional information, it is impossible to distinguish between temporal variations in the external magnetic field and spatial variations in the internal magnetic field sampled as the magnetic satellite flies though its orbit.

**Figure 15** Satellite responses from the MAGSAT (circles, from Constable and Constable, 2004b) and Ørsted (triangles, from Olsen *et al.*, 2003) missions, compared with Olsen's (1999b) long period observatory response for Europe (squares). The real components of C are positive, the imaginary are negative; error bars are one standard deviation.

distinguish between time variations in the ring current source field and spatial variations in the main and crustal fields sampled as the spacecraft flies over Earth. This is illustrated in Figure 14. A model of the main field that includes secular variation, along with a model of the crustal fields and possibly the daily variation, electrojets, and field-aligned currents must be used to remove all these elements before the induction analysis can be carried out. A convenient tool for removing these contributions is the Comprehensive Field Model of Sabaka *et al.* (2004).

Figure I5 shows GDS response functions from the MAGSAT and Ørsted satellite missions, compared with a response function generated using magnetic observatories. The agreement is generally good, and radial conductivity models generated from observatory data also fit the satellite responses fairly well. However, differences do exist. At short periods, the satellite response is influenced by oceans (Constable and Constable, 2004b). At long periods, there may be contamination of the source-field geometry, and some differences are undoubtedly due to the various analysis techniques. The subject of magnetic satellite induction is relatively young and many issues remain to be addressed. For example, there are complications to the ring current geometry that have largely been ignored (e.g., Balasis et al., 2004). The daily variation in the magnetic field has variously been considered a source of noise (Constable and Constable, 2004b) and a signal for 3D induction studies (Velimsk and Everett, 2005). Ultimately, the goal of satellite induction is to move beyond global response functions and radial conductivity models toward true 3D conductivity structure.

# INHOMOGENEOUS BOUNDARY CONDITIONS AND THE DYNAMO

#### Thermal core-mantle coupling and geodynamo

Modern observations indicate that the Earth's magnetic field takes the form of an approximate geocentric axial dipole, i.e., a dipole positioned at the Earth's center and aligned with the axis of rotation. Paleomagnetic measurements indicate that, when it is averaged over a sufficiently long time, this has been the case for the observable past. This suggests that the observed Earth's magnetic field is primarily the result of a geodynamo consistent with turbulent flows and rapid rotation (Moffatt, 1978). In consequence, the geocentric axial dipole is widely employed to provide a reference state for the Earth's magnetic field. Any persistent departure from the axial dipole is indicative of the external influence such as inhomogeneous boundary conditions on the geodynamo imposed by the overlying mantle (Hide, 1967; Bloxham and Gubbins, 1987; Bloxham, 2000).

Convection is occurring in both the Earth's outer core and mantle. However, there exists a huge difference between the timescales of mantle and core convection. Core convection has an overturn time of several hundred years while that of mantle convection is a few hundred million years. As far as the Earth's mantle is concerned, the core-mantle boundary is a fixed temperature interface. As far as the Earth's fluid core is concerned, the core-mantle boundary is rigid and imposes a nearly unchanging heat-flux heterogeneity on the core convection and dynamo.

The structure of the inhomogeneous boundary condition can be inferred from the seismic tomography of the Earth's lower mantle (for example, Masters *et al.*, 1996; van der Hilst *et al.*, 1997). By assuming that the hotter regions of mantle correspond to the lower seismic velocity while the cold regions are related to the anomalously high seismic velocity, the inhomogeneous boundary condition at the core-mantle boundary for the core convection and dynamo can be determined. The temperature variations above the core-mantle boundary impose a nearly unchanging heat-flux heterogeneity on the core dynamo.

Paleomagnetic and historical magnetic field measurements suggest persistent distinct patterns of variation of the geomagnetic field taking place in different regions of the Earth. For example, secular variation under the Pacific region is much slower than that under the Atlantic region (Bloxham and Gubbins, 1985; McElhinny et al., 1996). This longitudinal asymmetry of the geomagnetic field, the so-called Pacific dipole window, may be explained by thermal heterogeneity at the lower mantle. Bloxham and Gubbins (1987) proposed that thermal interaction whereby lateral variations in heat flux across the coremantle boundary drive core flows directly and influence the preexisting deep convection. Furthermore, comparison of the geomagnetic field at the core surface with lower mantle temperature or seismic velocity suggests a close connection between them (Gubbins and Richards, 1986; Gubbins and Bloxham, 1987) and order-of-magnitude estimates also suggest the variations are large enough to drive the core flow required for secular variation of the Earth's magnetic field (Bloxham and Gubbins, 1987).

The inhomogeneous boundary condition in heat flux or temperature at the core-mantle boundary, together with the strong effect of rotation, drive fluid motions directly in the outer core which influence the generation of geomagnetic field in the core. Moreover, an inhomogeneous boundary condition may also influence the core convection being driven from below by locking it to the nonuniform boundary condition (Zhang and Gubbins, 1993; Sarson *et al.*, 1997).

#### Inhomogeneous boundary conditions: models

With a uniform thermal boundary, convection takes place when and only when a sufficient radial temperature gradient, measured by the size of the Rayleigh number, exists to drive it. With a nonuniform thermal boundary, there are two driving parameters: one measures the radial buoyancy and the other the strength of the lateral heating. It follows that how an inhomogeneous boundary condition affects the core convection and dynamo can be illustrated by a simple nonlinear amplitude equation in the form

$$\dot{A} = (\mu + i)A - A|A|^2 + \epsilon, \qquad (Eq. 1)$$

where the flow amplitude A is a complex variable,  $i = \sqrt{-1}$ ,  $\epsilon$  is a positive parameter measuring the strength of the imposed inhomogeneous boundary condition (thermal or nonthermal) at the base of mantle, and  $\mu$  is a positive parameter like the Rayleigh number in connection with the deep core convection. The amplitude equation is simple but provides a helpful mathematical framework in the understanding of complicated nonlinear dynamics affected by an imposed inhomogeneous boundary condition.

Without lateral heterogeneity of the lower mantle,  $\epsilon = 0$ , convection is always in the form of an azimuthally traveling wave, such as convection rolls aligned with the axis of rotation. With the influence of the lateral heterogeneity  $\epsilon \neq 0$ , a steady equilibrium solution  $A_0$ becomes possible and can be obtained by setting  $\dot{A}_0 = 0$ . Denoting  $A_0 = X_0 + iY_0$  and  $Z = |A_0|^2 = X_0^2 + Y_0^2$ , we obtain the cubic equation

$$Z^{3} - 2\mu Z^{2} + Z(\mu^{2} + 1) - \epsilon^{2} = 0$$
 (Eq. 2)

for steady solutions of convection, which can be solved analytically using a standard formula. The stability of a steady solution  $A_0$  can be investigated by linearizing the nonlinear equation by letting

$$A = (X_0 + x) + i(Y_0 + y),$$
 (Eq. 3)

where x and y are small perturbations of  $X_0$  and  $Y_0$ . Stability of the nonlinear equilibrium  $A_0$  is then related to the two linear equations

$$\dot{x} = (\mu - 3X_0^2 - Y_0^2)x - (1 + 2X_0Y_0)y,$$
 (Eq. 4)

$$\dot{v} = (1 - 2X_0Y_0)x + (\mu - 3Y_0^2 - X_0^2)y.$$
 (Eq. 5)

The corresponding growth rate  $\sigma$  of the perturbations, or stability of the boundary-driven steady solution, is then described by

$$\sigma = (\mu - 2|A_0|^2) \pm (|A_0|^4 - 1)^{1/2}.$$
 (Eq. 6)

Two important features are evident from the stability of the boundarydriven steady solution: (i) a Hopf bifurcation (traveling wave convection) cannot occur if the amplitude is sufficiently large,  $|A_0| > 1$ ; (ii) a necessary condition for the occurrence of a Hopf bifurcation is  $\epsilon < \sqrt{2}$ . In other words, the core convection and dynamo in the presence of an inhomogeneous core-mantle boundary can be locked into the boundary provided that the effect is sufficiently strong,  $\epsilon > \sqrt{2}$ . It follows that the Pacific dipole window may reflect the thermal structure of mantle convection under the Pacific region.

Complex three-dimensional numerical simulations in rotating spherical geometry show a similar behavior revealed by the above simple model, demonstrating that an inhomogeneous boundary condition imposed by the lower mantle can alter the properties of core convection and dynamo in a fundamental way (Zhang and Gubbins, 1992, 1993; Sarson *et al.*, 1997; Olson and Christesen, 2002). The mantle convection imposes a different length scale upon the system of the core convection and dynamo. When a geodynamo model uses the inhomogeneous boundary condition derived from seismic tomography, it can produce an anomalous magnetic field and westward fluid velocity which are largely consistent with the observed features of the Earth's magnetic field (Olson and Christensen, 2002).

# INNER CORE ANISOTROPY

### Evidence for anisotropy of inner core

Anisotropy is the general term used to describe a medium whose properties (i.e., elastic properties in the case of seismic anisotropy) depend on orientation. Seismic waves in an anisotropic medium travel with different speeds depending on both their particle motion and propagation directions. The Earth's solid inner core was found to possess significant anisotropy in seismic velocity in the 1980s and early 1990s. Before that time, the inner core was known to us as a featureless small solid ball (at a radius of 1220 km) of iron-nickel alloy with some light elements.

The evidence for the anisotropy of the inner core came from two different kinds of observations: directional variations of travel-times

(a)

of seismic body waves that go through the inner core and anomalous splitting, splitting not explainable simply by Coriolis and ellipticity effects, of the Earth's normal modes that are sensitive to the structure of the Earth's core. Anomalies in inner core arrival times and in normal-mode splitting were observed in early 1980s (Masters and Gilbert, 1981; Poupinet *et al.*, 1983) and the hypothesis that the inner core is anisotropic was first proposed in 1986 (Morelli *et al.*, 1986).

Subsequent studies using travel-time data (e.g., Shearer et al., 1988) generally favored the existence of inner core anisotropy. However, the interpretation that anomalous splitting of core-sensitive modes is primarily caused by the anisotropy of the inner core was controversial (e.g., Widmer et al., 1992). Strong support for the inner core anisotropy was provided in the early 1990s when new sets of information started to emerge. Measurements of high quality differential travel-times of PKP waves (waves that pass through the Earth's core) show large travel-time anomalies (2-6 s) for rays traveling through the inner core nearly parallel to the Earth's spin axis (polar paths) (Creager, 1992; Song and Helmberger, 1993; Vinnik et al., 1994). Reanalysis of arrival time data also confirmed large travel-time anomalies (Shearer, 1994; Su and Dziewonski, 1995). At the same time, Tromp (1993) demonstrated that a simple transversely isotropic inner core explained the anomalously split core-sensitive modes and the larger, newly observed PKP differential travel-time anomalies reasonably well.

An example of the evidence for the inner core anisotropy from travel-time observations is shown in Figure I6. In analyzing travel-time data, residuals of travel-times that seismic waves (phases) take from an earthquake to arrive at recording stations are often formed by subtracting the times predicted for a standard Earth model from measured travel-times; similarly, residuals of differential travel-times are formed

**Figure 16** (a) Ray paths of PKP(AB) and PKP(DF) phases at near antipodal distances. The PKP(AB) phase turns at mid-outer core and the PKP(DF) phase passes through the inner core, sampling the bulk of the inner core at near antipodal distances as shown in this example. (b) Residuals of differential PKP(AB)-PKP(DF) travel-times for near antipodal paths (modified from Sun and Song, 2002). Assuming uniform cylindrical anisotropy in the inner core, the curve is the best fit to the data.

by subtracting the time differences between two phases concerned predicted for a standard Earth model from measured differential traveltimes. Figure I6b shows the residuals of differential between AB and DF branches of PKP waves (Figure I6a). Here the PKP(AB) is used as a reference phase to form the differential travel times, which eliminates bias from uncertainties in earthquake origin times and reduces the biases from earthquake mislocations and heterogeneous upper mantle; heterogeneity in the outer core is assumed to be small because of efficient mixing in the fluid core (Stevenson, 1987). The residuals for the polar paths are systematically larger than those of the equatorial paths, suggesting faster wave speed along the NS direction through the inner core than along the equatorial plane. Assuming cylindrical anisotropy with fast axis parallel to the spin axis, this data set indicates an average anisotropy of about 2.5% in P-velocity in the inner core.

## Three-dimensional structure of inner core anisotropy and heterogeneity

The presence of significant anisotropy in the inner core is now well accepted. The anisotropy appears to be dominantly cylindrical, with the axis of symmetry aligned approximately with the NS spin axis of the Earth. The detailed structure of the inner core anisotropy is still being mapped out. Some studies suggest the inner core has a simple constant anisotropy except for the innermost inner core (Ishii and Dziewonski, 2002). Other studies, however, suggest that the inner core anisotropy is more complex, varying both laterally and in depth, although some of the complexity may be due to contamination from the lowermost mantle heterogeneity (Breger *et al.*, 2000; Tromp, 2001).

The outermost part of the inner core appears nearly isotropic (Shearer, 1994). The thickness of the weak anisotropy layer varies from upper 100-250 km in the western inner core to upper 400 km or more in the eastern inner core (Creager, 2000; Souriau *et al.*, 2003). The transition from isotropy in the upper inner core to strong anisotropy in lower inner core under Central America appears to be sharp enough to cause multipathing of seismic waves (Song and Helmberger, 1998).

There is also growing evidence for strong lateral variation in inner core structure. The inner core appears to vary on all scales, from the scale of half a hemisphere to the scale of a few kilometers (Vidale and Earle, 2000; Cormier and Li, 2002). At the uppermost 100 km of the inner core, the P-velocity in the quasi-eastern hemisphere (40°E-180°E) is isotropically faster than the quasi-western hemisphere (180° W-40° E) by about 0.8% (Niu and Wen, 2001). At intermediate depth, 100-400 km below the inner core boundary (ICB), the inner core possesses a hemispherical pattern of a different form. The quasi-western hemisphere is strongly anisotropic but the quasi-eastern hemisphere is nearly isotropic (Tanaka and Hamaguchi, 1997). Deeper into the inner core, significant anisotropy ( $\sim$ 3%) seems to exist in both hemispheres (Creager, 2000; Souriau et al., 2003); however, in the innermost 300-400 km of inner core, it is suggested that the form of the anisotropy is distinctly different (Ishii and Dziewonski, 2002; Beghein and Trampert, 2003).

#### Sources of inner core anisotropy

Apparent seismic velocity anisotropy can, in general, arise from preferred orientation of anisotropic crystals or from lamination of a solid. The properties of the inner core are widely believed to be consistent with those of anisotropic iron crystals in the hexagonal close-packed (hcp) phase (e.g., Brown and McQueen, 1986). Thus, the anisotropy is believed to be due to a preferred orientation of the hcp iron (e.g., Stixrude and Cohen, 1995). However, the mechanisms responsible for creating such a preferred alignment are under debate.

One category of the proposed models involves texturing established during the solidification of iron crystals at the surface of the inner core. Possible mechanisms of solidification texturing include dendritic growth of iron crystals as they solidify (Bergman, 1997) and the development of anisotropic polycrystalline solid due to the presence of thermal gradient and initial nucleation in the melt (Brito *et al.*, 2002).

However, solidification texturing alone cannot explain the observed depth dependence of the anisotropy. The other category of the proposed models involves the alignment of iron crystals from plastic deformation in the inner core after solidification. Proposed mechanisms of plastic deformation in the inner core include solid state thermal convection driven by internal heating (Jeanloz and Wenk, 1988); flow induced by Maxwell stress (stress due to magnetic field) (Karato, 1999; Buffett and Wenk, 2001); and flow induced by a differential stress field created by preferential growth of the inner core in the equator than near the polar regions (Yoshida *et al.*, 1996).

#### Implications of inner core anisotropy

The inner core anisotropy has important implications for improving our understanding of the structure, composition, and dynamics of the Earth's deep interior. It has been suggested that the inner core is rotating relative to the mantle (Song and Richards, 1996). Detailed mapping of the lateral variations of the inner core anisotropic structure is crucial for quantification of the rotation rate (Creager, 1997), which would contribute to our understanding of the geodynamo (e.g., Glatzmaier and Roberts, 1995; Kuang and Bloxham, 1997) and could influence our interpretation of decadal variations in the length of day (Buffett and Glatzmaier, 2000). The understanding of the source of the inner core anisotropy is expected to improve our understanding of the inner core evolution and its interactions with the outer core (e.g., Romanowicz et al., 1996; Buffett, 2000). Viable models for the origin of anisotropy must be compatible with the estimates of symmetry, depth-dependence and lateral variations. The basic cylindrical symmetry of the inner core anisotropy probably reflects the strong influence of rotation on the dynamics of the fluid core. The absence of anisotropy from the uppermost region of the inner core suggests that any texture acquired during solidification is weak. However, a weak initial texture could be subsequently amplified by grain growth and plastic deformation. In this case, the rate of increase in anisotropy with depth is closely related to the relative rates of inner core growth, grain growth, and strain accumulation. The existence of sharp increase with depth and strong lateral variations of inner core anisotropy poses serious restrictions of the mechanisms responsible for the anisotropy. Improved models of the anisotropic structure of the inner core from seismic imaging will be vital in addressing these issues.

## INNER CORE COMPOSITION

#### Why is the inner core important?

The solid inner core is complex and not yet fully understood. This is hardly surprising given that the temperature of the Earth's core (q.v.)is in the range 5000-6000 K and inner core pressures are  $\sim$ 330-360 GPa. Knowledge of the exact composition and structure of the Earth's inner core would enable a better understanding of the internal structure and dynamics of the Earth as a whole; in particular, better constraints on *core composition* (q.v.) would not only have fundamental implications for models of the formation, differentiation, and evolution of the Earth, but would also enable successful interpretation of seismic observations which have revealed inner core anisotropy (q.v.), layering and heterogeneity (e.g., Creager, 1992; Song, 1997; Beghein and Trampert, 2003; Cao and Romanowicz, 2004; Koper et al., 2004). The elastic anisotropy of the inner core is well established: seismic velocities of the inner core (q.v.) show P-wave velocities  $\sim 3\%$  faster along the polar axis than in the equatorial plane (e.g., Creager, 1992). However, more recent seismic observations suggest further complexity. The evidence is for a seismically isotropic upper layer, with lateral variations in thickness of  $\sim 100-400$  km,

overlaying an irregular, nonspherical transition region to an anisotropic lower layer (Song and Helmberger, 1998; Ouzounis and Creager, 2001; Song and Xu, 2002). The existence of an isotropic upper layer implies that the magnitude of the seismic anisotropy in the lower inner core must be significantly greater than previously thought, possibly as much as 5%–10%. The observed layering also implies that the upper and lower inner core are compositionally or structurally different. Small-scale heterogeneities in the Earth's inner core have also been observed, possibly associated with phase changes, a "mushy layer," melt inclusions and/or compositional differences (Cao and Romanowicz, 2004; Koper *et al.*, 2004). The question now arises as to the mechanisms by which such complexity can occur, all of which could be highly compositionally dependent. Therefore, we cannot test any hypotheses for the observed features without knowing the inner core composition.

## The inner core is not just made of iron

The exact composition of the Earth's inner core is not very well known. On the basis of cosmochemical and geochemical arguments, it has been suggested that the core is an iron alloy with possibly as much as  $\sim$ 5 wt% Ni and very small amounts (only fractions of a wt% to trace) of other siderophile elements such as Cr, Mn, P, and Co (McDonough and Sun, 1995). On the basis of materials-density/ sound-wave velocity systematics, Birch (1964) further concluded that the core is composed of iron that is alloyed with a small fraction of lighter elements. The light alloying elements most commonly suggested include S, O, Si, H, and C, although minor amounts of other elements, such K, could also be present (e.g., Poirier, 1994; Gessmann and Wood, 2002). From seismology it is known that the density jump across the inner core boundary is between  $\sim 4.5\%$  and 6.7% (Shearer and Masters, 1990; Masters and Gubbins, 2003) indicating that there is more lighter element alloying in the outer core. The evidence thus suggests that the outer core contains  $\sim 5\%$ -10% light elements, while the inner core has  $\sim 2\% - 3\%$  light elements. Our present understanding is that the Earth's solid inner core is crystallizing from the outer core as the Earth slowly cools and the partitioning of the light elements between the solid and liquid is therefore crucial to understanding the evolution and dynamics of the core.

## Which phase of iron exists in the inner core?

Before tackling the more detailed problem of inner core composition (q.v.) in terms of alloying elements, it is essential to know what crystalline structure(s) are present and also their seismic properties, as these will greatly affect both interpretations made from seismic data and also the possible alloying mechanism. Many experimentalists have put an enormous effort over the last 10-15 years into obtaining a phase diagram of pure iron under core conditions, but above relatively modest pressures and temperatures there is still much uncertainty. Experimental techniques have evolved rapidly in recent years, and today, using diamond anvil cells or shock wave experiments (q.v.), the study of minerals at pressures up to  $\sim 200$  GPa and temperatures of a few thousand Kelvin are possible. These studies, however, are still far from routine and results from different groups are often in conflict. At low pressures and temperatures the phase diagram of iron is well understood: the body-centered-cubic (bcc) phase is stable at ambient conditions, transforming to the hexagonal close-packed phase (hcp) at high pressure (>10-15 GPa) and to the face-centered-cubic phase at high temperature (>1200 K). Both experiments and also theoretical calculations of the static, zero-Kelvin solid (Stixrude et al., 1997; Vočadlo et al., 2000), have suggested that the hcp phase has a wide stability field at high pressures and temperatures right to the conditions of the Earth's inner core. However, this assumption that iron must have the hcp structure at core conditions has recently been challenged (Brown, 2001; Beghein and Trampert, 2003), especially if the presence of lighter

elements is included (Lin *et al.*, 2003). It now seems very possible that a bcc phase might be formed (Vočadlo *et al.*, 2003). Previously, the bcc phase of iron was considered an unlikely candidate for an inner coreforming phase because athermal calculations show it to be elastically unstable at high pressures, with an enthalpy considerably higher than that of hcp iron (Stixrude and Cohen, 1995; Söderlind *et al.*, 1996; Vočadlo *et al.*, 2000). However, more recent *ab initio* molecular dynamics calculations at core pressures and temperatures have suggested that the bcc phase of iron becomes entropically stabilized at core temperatures. Although for pure iron the thermodynamically most stable phase is still the hcp phase, the free energy difference is so very slight that a small amount of light element impurity could stabilize the bcc phase at the expense of the hcp phase (Vočadlo *et al.*, 2003).

## Alloying elements

It is generally assumed that the small amount of nickel alloyed to iron in the inner core is unlikely to have any significant affect on *core properties* (q.v.) as nickel and iron have sufficiently similar densities to be seismically indistinguishable, and addition of small amounts of nickel are unlikely to appreciably change the physical properties of iron. However, the presence of light elements in the core does have an affect on core properties. The light element impurities most often suggested are sulfur, oxygen, and silicon. Although these alloying systems have been experimentally studied up to pressures of around 100 GPa (e.g., Li and Agee, 2001; Lin *et al.*, 2003; Rubie *et al.*, 2004) there seems little prospect of obtaining experimental data for iron alloys at the highly elevated pressures and temperatures of the Earth's inner core.

An alternative approach to understanding inner core composition (q.v.) is to simulate the behavior of these iron alloys with *ab initio* calculations which are readily able to access the pressures and temperatures of the inner core. Alfè et al. (2000, 2002) calculated the chemical potentials of iron alloyed with sulfur, oxygen, and silicon. They developed a strategy for constraining both the impurity fractions and the temperature at the inner core boundary (ICB) based on the supposition that the solid inner core and liquid outer core are in thermodynamic equilibrium at the ICB. For thermodynamic equilibrium the chemical potentials of each species must be equal both sides of the ICB, which fixes the ratio of the concentrations of the elements in the liquid and in the solid, which in turn fixes the densities. If the core consisted of pure iron, equality of the chemical potential (the Gibbs free energy in this case) would tell us only that the temperature at the ICB is equal to the melting temperature of iron (q.v.) at the ICB pressure of 330 GPa. With impurities present, the ab initio results reveal a major qualitative difference between oxygen and the other two impurities: oxygen partitions strongly into the liquid, but sulfur and silicon, both partition equally in the solid and liquid. Having established the partitioning coefficients, Alfè et al. (2002) then investigated whether the known densities of the outer and inner core, estimated from seismology, could be matched by one of their calculated binary systems. For sulfur and silicon, their ICB density discontinuities were considerably smaller than the known seismological value at that time of  $4.5\% \pm 0.5\%$  (Shearer and Masters, 1990); for oxygen, the discontinuity was markedly greater than that from seismology. Therefore none of these binary systems were plausible, i.e., the core cannot be made solely of Fe/S, Fe/Si, or Fe/O. However, the seismic data can clearly be matched by a ternary/quaternary system of iron and oxygen together with sulfur and/or silicon. A system consistent with seismic data could contain 8 mol% oxygen and 10 mol% sulfur and/or silicon in the outer core, and 0.2 mol% oxygen and 8.5 mol% sulfur and/or silicon in the inner core (Alfè et al., 2002). However, it should be remembered that it is likely that several other light elements could exist in the inner core and would therefore have to be considered before a true description of inner core composition could be claimed.

## **INNER CORE OSCILLATION**

Earth's inner core, identified in relatively recent time (*Lehmann*, 1936) (q.v.), can be considered to be an elastic solid on timescales of seismic waves. With a radius of 1220 km and hence containing less than 1% of Earth's volume, the inner core's importance to our understanding of Earth structure far exceeds both its relative size and our knowledge of its properties.

Decadal changes in Earth's magnetic field, linked to *torsional oscillations* (q.v.) of the fluid outer core, can produce corresponding oscillations of the inner core through electromagnetic coupling. Since the inner core is well coupled gravitationally to the mantle, both changes in *LOD* (q.v.)and polar motion of the mantle on a decade timescale could be used to constrain torsional oscillations (Dumbery and Bloxham, 2003) (see also *Inner core rotation*).

Gravitational force is responsible for holding the slightly denser inner core at Earth's center in the surrounding fluid core. Thus the inner core will return to this central equilibrium position if displaced axially and subsequently oscillate at periods of a few hours. This fact was initially recognized by Slichter (1961) who also realized that Earth's rotation would lead to two additional circular modes, one prograde and one retrograde if the inner core were displaced in a direction perpendicular to the rotation axis.

Theoretical values of three modes of oscillation, often referred to as the Slichter triplet, depend on the physical properties of the core described by the Earth model chosen, as well as the method used to calculate their periods. In the case of the Earth model 1066A (Gilbert and Dziewonski, 1975), for example, the buoyancy oscillation period without Earth rotation or degenerate period, is reported as 4.599 h by Rogister (2003), 4.309 h by Rieutord (2002), and 4.45471 h by Smylie et al. (2001). The central period of the triplet has been calculated using normal mode theory (Rogister, 2003), yielding estimates near 5.309 h for the Earth model PREM (Dziewonski and Anderson, 1981) and 4.529 h for 1066A which closely agree with those from perturbation methods (e.g., Dahlen and Sailor, 1979; Crossley et al., 1992) that ignored ellipticity and centrifugal effects. A central period of 4.255 h for 1066A has been found by Rieutord (2002) who reminded us that the buoyancy of the inner core is determined by the difference between the mean density of the inner core and its surrounding fluid rather than the density jump at the inner core-outer core boundary. An even shorter central period of 3.7926 h is predicted (Smylie et al., 2001) for the Cal8 Earth model (Bullen and Bolt, 1985) with a higher density inner core that experiences a larger restoring force when displaced.

The Slichter triplet has been the subject of search in gravimetric records since a movement of the inner core will produce a small change in Earth's gravitational field. Following the Chilean earthquake of May 22, 1960, a peak in the gravimetric record near 86 min was tentatively identified as an inner core oscillation, implying a much denser inner core than would be consistent with existing Earth models. Significant attempts had been made to detect the Slichter triplet by locating gravimeters near the South Pole where the diurnal and semidiurnal tidal effects are small (Rydelek and Knopoff, 1984) but there was no identification of the triplet.

In recent years, stable, low noise, superconducting gravimeters have allowed for the measurement of changes in gravity down to  $\pm 2 \times 10^{-11} \text{ ms}^{-2}$  in Earth's gravity field of about 9.8 ms<sup>-2</sup>. Thus, long records can be analyzed in the frequency domain for three spectral peaks separated by precisely the amount predicted by the Earth model chosen. Even with the above sensitivity, however, the signalto-noise ratios are so small that no one has yet observed the Slichter triplet in a single gravimetric record. By combining several superconducting gravimetric records with a wide geographical distribution, through a method known as product spectral analysis (Smylie et al., 1993), a claim has been made (Smylie et al., 2001) to have observed the Slichter triplet at periods 3.5822, 3.7656, and 4.0150 h with a statistical error of 0.04%. These observed values are reported to correspond to periods of 3.5168, 3.7926, and 4.1118 h predicted from the Cal8 model assuming the fluid core is inviscid. This identification and the method of analysis reported by Smylie et al. (2001) are yet to be widely accepted. Other groups have either failed to find the Slichter triplet (Hinderer et al., 1995) or, more recently, have reported several possible candidate signals for the Slichter triplet depending on the Earth model chosen (Rosat et al., 2004). Still others have cautioned (Florsch et al., 1995) that there is a high likelihood in finding significant fits to a triplet of spectral peaks even if one chooses the frequencies at random.

The rotational splitting of the Slichter triplet should include a contribution from viscosity of the liquid outer core as noted by Smylie (1999). Using boundary layer theory, he calculated the viscosity of the outer core fluid in a layer next to the inner core boundary, based on the small discrepancy between the observed and predicted triplet periods. He found a very high kinematic viscosity, close to  $10^7 \text{m}^2 \text{s}^{-1}$ , that was interpreted as confirming the semifluid nature of the layer at the base of the fluid core as the source of energy for the geodynamo. Such a large viscosity, however, brings into question the validity of results obtained by using only the leading term of the asymptotic series, as pointed out by Rieutord (2002). Future models that include dissipation due to turbulence (see *Core turbulence*) and partial solidification in the boundary layer around the inner core would decrease estimates of viscosity of the fluid core.

Periods of the Slichter triplet are extremely sensitive to the mean density of the *inner core* (q.v.), about 3 h for each gm cm<sup>-3</sup> for the axial mode (Smylie *et al.*, 2001), and thus would provide an independent estimate of that important quantity. Confirmation of the measured periods of the Slichter triplet will provide the basis for an estimation of the density jump at the inner core-outer core boundary, that is central to estimation of the inner core's age and its role in a geodynamo driven by compositional convection. Further improvement in signal-to-noise ratio of gravity measurements and a larger excitation of the inner core, whose source remains unknown, are needed to validate the detection of the Slichter triplet.

## **INNER CORE ROTATION**

Observational evidence of inner core rotation is based on changes in the travel-time of seismic waves. The rotation rate appears to be a few tenths of a degree per year eastward with respect to the mantle.

#### Early speculations

The inner core with radius of about 1215 km resides concentrically within the much larger fluid outer core, which has a low viscosity (e.g., Poirier, 1998). Patterns of convection within the fluid core

associated with the geodynamo are presumed to undergo temporal variations because the Earth's magnetic field is changing on timescales ranging over several orders of magnitude. It is therefore reasonable to speculate (Gubbins, 1981; Anderson, 1983) that the inner core might have a rotation rate somewhat different from that of the rest of the solid Earth, which is dominated by the daily rotation. If such relative rotation could be detected, it would provide information on the energy of convection patterns that maintain the geomagnetic field.

The study of inner core motion relative to the mantle and crust is difficult, because of the remoteness of the inner core (more than 5150 km from the Earth's surface where the nearest observations can be made) and its small size (about 0.7% of the Earth's volume). Also there are intrinsic difficulties in telling whether a spherical object is rotating, unless a marker on or within the object can be identified and tracked if it moves.

# First claims, based on seismological observations and implications

The first published claim of observational evidence for inner core rotation, relative to the mantle and crust, was given by Song and Richards (1996). They noted that seismic waves originating in the South Sandwich Islands (in the southernmost South Atlantic) and recorded in Alaska, which had traveled through the inner core, appeared to have traveled systematically faster for earthquakes in the later years during the period from 1967 to 1995, compared to observations of seismic waves from earlier earthquakes in this time period. The rate of travel-time decrease amounted to about 0.01 s  $y^{-1}$ — a value that was close to the precision of measurement.

More detailed studies by Creager (1997), Song (2000), and Li and Richards (2003), have provided additional support for travel-time change of about this same value, for seismic P-waves crossing the inner core. Figure 17 shows a clear example of PKIKP waves (which pass through the inner core) showing a faster arrival for the later earthquake, when the seismograms are aligned on PKP waves (which avoid the inner core).

Song and Richards (1996) interpreted the travel-time change as an effect of anisotropy, which causes P-waves to travel with speeds that depend on direction relative to a crystalline axis that rotates with the inner core. Creager (1997) persuasively argued for a more important marker of inner core rotation, namely a lateral gradient of the P wavespeed (increasing from east to west) in the part of the inner core traversed by PKIKP waves. He and Song (2000), Richards (2000), and Li and Richards (2003) concluded the observed travel-time changes indicate an eastward rotation of the inner core amounting to a few tenths of a degree per year.

The concept of an inner core rotating fast enough to be detected on a human timescale has attracted numerous investigators since 1996. Dehant *et al.* (2003) describe inner core research in mineral physics, seismology, geomagnetism, and geodesy. The rate of inner core rotation is an indication of the vigor of convection in the outer core, associated with the geodynamo. A nonzero rotation rate can be used to place limits on the outer core's viscosity (Buffett, 1997).

#### Counterclaims, and additional methods and evidence

Several papers since 1996 have argued that the seismological evidence for inner core rotation is equivocal. Thus, Souriau and Poupinet (in Dehant *et al.*, 2003) claim the reported travel-time changes of PKIKP waves on the path between the South Sandwich Islands and Alaska are an artifact of mislocated earthquakes. Early reports of purported changes in the absolute arrival times (not differential times) of PKIKP waves were later dismissed as based on inadequate evidence.

**Figure 17** One minute segments of short-period seismograms recorded at College, Alaska, for two earthquakes in the South Sandwich Islands (March 28, 1987 and August 14, 1995). For 30 s following the PKP arrival, and for an additional 3 min (not shown here), these seismograms (passed in the band from 0.6 to 3 Hz) show excellent waveform agreement for signals that have traversed the Earth but not via the inner core. For the PKIKP waveform, from time 250 to 255 s, an insert shows an expanded view of the narrowband filtered version of the two arrivals (in the passband from 0.8 to 1.5 Hz) that have traversed the inner core. With the two seismograms aligned on the PKP phase, it is seen that the PKIKP phase of the later event (shown in gray) traveled slightly faster. An explanation is that the inner core rotated during the 8-year period between the earthquakes, in a manner that provided a faster path for the later PKIKP signal through the inner core.

Laske and Masters have used normal mode data to study inner core inhomogeneities. Some modes appear to indicate eastward rotation, others westward, and their paper in Dehant *et al.* (2003) concludes the rate is only marginally indicative of a small eastward rotation, about  $0.15^{\circ} \text{ y}^{-1}$  (but alternatively estimated as  $0.34 \pm 0.13^{\circ} \text{ y}^{-1}$  if the normal modes likely to be most contaminated by upper mantle structure are excluded). Vidale and Earle (2000) used backscatter from within the inner core, following PKIKP waves, to find an eastward rotation of the inner core amounting to a few tenths of a degree per year.

It appears that the strongest claims of evidence for inner core rotation derive from differential traveltimes, for earthquakes separated by several years and which occur at essentially the same location, generating very similar waveforms. The evidence for inner core rotation is still under debate, and consensus on inner core rotation will likely depend on whether examples such as that given in Figure 17 can be accumulated, since waveform doublets avoid artifacts of event mislocation. A report on 18 high-quality doublets with time separation of up to 35 years in the South Sandwich Islands region, observed at up to 58 stations in and near Alaska, provides such an accumulation (see Zhang *et al.*, 2005).

## INNER CORE ROTATIONAL DYNAMICS

For several decades after its discovery in 1936, the Earth's solid inner core (IC) played only a passive role in geodynamics. Now the ICs material properties, internal structure, and rotational dynamics are lively concerns of geomagnetism, seismology, and geodesy. Suppose the mantle spins about its figure axis  $\mathbf{e}_3$  at rate  $\Omega$  relative to the stars, i.e.,  $2\pi/\Omega = 1$  sidereal day (sd). In principle the IC can exhibit:

- a. differential rotation, i.e., spin relative to the mantle at angular rate  $\Delta \omega$  about the IC figure axis  $\mathbf{i}_3$  (where  $\mathbf{i}_3$  is possibly inclined at angle  $\epsilon$  to  $\mathbf{e}_3$ ) and
- b. small periodic changes in orientation of  $i_3$  relative to  $e_3$  (wobble) and relative to the stars (nutation).

The spinning IC can be regarded as a gyroscope bathed in the surrounding liquid outer core (OC), and will orient itself relative to the mantle in response to the torques exerted on it. Changes in OC flow will cause *fluid pressure torques* at the inner core boundary (ICB). The dominantly iron IC (see *Inner core composition*) is expected to have an electrical conductivity comparable to that of the OC, allowing it to be penetrated by changing magnetic fields generated by dynamo action in the OC, and experience *electromagnetic torques* as a result of Lenz's law. The OC viscosity is probably so small near the ICB that viscous torques are negligible (see *Core viscosity*). The vital importance of *gravitational torques*, exerted on the body of the IC not only by the OC but also by the mantle, has been realized only in the past two decades.

Braginsky (1964) first noted that one boundary condition on the geomagnetic dynamo is a (possibly nonzero) value of  $\Delta \omega$  fixed by the requirement of zero net electromagnetic torque on the IC. Gubbins (1981) pointed out that any equatorial component of  $\Delta \omega$  would be shielded by the electrically conducting lower mantle, and (by modeling the OC as a solid spherical shell rotating with the mantle) showed that a steady axial component could result from the balance of two electromagnetic torques: one exerted by the dynamo-generated field in the OC, and the other induced by the nonzero  $\Delta \omega$  itself. Such a torque balance was incorporated in their 2-D numerical hydromagnetic dynamo model by Hollerbach and Jones (1993), who found that the IC (by virtue of its finite electrical conductivity and solidity) played a crucial role in stabilizing dynamo operation. This was confirmed by the numerical 3-D model of a self-sustaining geodynamo created by Glatzmaier and Roberts (1995). This model predicted that, under the balance of both electromagnetic and viscous torques (assuming an artificially large value for OC viscosity for computational reasons), the IC rotates dominantly eastward relative to the mantle at a few degrees per year, changing on a timescale of 500 years. However Kuang and Bloxham (1997) found that a much smaller, more realistic, value of OC viscosity leads to an alternative dynamo in which  $\Delta \omega$ fluctuates, on a timescale of several thousand years, between eastward and westward values. (See Geodynamo, numerical simulations for details.) Buffett and Glatzmaier (2000) showed that dynamo models incorporating gravitational torques between the mantle and IC yield much smaller values of  $\Delta \omega$ , on average about 0.17 or 0.02° y<sup>-1</sup> eastward according as viscous torques do or do not act on the ICB.

Seismological evidence that the IC departed from isotropy and radial stratification began to emerge nearly two decades ago (see *Inner core anisotropy* and *Inner core composition* for details). Using such nonuniformities to directly determine IC rotation became an exciting new branch of seismology when Song and Richards (1996) realized that any tilt of the anisotropy axis away from the rotation axis would cause a systematic change with time in the travel-times of P-waves through the IC from the same source location to the same seismograph. They used 30 years of data to estimate a tilt of about 10° and  $\Delta \omega \cong 1^{\circ} \text{ y}^{-1}$  eastward. Su *et al.* (1996), analyzing a different but equally long data set, found  $\Delta \omega \cong 3^{\circ} \text{ y}^{-1}$ . However most subsequent studies, involving the passage

426

of a particular IC feature (anisotropy or lateral heterogeneity) across a particular ray path, led to smaller values of  $\Delta \omega$ , of order  $0.1^{\circ}$  y<sup>-1</sup> (e.g., Creager, 1997; Poupinet *et al.*, 2000; Vidale *et al.*, 2000; Isse and Nakanishi, 2002). A very different seismological approach (Laske and Masters, 1999) examined the effects of such nonuniformities on the spectra of nine free oscillations sampling the IC, and yielded  $\Delta \omega = 0.01 \pm 0.21^{\circ}$  y<sup>-1</sup>. Because such vibrations are comparatively unaffected by errors in locating seismic events and by local IC structure, and are independent of the earthquake source mechanism, this result seems particularly robust and provides strong evidence that  $\Delta \omega$  is likely to be small, possibly not significantly different from zero.

The latter result is consistent with the inference that the IC is likely to be gravitationally locked to the mantle, because the gravitational torque exerted on the IC by mantle heterogeneities, when the IC and mantle are not in their equilibrium orientation, greatly exceeds any other (e.g., electromagnetic) torque that might act to maintain such a misalignment (Buffett, 1996). A more extensive analysis of gravitational coupling between IC and mantle by Xu *et al.* (2000) showed that IC superrotation cannot be supported by such torques alone, and that unless  $\epsilon < 3^{\circ}$  the corresponding values of  $\Delta \omega$  far exceed those inferred from seismology. However, Buffett (1996) pointed out that a nonzero  $\Delta \omega$  could be sustained if the IC viscosity is low enough ( $<5 \times 10^{16}$  Pa s) to allow its shape to deform as the IC moves out of alignment with the mantle, but not so low as to quickly annul any misalignment.

Any seismological indications of a value for  $\Delta \omega$ , whether zero or nonzero, constitute only a recent snapshot of its possible behavior on the longer timescales of the geodynamo. Hollerbach (1998) concluded that a value for  $\Delta \omega$  will indicate the average angular velocity of the OC just above the ICB, but is unlikely to suggest a reliable estimate of magnetic field strength at the ICB unless seismology can detect fluctuations in  $\Delta \omega$  induced by torsional oscillations in the OC. At present, seismological data is not inconsistent with, but can hardly be regarded as constraining, recent dynamo models.

Periodic changes in orientation of  $i_3$  relative to  $e_3$  are a particularly interesting subset of the Earth's free oscillations, involving a redistribution of angular momentum within the rotating planet. The presence of the IC potentially adds two free modes to the Earth's polar motion spectrum: an ultralong period prograde inner core wobble (ICW) and a nearly diurnal retrograde wobble accompanied by a much larger, and prograde, long period free inner core nutation (FICN) The first discussions of the ICW (Busse, 1970; Kakuta et al., 1975) neglected gravitational coupling of the IC to the mantle. Models of IC rotational dynamics, taking into account gravitation, fluid pressure at the ICB, and elastic deformation using Earth properties from PREM, predict periods for the FICN of 475 sd and for the ICW about 2400 sd (Mathews et al., 1991). However, the first reported detection of the FICN, in an analysis of data from very long baseline radio interferometry (VLBI) by Mathews et al. (2002), indicated a period in the range 930-1150 sd. Buffett et al. (2002) attributed the lengthening over previous predicted periods to IC-OC electromagnetic coupling, due to penetration of the IC by a magnetic field of 7 mT at the ICB. So far the ICW remains below the level of detection in the data from VLBI and gravimetry (Guo et al., 2005). For the case of a rigid IC and mantle coupled only by gravitation and fluid pressure, Guo and Ning (2002) found that nonzero  $\Delta \omega$  has no effect on the FICN period but slightly shortens the ICW period, and inclination  $\epsilon$  slightly lengthens both periods. Dumberry and Bloxham (2002) showed that electromagnetic torques applied to the ICB by a radial magnetic field of a few microteslas can drive the Markowitz wobble, a somewhat enigmatic feature of the Earth's polar motion in which the rotation pole traces out (relative to the crust) a highly elliptical path with period about 30 years.

No longer treated with benign neglect, the rotational dynamics of the IC now provides essential content in geodynamo models, an interpretive challenge to seismologists probing the deepest interior of the Earth, and intriguing new features for geodesists exploring the small changes in the length of day and the motion of the pole.

## **INNER CORE SEISMIC VELOCITIES**

The inner core was discovered in 1936 by the Danish seismologist Inge Lehmann (1888–1993) from the observation of short-period P-wave arrivals in the shadow zone of the core, at a distance where no P-wave would arrive if the core was totally fluid. Since her discovery, major advances concerning the structure of the inner core have been made thanks to seismological studies, combined with observational and computational results in mineral physics. A good knowledge of inner core structure is important to specify the chemical and mineralogical nature of the iron alloy which constitutes the center of the Earth, and to constrain the Earth's differentiation process. It also has important outcomes for the thermodynamical and geodynamical properties of the Earth.

#### Investigation tools: seismic waves and normal modes

The structure and properties of the inner core are mostly constrained by two body waves: PKIKP, a P-wave transmitted through the inner core, and PKiKP, a P-wave reflected at the inner core boundary (ICB). They give information on the P-wave velocity and attenuation inside the inner core, on the topography and properties of ICB, and on the S-velocity and density contrasts at the ICB, as these parameters influence the P-wave reflection and transmission coefficients. In theory, the S-velocity is constrained by the phase PKJKP, which propagates as an S-wave in the inner core, but its observation is still controversial. The normal modes sensitive to inner core give information on the mean P- and S-velocities and mean density in the inner core. However, most of the modes sensitive to inner core structure have stronger energy in the mantle and in the liquid core.

The phase PKIKP, also called PKPdf, is often compared to core phases having their turning points inside the liquid core, namely PKPbc (which turns at the base of the liquid core with a path in the mantle very close to that of PKPdf), and PKPab (which turns in the middle of the liquid core) (See Figure 18, and Kennett's article on seismic phases). The differential travel-times between PKPbc and PKPdf, or between PKPab and PKPdf, are less sensitive than absolute travel-times to hypocenter mislocations, origin time errors, and upper mantle heterogeneities. PKPab, however, is strongly affected by the heterogeneities in the D" layer at the base of the mantle.

#### Mean radial model

The P-velocity profile inside the inner core is rather well constrained. The P-velocity increases from about  $11.02 \pm 0.02$  km s<sup>-1</sup> at the radius of ICB ( $1219 \pm 2$  km) to 11.26 km s<sup>-1</sup> at the center of the Earth (Dziewonski and Anderson, 1981; Kennett *et al.*, 1995). The P-velocity jump at the ICB is about 0.6-0.7 km s<sup>-1</sup>.

**Figure 18** Main seismological phases sampling the inner core, and reference phases sampling the liquid outer core which are used for comparison (see *Seismic phases*).

The S-velocity is mostly constrained from the periods of normal modes, which first gave evidence of the rigidity of the inner core (Dziewonski and Gilbert, 1971), and from the modeling of amplitudes of core phases with synthetic seismograms (Müller, 1973). It increases from 3.50 km s<sup>-1</sup> at the ICB to 3.67 km s<sup>-1</sup> at Earth's center. This leads to a high Poisson's ratio  $\sigma \approx 0.44$  inside the inner core (compared to 0.28–0.30 in the mantle), which is characteristic of solid metals.

The density is poorly constrained by the seismic data. The density jump at the ICB is deduced from the P-wave reflection coefficient at vertical incidence, and from the normal modes. A very large range of possible values have been obtained, the most recent ones being in the range  $0.6-1.0 \text{ g cm}^{-3}$  (Shearer and Masters, 1990; Cao and Romanowicz, 2004; Masters and Gubbins, 2004).

The velocity and density profiles are smooth, suggesting the absence of chemical stratification inside the inner core. Assuming the inner core results from the solidification of the liquid core, and taking into account the pressure at inner core condition (P = 330 GPa at the surface to 360 GPa at Earth's center), the velocity and density values favor an inner core composition depleted in light elements compared to the liquid core. Estimation of the temperature in the inner core, 5500–6500 K (see *Core temperature*), is strongly dependent on the presence and nature of these light elements, as well as the power released by compositional buoyancy, which is available to maintain the geodynamo.

The attenuation  $\gamma$  inside the inner core (or the quality factor  $Q = 1/\gamma$ ) is estimated from the broadening of the peaks of the core-sensitive eigenmodes, and from the amplitude variations of PKPdf. Normal modes generally lead to much higher *Q*-values than body waves. This discrepancy is possibly due to the different contributions in bulk and shear dissipation; it is however, not fully understood. For P-waves, the comparison of the amplitudes of PKPdf and PKPbc leads to a *Q*-value of the order of 200 in the uppermost 100 km of the inner core, increasing to about 400 between 150 and 300 km below ICB. The presence of liquid inclusions is proposed, at least in the external part of the inner core, to account for the low value of the quality factor (see Romanowicz and Durek, 2000, for a review).

## Anisotropy

Since the first observation of large-scale travel-time anomalies of PKPdf (Poupinet *et al.*, 1983), there have been many studies revealing the existence of a strong anisotropy in the inner core. Paths parallel to

the Earth's rotation axis ("polar paths") are about 3.5% faster than those parallel to the equatorial plane. This anisotropy is well established from absolute travel-times of PKPdf (e.g., Morelli *et al.*, 1986; Shearer, 1994; Su and Dziewonski, 1995), and from differential travel-times of core phases (e.g., Creager, 1992) (Figure 19). It takes about 1210 s for a P-wave to cross the Earth in the equatorial plane, 7 s less to cross it along the pole axis, once the influence of Earth ellipticity has been corrected. The anomalous splitting of inner core-sensitive modes is another argument in favor of P-anisotropy (Woodhouse *et al.*, 1986; Tromp, 1993; Romanowicz *et al.*, 1996; Ishii *et al.*, 2002); it may also give insight into S-anisotropy (Beghein and Trampert, 2003).

The question has arisen whether the anomalous propagation times and mode splittings could originate outside the inner core. A structure in the liquid core, in particular heterogeneity or anisotropy inside the inner core tangent cylinder or beneath the polar caps, which is

**Figure 19** Evidence for anisotropy in the inner core. *Top*: Travel-time anomalies (with respect to a mean model) of the inner core seismic phase PKPdf, compared to the liquid core phase PKPbc, as a function of the angle of the ray with respect to the Earth's rotation axis. Data sample the uppermost 500 km of the inner core. A faster propagation (low residuals) is observed for polar paths. The curve corresponds to a uniform structure with hexagonally symmetric anisotropy. *Bottom*: Same for absolute PKPdf travel-times extracted from bulletin data, for rays turning at different depths below inner core boundary (ICB). Note the absence of anisotropy at the top of the inner core. Data have been binned to avoid the predominance of some oversampled regions.

compatible with normal modes (Romanowicz and Bréger, 2000), is ruled out by the propagation times of core phases (Souriau *et al.*, 2003), and seems in any case hardly acceptable from a geodynamical point of view. On the other hand, an anomalous ellipticity of the inner core is ruled out by the PKiKP travel-times (Souriau and Souriau, 1989).

The favored explanation for anisotropy is the preferred orientation of anisotropic iron crystals. The hexagonal closed-packed form, Fe- $\epsilon$ , is often proposed (Stixrude and Cohen, 1995), but other structures of iron are also possible. The orientation of elliptical fluid inclusions provides another possible explanation. The mechanism able to generate a preferred orientation is however debated; processes such as convection in the inner core, solidification in the presence of a magnetic field, solidification texturing at the ICB, or growth in a stress field, have been proposed (see reviews and discussions in Buffett, 2000; Bergman, 2003).

The depth variation and lateral variation of anisotropy are important for understanding its physical nature and origin. Early studies proposed an anisotropy with cylindrical symmetry and possibly a slightly tilted symmetry axis (Creager, 1992; Su and Dziewonski, 1995). This tilt is however not strongly required by the data (Souriau *et al.*, 1997). The variation with depth of anisotropy reveals that the uppermost part of the inner core is isotropic (Song and Helmberger, 1995). The thickness of the isotropic layer seems to vary with longitude, from 100 km beneath the western hemisphere to about 400 km beneath the eastern hemisphere (Creager, 1999; Garcia and Souriau, 2000) (Figure 110). This difference explains the apparent hemispherical pattern of the anisotropy (Tanaka and Hamaguchi, 1997). However, an artifact due to strong heterogeneities in the lowermost mantle along some particular polar paths (in particular the very anomalous path from South Sandwich Islands to Alaska) cannot completely be ruled out.

At greater depth, there are some presumptions that the anisotropy may be different in the central 300-400 km of the inner core. Ishii and Dziewonski (2002) observe an orientation of the slow axis at  $45^{\circ}$  from the pole axis for waves penetrating deep in the inner core. From a normal mode inversion, Beghein and Trampert (2003) find a fast axis perpendicular to the Earth's rotation axis in the lowermost 400 km, which could suggest the presence of a different phase of iron.

**Figure 110** A possible model of inner core anisotropy explaining body wave data. Meridian cross-section. Structure with 3% anisotropy and fast axis parallel to Earth rotation axis surrounded by an isotropic layer of variable thickness. A different form of anisotropy may be present in the central 300–400 km of the inner core.

## Heterogeneities

Even though most of the propagation time anomalies are well explained by anisotropy, it is important to estimate whether heterogeneities could also contribute to these anomalies. Voigt's isotropic average of P-wave velocity seems almost invariant between the western and eastern hemispheres (Creager, 1999), indicating the same chemical composition of the two hemispheres. However, in the uppermost 50 km, a hemispherical P-heterogeneity has been detected by modeling the PKP waveforms sampling the ICB region (e.g., Niu and Wen, 2001). The absence of heterogeneity in the range of wavelengths 200–1000 km is evidenced from stochastic methods: the heterogeneity level is less than 0.3% at any depth (Garcia and Souriau, 2000). In the range 50–200 km, many studies have reported the possible existence of heterogeneities. However, it is not possible to prove that the heterogeneities effectively take place in the inner core, and not in the mantle.

On the other hand, the splitting functions of inner core-sensitive normal modes exhibit large-scale variations, a result which seems in contradiction with the previous ones. Note, however, that modes are mostly sensitive to S-heterogeneities, and that single modes give access only to the even part of the structure of the inner core (Laske and Masters, 2003).

Heterogeneities at very short wavelength have been detected in the uppermost 300 km of the inner core from the energy present in the coda of the PKiKP waves (Vidale and Earle, 2000). The observations are explained by scatterers of size  $\sim$ 2 km, with velocity contrast of 1.2%. The modeling of the inner core attenuation also suggests the presence of scatterers: small heterogeneities of length scale  $\sim$ 10 km with velocity perturbations of about 8%, due to the boundaries between single or ordered groups of crystals with various orientations, could explain the mean level of attenuation, as well as the apparent anisotropy in velocity and attenuation (Cormier and Li, 2002).

#### Conclusion

Our knowledge of inner core structure has been considerably improved during the last two decades, thanks to an increasing number of digital records with worldwide distribution, and to the availability of about 40 years of bulletin data. Major observational difficulties come from the perturbing effect of the D" layer, at the base of the mantle and from the uneven sampling of the Earth, in particular the scarcity of polar paths, that are crucial for investigating the anisotropy. The deployment of permanent ocean bottom observatories will help to overcome this difficulty in a near future.

There is general agreement about a 3% to 3.5% anisotropic internal structure with fast axis parallel to the Earth's rotation axis, surrounded by an isotropic layer. Other features, such as the hemispherical variation of the thickness of the isotropic layer, or the possibility of a different anisotropy in the deeper inner core, are still debated. Numerous questions remain unanswered, concerning in particular the S-velocity model, the P-anisotropy near the center of the Earth, and the physical cause of the anisotropic P-wave velocity.

An accurate knowledge of the inner core heterogeneities appears also necessary for being able to quantify a possible superrotation of inner core with respect to the mantle. Such analyses rely on the possibility to track inner core heterogeneities over several years or several decades. Although the results are still controversial, with most recent rotation rates in the range -0.2 to  $+0.4^{\circ}$ yr<sup>-1</sup> (Souriau and Poupinet, 2003), they will certainly improve in the future with the availability of longer and denser series of data.

# **INNER CORE TANGENT CYLINDER**

The Earth's core consists of a solid inner core of radius  $r_i = 1220$  km, and a fluid outer core of radius  $r_o = 3480$  km. The obvious geometry to study it would therefore appear to be spherical (or perhaps spheroidal, if one insists on taking into account the slight flattening induced by the rotation). However, one could also view it in terms of cylindrical geometry, in which case a new feature emerges, namely the inner core tangent cylinder, the cylinder just touching the inner core and parallel to the axis of rotation. Figure I11 shows this tangent cylinder C, as well as how the outer core is then divided into regions inside and outside C, with the region inside C further subdivided into two parts above and below the inner core. The purpose of this article is to discuss why it might be sensible to consider the Earth's core in terms of cylindrical geometry, and what the significance of this tangent cylinder therefore is.

**Figure 111** The circles represent the inner and outer core boundaries; the dashed lines then show the location of the inner core tangent cylinder. The dotted lines are the paths over which (Eq. 4) is to be integrated, with the dots at the ends indicating where the no normal flow boundary conditions are to be imposed. Note how these boundary conditions change abruptly across the tangent cylinder. See also Hollerbach and Proctor (1993) for the details of how this constant of integration  $U_0$  is determined (or not).

#### Cylindrical coordinates

To see why cylindrical coordinates in fact arise quite naturally, we begin by considering the Navier-Stokes equation governing the fluid flow in the outer core. In its simplest, Boussinesq form, this takes the form

$$Ro\left[\frac{\partial}{\partial t} + \mathbf{U} \cdot \nabla\right] \mathbf{U} + 2\hat{\mathbf{e}}_{z} \times \mathbf{U} = -\nabla p + E\nabla^{2}\mathbf{U} + \mathbf{F}_{\mathrm{M}} + \mathbf{F}_{\mathrm{B}},$$
(Eq. 1)

where  $\mathbf{F}_{M}$  and  $\mathbf{F}_{B}$  are the magnetic and buoyancy forces, respectively, the Rossby number  $Ro = \eta/\Omega r_{o}^{2}$  measures the importance of inertia, and the Ekman number  $E = v/\Omega r_{o}^{2}$  the importance of viscosity, both relative to the Coriolis force  $2\hat{\mathbf{e}}_{z} \times \mathbf{U}$ . Here  $\Omega$  is the Earth's rotation rate  $(7.27 \times 10^{-5} \text{ rad s}^{-1}), \eta \approx 2 \text{ m}^{2} \text{ s}^{-1}$  and  $v \approx 10^{-6} \text{ m}^{2} \text{ s}^{-1}$  the magnetic diffusivity and viscosity, respectively. Inserting the numbers, we therefore find that  $Ro = O(10^{-9})$  and  $E = O(10^{-15})$ , indicating the extreme dominance of rotation over inertia and viscosity.

If the dominant balance in the Navier-Stokes equation is thus

$$2\hat{\mathbf{e}}_z \times \mathbf{U} \approx -\nabla p + \mathbf{F}_{\mathrm{M}} + \mathbf{F}_{\mathrm{B}},\tag{Eq. 2}$$

then taking the curl (and using  $\nabla \cdot \mathbf{U} = 0$ ) one obtains

$$-2\frac{\partial}{\partial z}\mathbf{U}\approx\nabla\times(\mathbf{F}_{\mathrm{M}}+\mathbf{F}_{\mathrm{B}}). \tag{Eq. 3}$$

So we see that even though the geometry of the core is most obviously defined in terms of spherical coordinates  $(r, \theta, \phi)$ , the dynamics of the outer core naturally, indeed almost inevitably, lead to cylindrical coordinates  $(z, s, \phi)$ . And as we saw above, once one acknowledges the relevance of cylindrical coordinates, one invariably must consider the tangent cylinder as well.

## Shear layers on C?

One might suppose that the solution of (Eq. 3) is then simply

$$\mathbf{U} = -\frac{1}{2} \int^{z} \nabla \times (\mathbf{F}_{\mathrm{M}} + \mathbf{F}_{\mathrm{B}}) \mathrm{d}z' + \mathbf{U}_{0}(s, \phi), \qquad (\mathrm{Eq.}\ 4)$$

where the constant of integration  $U_0(s, \phi)$  is to be determined by the appropriate boundary conditions (no normal flow at  $r = r_i$  and  $r_o$ ). There are in fact severe difficulties with this approach (see *Taylor's condition*). However, here we simply wish to consider what happens as one crosses C. In particular, the boundary conditions to be imposed change discontinuously as one crosses C, as indicated in Figure 111. If the boundary conditions change abruptly though, one must expect that the constant of integration  $U_0(s, \phi)$  will also change, so according to (Eq. 4) the flow itself will be discontinuous everywhere along the tangent cylinder.

Any finite viscosity will of course smooth these discontinuities out into shear layers of small but finite thickness. Figure I12 shows two examples of such layers, at  $E = 10^{-5}$ . The panel on the left shows contours of the angular velocity in the so-called Stewartson layer problem, in which one imposes a slight differential rotation on the inner core (such as may indeed exist in the Earth—see *inner core rotation*).

In the axisymmetric Stewartson layer problem, the only component of the flow that would be discontinuous in the  $E \rightarrow 0$  limit is the angular velocity  $U_{\phi}/s$ , that is, a component of the flow tangential to C. If one considers the more general nonaxisymmetric problem, one finds that even the normal component  $U_s$  may be discontinuous. The right panel in Figure I12 shows such an example, and sure enough, we note that the layer that resolves the discontinuity at finite E is more severe than it was in the Stewartson layer problem.

Both the axisymmetric and nonaxisymmetric layers shown in Figure I12 are purely nonmagnetic. If one includes a magnetic field,

it seems likely that the tension in the field lines would tend to suppress such strong shear layers. At least in the nonaxisymmetric case, however, there is also a price to pay: Hollerbach and Proctor (1993) showed that a shear layer can only be avoided if the forcing (that is,  $\mathbf{F}_{M} + \mathbf{F}_{B}$ ) satisfies a certain integral constraint on C, and Hollerbach (1994b) showed further that the magnetic field does indeed evolve so as to satisfy this constraint. It would thus appear that there probably are no shear layers on C (the axisymmetric Stewartson layer is similarly suppressed by a magnetic field), but that instead one has certain integral constraints on C. The dynamical significance—and indeed the physical interpretation—of these constraints is not fully understood though.

**Figure 112** The panel on the left is from Hollerbach (1994a), and shows contours of the angular velocity  $U_{\phi}/s$  in the axisymmetric Stewartson layer problem. The panel on the right is from Hollerbach and Proctor (1993), and shows contours of  $U_s$  in a nonaxisymmetric shear layer problem. Both layers are at  $E = 10^{-5}$ .

b Core Field 1980, North Polar View

**Figure 113/Plate 10b** Contours of the radial magnetic field at the surface of the Earth's core in 1980, northern hemisphere, in equal area projection. The circle denotes the end of the tangent cylinder. Blue indicates a region where field lines enter the core, yellow to red where they exit, and the zero contour is a "magnetic equator" where the field is horizontal. Note the concentration of flux into two lobes in the northern hemisphere just outside the tangent cylinder, and the lack of flux inside the tangent cylinder.

#### Inside versus outside C

There are also a number of issues where it is not so much C itself, but rather whether one is inside or outside that matters. For example, the fact that the region inside C is further subdivided into parts above and below the inner core means that inside C Taylor's condition consists of two distinct integral constraints (at any given cylindrical radius s), whereas outside C there is only one integral over the entire extent of the cylindrical shell. What effect this has on the geodynamo is not known for certain, but given the general importance of Taylor's condition, it could be significant.

Another difference between inside versus outside C is how the height of fluid columns parallel to the rotation axis varies with *s*. Inside C, dH/ds is positive, whereas outside it is negative. The reason this may be important is that so-called Rossby waves (e.g., Salmon, 1998) propagate in the direction  $\nabla H \times \Omega$ , that is, westward inside C, eastward outside. However, as with the Stewartson layer, classical Rossby waves are a nonmagnetic phenomenon more usually associated with oceanography or meteorology, so it is not entirely clear how relevant they are to the Earth's core. Similar effects have also been observed though in convection-driven hydromagnetic waves (Zhang and Gubbins, 2002), so it seems that this distinction between inside and outside C does indeed persist into the magnetic regime as well.

Speaking of convection, numerous simulations have shown that the overall pattern of convection appears to be quite different inside versus outside C. (See *Core convection* or Kono and Roberts, 2002 for a summary of some of these results.) The reasons for this are not always apparent, but one effect that is likely to play a role is simply that inside C gravity and the rotation vector are largely parallel, whereas outside C they are predominantly perpendicular. Given the powerful influence that both of these effects have on convection (with gravity driving the whole process, of course), it seems likely that their relative orientation will also be important.

The inner core may also impart some stability to the geodynamo, because the magnetic field can only change inside it by diffusion, whereas in the outer core it can change by the much more rapid process of advection (Hollerbach and Jones, 1993). This longer timescale of the inner core has been used to explain the preponderance of *geomagnetic excursions* (q.v.), or aborted reversals, over full reversals of the geomagnetic field (Gubbins, 1999). The tangent cylinder may

enhance this stabilizing effect by providing a larger, cylindrical volume of "dead" space where the flow does not affect the magnetic field to any great extent. In particular, we note that the inner core by itself constitutes only 4% of the whole core volume, whereas the total region inside the tangent cylinder constitutes 18%. If the fluid inside C is relatively quiescent, it would therefore considerably boost this stabilizing influence.

## Observed effects on the Earth's field

Surprisingly, the effect of the inner core tangent cylinder is spectacularly visible in the Earth's magnetic field when projected down to the core surface. Figure I13/Plate 10b shows the vertical component

**Figure 114/Plate 10a** Contours of the same magnetic field as in Figure 113. The inner core is shown in red and the tangent cylinder is indicated, along with the circle where it intersects the surface in the northern hemisphere.

of the magnetic field at the surface of the core in the northern hemisphere. The dark circle is the top of the tangent cylinder, with radius  $20^{\circ}$ . Figure I14/Plate 10a shows the same field with a cutaway liquid core to illustrate the tangent cylinder. The vertical field is strongest not at the pole, which would be the case for an axial dipole, but in two lobes just outside the tangent cylinder. Similar lobes are present in the southern hemisphere: these are the four main lobes of the geomagnetic field responsible for the predominance of its dipole character; they are less mobile than the features at lower latitude associated with the *westward drift* (*q.v.*).

The pattern of lobes is symmetrical about the equator, Figure I15/ Plate 10c, suggestive of straight convection rolls touching the inner core (see *Convection, nonmagnetic rotating*). Numerical simulations and kinematic dynamo calculations show magnetic flux being concentrated at the surface by shear around the tangent cylinder and by downwelling associated with the convection rolls (see *Geodynamo, numerical simulations* and Gubbins *et al.*, 1999). It appears that the geomagnetic field is not generated strongly inside the tangent cylinder, and that most of the generation occurs just outside, as in some of the models. Note that the radial field is almost zero within the tangent cylinder in the northern hemisphere, and in Figure I13/Plate 10b there is a similar null patch in the southern hemisphere.

This lack of field near the poles probably explains why virtual paleomagnetic poles (VGPs), those determined from a single site measurement of the magnetic field direction assuming a *geocentric axial dipole* (*q.v.*), usually lie some distance (typically  $10^{\circ}$ ) from the geographic pole. The same is true of the present-day field. Only when a time average is done to produce a paleomagnetic pole, by averaging many samples from a rock unit that spans many thousands of years, is a reliable estimate obtained for the geographic pole (see *Pole, paleomagnetic*), and even then the match is not perfect. The departure of the VGP from the geographic pole is caused by the nonaxisymmetric nature of the field near the poles; this largely averages out with time as the main lobes drift. The departure of the resulting paleomagnetic pole is usually attributed to a nondipolar time average. For further discussion of the time average see Gubbins (1998).

## **INNER CORE, PKJKP**

#### General background

The inner core was detected by Lehmann in 1936 (Lehmann, 1936) based on observations of P-waves through the inner core (later called PKIKP phases) that were unexplained by the Earth models of that time. In her noteworthy paper Lehmann concluded: "The question of the existence of the inner core cannot however be regarded solely from a seismological point of view, but must be considered also in its other geophysical aspects." Indeed, in 1940 Birch hypothesized that the inner core may be the result of a liquid-solid phase change in iron (Birch, 1940). A solid inner core implies that shear waves can be locally present, and the phase PKJKP with a shear wave leg in the inner core should exist (Figure 116). The letter J in this phase notation denotes the shear wave path in the inner core, whereas I represents an inner core P-wave path. Similarly, the letter K denotes a P-wave passage through the outer core, and P and S stand for mantle P- and S-wave legs, respectively.

Thus, to confirm the inner core's solidity, the search for observations of PKJKP started in the 1940s. In his article on the history of inner core research, Bolt (1987) recalls Bullen's attempts to find PKJKP (see also Bullen, 1951), and numerous other seismologists have tried to identify PKJKP as well. The detection of PKJKP, however, has proven to be extremely difficult. The solidity of the inner core was eventually established in 1971 based on normal mode observations (Dziewonski and Gilbert, 1971), but identification of PKJKP remained a challenge to many seismologists.

## **PKJKP identifications**

PKJKP is difficult to detect because of its small amplitude. This is a consequence of its large spreading (see Figure 116), inefficient P-to-S and S-to-P conversions at the inner core boundary, and significant inner core attenuation (Doornbos, 1974). Furthermore, interference with other larger amplitude phases severely hampers a proper interpretation. PKJKP cannot be identified on individual seismograms, and therefore stacking of large number of seismograms is required. If different stations are used in the stack, slowness information can be obtained, which is essential for an unambiguous identification.

Julian *et al.* (1972) were the first to report observations of PKJKP. They stacked data of five earthquakes with magnitudes ranging from 6.0–6.3 recorded by the Large Aperture Seismic Array (LASA) in

**Figure 116** Schematic ray paths of PKJKP through mantle (P), outer core (K), and inner core (J).

Montana (USA). This first PKJKP claim was, however, controversial because the inferred inner core shear velocity is at odds with the shear velocity determined from the normal mode data  $(3.5-3.6 \text{ km s}^{-1})$ . It has been speculated that the observed signal was in fact the SKJKP phase instead of PKJKP, but the data were not reanalyzed.

It took more than 60 years after the detection of the inner core before two new reports of PKJKP were made. Both papers rely on advanced signal detection techniques combined with data from large magnitude (7.9-8.2) deep earthquakes. Okal and Cansi (1998) applied a multichannel correlation method to data of the 1996 Flores Sea event for eight stations of the French short-period seismic network. They identified PKJKP and the surface-reflected pPKJKP phase. Deuss et al. (2000) used 47 globally recorded broadband seismograms for the same Flores Sea event and employed a nonlinear stacking technique based on phase coherency. They compared the data stack with theoretical stacks computed from normal mode seismograms: (1) for a model with a solid inner core, and (2) for a model with a fluid inner core. Evidently, the difference between these two synthetic stacks is due to the presence of J-phases. Deuss et al. (2000) found that, due to interference, PKJKP cannot be identified unambiguously in the data of the Flores Sea event, but the combination of pPKJKP and SKJKP can be identified in the data.

Although recent claims have now been made, it remains difficult to observe the J-phases. For instance, Deuss *et al.* (2000) showed that the global broadband data do not allow identification of the J-phases for the magnitude 8.2 Bolivia earthquake of 1994 due to interference effects of other signals. For the same reason they dispute the PKJKP identification of Okal and Cansi (1998) in their data set.

#### Implications of PKJKP observations

PKJKP and other J-phases may now be detected under very favorable conditions: a very big earthquake ( $M \approx 8$ ), a station distribution with a large number of stations in the appropriate distance range, a favorable source depth and radiation pattern, and use of a sophisticated stacking technique. The detection itself, however, is not crucial anymore as the shear velocity is determined from normal mode data. Yet, observations of J-phases can still be important because they contain information

about attenuation and anisotropy, constraining the physical state of the inner core. The issue of inner core attenuation is briefly addressed by Deuss *et al.* (2000). They find that the shear-wave attenuation as given by reference model PREM (Dziewonski and Anderson, 1981) is in agreement with their data. It corresponds to a relatively high level of attenuation possibly due to partial melting (Loper and Fearn, 1983). Inner core shear wave anisotropy may be investigated by directional dependence of the PKJKP observations (e.g., parallel and perpendicular to the Earth's rotation axis). After the detection, this could be the next challenge in PKJKP research. However, normal mode measurements proved to be more efficient to determine these properties (Beghein and Trampert, 2003).

All in all, PKJKP is a phase that does not easily reveal the information it contains.

## INSTRUMENTATION, HISTORY OF

# Geomagnetic instruments before 1800: instruments in early navigation and science

Scientists and various practitioners have used a bewildering array of magnetic instruments over the last thousand years or so: the mariner's compass (many types), circumferentors, declinometers, variation

compasses, dip circles or inclinometers, theodolite magnetometers, variometers, bifilar magnetometers, Lloyd's and Schmidt's balances, earth inductors, and more recently, nuclear magnetic resonance magnetometers, saturable-core magnetometers, induction magnetometers, and more. This rich history, however, is characterized by short bursts of inventive activity followed by longer periods of diffusion of instrumental designs. Because this volume includes articles on the more common contemporary magnetic instruments (see *Archaeology, magnetic methods; Compass; Magnetometers, laboratory; Magnetic surveys, marine;* and *Observatories, instrumentaino*), this article emphasizes the earlier history of magnetic instruments and their use. It sets some current instruments against this backdrop (see also *History of geomagnetism*).

Although magnetism as a property of the lodestone was known since antiquity in both China and Greece, the first magnetic instruments unequivocally appear in the historical record in the 12th century CE (see Compass). Strong evidence now shows that the magnetic compass was in use in Europe around 1150 and in China around 1100 (Smith, 1992, pp. 25 and 33–38), with evidence the Chinese knew something of the magnetic needle's directionality for centuries. The first accounts that can be dated are the Meng Chhi Pi Than, a chronicle written by Shen Kua in 1088, and Alexander Neckam's De Nominibus Utensilium, written between 1175 and 1183. Shen Kua not only mentioned a "wet" compass (a needle floating on water) and balancing a needle on a horizontal edge, but also magnetic declination. Neckam's was the first European reference to a compass needle on a pivot (a "dry" compass), but it is possible he had never used one and was only reporting an increasingly common practice on ships at sea. The best known magnetic investigator of the 13th century, Petrus Peregrinus (Pierre de Maricourt), wrote his famous Epistola ... de Magnete in 1269. Peregrinus was a consummate experimenter and careful thinker. Familiar with the compasses used and discussed for about a century, he developed improved wet and dry compasses, with a scale of 360° attached (Smith, 1992, pp. 70–72). His significance lies in the clarity and completeness of his summation of magnetic knowledge.

From 1200 until around 1600, use of the compass and knowledge of its phenomena were restricted mainly to navigators and cartographers, although poets and philosophers discussed it frequently from the mid-13th century. Early 15th century German makers of sundials had a new use of the compass, the orientation of portable sundials. The mid- to late 16th century was a period of instrumental innovation and investigation of the nature of environmental magnetism, indeed, the beginning of geomagnetism. The Portuguese Pedro Nunes and João de Castro and the Englishmen *Robert Norman*, William Borough, and *William Gilbert* (q.v.) stirred interest in Earth's magnetism partly because of phenomena revealed by instrumental improvements.

These magnetic workers represent a mixing of the practical goals of navigators and more esoteric goals of improving the instruments and studying the phenomena revealed by them. Nunes and de Castro developed an improved "variation compass" and began paying closer attention to magnetic declination in the 1530s (Fara, 1998, p. 136). Norman focused on the dipping needle, conceived the dip circle (first described in print in 1581), and concluded that the seat of magnetism is within the Earth. Borough concentrated on improving instruments for measuring magnetic declination and Gilbert assembled the most complete résumé of magnetic experiments, a summa of magnetic knowledge to the time. No fundamental changes in instrument design occurred until near 1800. Nevertheless, two fundamental discoveries were made using improved instruments: the discovery by Henry Gellibrand (q.v.) in 1634 that declination varies over time and by George Graham in 1722 that declination varies daily according to a set pattern. During the 18th century artisans modified the variation compass with lighter needles, a box to enclose the needle, and the addition of reading microscopes and vernier scales. Another 18th century innovation was the tall azimuth visor, which allowed mariners to sight celestial objects high above the horizon.

Navigators and surveyors continued into the 18th and 19th centuries to be among the primary users of compasses. Their compasses "compensated" for declination by rotating the compass card so the needle pointed east or west of north (and by other means) and for inclination by weighting one end of the needle. In the 18th century, John England (of London) introduced steel needles in 1705, as did the Dutch in 1731 and P. Le Maire and d'Après de Mannevillette in 1745. Gowin Knight and John Smeaton, among others, continued to experiment with new designs (Fara, 1998, p. 136). More improvements were aimed at ease of use and dependability. Innovations were often encouraged by the British Board of Longitude, the French Academy of Sciences, and other institutions.

Ever since Robert Norman first discussed it in the late 16th century, the dip circle had been the least reliable magnetic instrument. The vertical needle was supported by a metal axis with pointed ends, inserted in glass or crystal cups. Friction often stopped the needle short of the direction of dip. Instrument makers tried many methods to minimize this friction, from lining the axle points and cups with gold or bell metal to adding "friction" wheels (McConnell, 1980, pp. 16–17; Good, 1998a, pp. 175–177).

Natural philosophers meanwhile, fascinated by the detail and complexity of the phenomena, worked with artisans to modify instruments. In 1777, Charles Coulomb proposed using a thread to suspend the needle and he derived the mathematical theory of torsional suspensions (see *Oscillations, torsional*). Jean Jacques Cassini soon used this type instrument at the Paris Observatory; Tiberius Cavallo, *Christopher Hansteen* (q.v.), and ultimately *Carl Friedrich Gauss* (q.v.) in the 1830s, elaborated on and perfected fiber-suspension instruments (Multhauf and Good, 1987, pp. 5–20; Good, 1998b). The instrument makers responsible for these devices included Étienne Lenoir, Thomas Jones, and George Dolland.

Instrument makers produced a variety of instruments for both navigation (and surveying) and for scientific investigation. The former instruments stressed durability and ease of use, the latter precision. Scientific use, however, included both fixed observatories—where size of the instrument was no concern—and expeditions by land or sea, in which size mattered. From the 1780s on, expeditions included geomagnetic research more often, though not until the late 19th century were dedicated geomagnetic surveys more commonplace.

The first completely new line of instruments to appear after the compass and dip circle started out simply as a different way to use these two instruments. George Graham observed the oscillating needle of a dip circle in 1723 but did not draw any conclusion regarding the intensity of magnetic force (McConnell, 1980, p. 26). Frederick Mallet used an oscillating compass needle in 1769 to measure the horizontal magnetic force. And in 1776 Jean Charles Borda discussed oscillations of a dipping needle as a measure of total magnetic force. An oscillating needle indicated magnetic intensity in the same way that a pendulum measured gravity: the shorter the period, the stronger the force. Until the 1830s, however, the results of different instruments could not be compared and were called "relative" measurements.

Soon many investigators were improving intensity instruments, developing methods to counteract problems like friction and the asymmetry of needles. Soon, too, scientists carried out magnetic intensity measurements on several expeditions: Jean-Françoise La Pérouse made measurements lost at sea in the 1780s. E.P.E. De Rossel, with the D'Entrecasteaux expedition, counted dip circle oscillations in 1792 and 1793 during a circumnavigation. *Alexander von Humboldt* (q.v.) continued and popularized the study of magnetic intensity during his expedition to South America, and Humboldt and J.L. Gay-Lussac continued this around Europe (Parkinson, 1998, p. 448). Humboldt used both instruments but began a trend among researchers to prefer to measure horizontal intensity with an oscillating, suspended needle. This led to a famous and popular instrument made by Christopher Hansteen in 1824, a needle suspended by a fiber. But the type was already widely established and used by others, too, including Coulomb

(McConnell, 1980, pp. 26–29). Hansteen used it for indicating both declination and horizontal intensity. Other magnetic researchers across Europe used and designed fiber-suspension instruments, including François Arago and C.F. Gauss (Multhauf and Good, 1987, pp. 15–16). Around 1830, the word magnetometer was applied to these instruments that measured magnetic intensity.

By 1800, all of the forms of magnetic instruments based on magnetic needles, for both application and research, were available, but the most dramatic innovations were still to come. The efforts by Arago and Humboldt to improve the quality of magnetic observations and to popularize them established a solid trade in magnetic instruments. The favorite maker of magnetic instruments of Arago and Humboldt, H.P. Gambey of Paris, supplied variation and dip instruments around the globe during the 1820s–1840s (see Figure I17). Soon, Gauss and Weber would change how the instruments were used and how the data obtained were analyzed, bringing on a new period of instrumental innovation in the 1830s.

# Classical geomagnetic instruments, from Gauss and Weber to the 1920s

When Carl Friedrich Gauss and Wilhelm Weber turned to geomagnetism in the 1830s, they developed several new geomagnetic instruments and procedures. Gauss and Weber developed a much larger fibersuspension instrument than usual for determining declination. Their magnetic needle weighed over 2 kg (and later ones 10 kg or more), in contrast with, e.g., Hansteen's needles measured in grams, to mitigate the effects of air currents. They used a much longer suspension, about 2 m. Hansteen's suspensions were under 20 cm. Most importantly, Gauss and Weber borrowed an innovation from J.C. Poggendorff. He had fixed a mirror to the end of the needle and observed it from about 5 m away using an observing telescope, arranged so that he could see in the mirror a scale fixed to the base of the tripod of the telescope. Gauss wrote that this new instrument, the Gauss-Weber magnetometer, let them measure declination with a dramatically higher precision, similar to that known in astronomy. Indeed, he wrote that this instrument made possible the scientific study of declination and horizontal intensity (Gauss and Weber, 1837, p. 11).

Gauss and Weber also changed the fiber-suspension, horizontal magnetometer fundamentally by changing the way it was used. Gauss announced a two-step procedure in 1832 for calculating Earth's horizontal magnetic intensity in mechanical terms, i.e., length, mass, and time. He called this an "absolute" method (see Gauss' determination of absolute intensity). Gauss and Weber's magnetometer described above was so large it filled the building. It became the standard observatory instrument for the Magnetische Verein, an association of magnetic observatories, which collaborated with Gauss and Weber in the 1830s and 1840s. They worked with instrument makers Moritz Meyerstein of Göttingen, F.W. Breithaupt of Kassel, and others to supply more than a dozen of these instruments for observatories from the United States to Russia. They also developed the first bifilar magnetometer for direct indication of changes in the horizontal magnetic force and several portable instruments. In the bifilar instrument, the twofilament suspension was twisted so that the magnetic needle was held perpendicular to the magnetic meridian. As the Earth's magnetic force changed, the needle moved (Multhauf and Good, 1987, pp. 16-19). This instrument type was later termed a "variometer" because it indicated directly the variation of a magnetic variable. Hence, while they did not use the word, Gauss and Weber's bifilar magnetometer was the first variometer.

Besides Gauss and Weber, Humphrey Lloyd (q.v.) most carefully analyzed magnetic instruments and their use in the 1830s. Like Gauss and Weber, Lloyd investigated sources of error and ways to optimize instruments. He developed "Lloyd's balance" to indicate changes in the vertical magnetic force (hence the second variometer) and an indirect method of measuring the vertical force through induction, in addition to his own designs for unifilar and bifilar magnetometers, both for observatories and for field use. He, like Weber, recognized that no portable magnetic instrument could match the precision of an observatory magnetometer. Also like Weber, he designed portable instruments of the greatest possible precision. Lloyd's instruments supplanted Gauss and Weber's for the British "Magnetic Crusade" of the 1840s and 1850s. C.J.B. Riddell illustrated and explained the selection of magnetic instruments used by British observers during the Magnetic Crusade, including their shortcomings, in his Magnetical Instructions (1844). He even included a catalog of the instruments, available from three British instrument-making shops.

Clearly, the mid-19th century witnessed a remarkable burst in instrumental innovation. The best illustration of this goes far beyond any instruments seen before: photographically self-registering instruments. Introduced in 1846, they transformed magnetic research. Variants came and passed quickly at first, but by the 1850s the market settled to just a few models, especially those by Charles Brooks and Patrick Adie, both of London. Self-registering instruments used a tightly focused light beam, directed by mirrors attached to the instruments' magnets, to trace a graph of varying declination, intensity, etc., on a moving film or paper. These instruments removed the drudgery of off-repeated visual measures. The data cascaded and overwhelmed magnetic workers, requiring greater staffing and more computational power.

National or regional magnetic surveys in France, England, the United States, and India, for example, in the late 19th century organized and routinized magnetic measurements. This spurred agencies in several countries to produce lightweight, robust field instruments. The "Kew-pattern" dip circle and magnetometer became standard in Britain, its colonies, and in the United States (Figures I18 and I19, Multhauf and Good, 1987, Figure 63). For the French magnetic survey, elegant, gem-like magnetometers and dip circles were fashioned of brass (Figure 120; Multhauf and Good, 1987, Figures. 38, 61, 64). The Prussian survey adopted a design by J.F.A.M. Eschenhagen, which other agencies decided was more appropriate for observatories because of its complexity (Multhauf and Good, 1987, Figure 41).

From the 1890s until about 1915, the US Coast and Geodetic Survey and then the *Carnegie Institution of Washington's Department* 

of Terrestrial Magnetism (DTM) (q.v.) systematically extended the traditional instruments based on magnetic needles and induction almost as far as they could go. The culmination was the DTM "Universal Magnetometer," (Figures 121 and 122) which packaged nearly everything needed for a complete magnetic survey in Tibet or deepest Amazonia into a wooden box barely 20 cm square and weighing 17 kg.

Schmidt's vertical balance, designed by Adolf Schmidt in 1915 at the Prussian Meteorological Institute, improved the measurement of vertical intensity. Instruments by Askania-Werke AG were very popular in prospecting in the mid-20th century. The Askania firm resulted from the combination of Werkstätten für Praezisions-Mechanik und Optik of Berlin with Centralwerkstatte Dessau in 1921.

The ultimate instruments along traditional lines were devised by Daniel La Cour of Denmark for the Second International Polar Year (1932–1933). His quartz horizontal magnetometer (QHM) and balance magnétique zero (BMZ) were "semiabsolute" instruments, which only required calibration yearly (Parkinson, 1998, p. 450; Chapman and Bartels, 1940, 1: 89–93). The QHM's high standard of accuracy within  $1\gamma$  or nT kept the La Cour instruments in use even into the 1980s (Forbes, 1987). Nevertheless, even in the 1920s and 1930s instruments were beginning to change dramatically again.

# Geomagnetic instruments since 1920: a second generation

As Parkinson has written, advances in magnetic materials and improvements in electronics ushered in the "second generation" of magnetic instruments around World War II(Parkinson, 1998, p. 450). Efforts to develop electrical methods of measuring geomagnetic variables started on simpler lines, shortly after 1900, under Arthur Schuster, L.A. Bauer, Adolf Schmidt, and others. These first instruments of the second generation used accurately determined electrical currents and tight engineering standards to measure magnetic variables. The Carnegie's DTM developed the first practical field earth inductor in 1913. Earth inductors improved the accuracy of inclination measurements to 0.1 min and eliminated time-consuming procedures with dip circles. In 1921, S.J. Barnett also developed a sine galvanometer at the DTM for absolute measurement of horizontal intensity.

Frank Smith, at Britain's National Physical Laboratory (NPL) in Teddington, developed one of the first standard instruments to use Helmholtz-Gaugain coils to measure a magnetic variable, in this case horizontal force. He did this in 1920, following an idea that Schuster suggested in 1914. According to one estimate, the Schuster-Smith magnetometer required only 8 min to produce and reduce an absolute measure of H, whereas the Gaussian oscillation/deflection method required 2.5 h. This magnetometer had an accuracy for horizontal intensity of 1 $\gamma$  or nT. In 1928, D.W. Dye developed a similar instrument at the NPL for vertical intensity, accurate to between 2 and  $4\gamma$ .

The US Naval Research Laboratory and Gulf Research and Development perfected absolute magnetometers based on Helmholtz-Gaugain coils in the 1930s and 1940s, with one eye especially on improving measurement of vertical intensity (always problematic) and the other eye on greater magnetic stability and greater accuracy in measuring horizontal intensity and declination as well. Victor Vacquier started developing a vertical-force instrument in 1940 in cooperation with the US Coast and Geodetic Survey. Vacquier continued during the War, and announced the Gulf Absolute Magnetometer in 1945. Commercialized forms of Helmholtz-Gaugain coil instruments became standards at observatories for decades.

The biggest changes came, however, when researchers started applying totally new materials and ideas to magnetic measurements from 1940 onward. Vacquier developed the saturable-core magnetometer (or fluxgate magnetometer) about 1940 for the Gulf Research and Development Corporation (see *Magnetometer*). He based it on the first saturable-core compass, patented in 1931 by H.P. Thomas, and a simple, saturable-core magnetometer by H. Aschenbrenner and G. Goubau of 1936. The core of the sensing element has a high magnetic permeability and is surrounded by an excitation coil. This is a vector instrument, which measures magnetic intensity in the direction of the sensor core.

World War II spurred on development of a fluxgate magnetometer in the United States for the detection of German submarines. Vacquier elaborated his "fluxgate" instrument and method. In 1941 Vacquier and a team developed a device called the magnetic airborne detector (MAD). The challenge was to align the magnetometer along Earth's total magnetic vector, a goal achieved by a stabilizing system driven by input from two mutually perpendicular "orienting" fluxgates in a plane perpendicular to the sensing fluxgate. One system used servo motors to move the instrument in a gimbal and a second system used an air-driven gyroscope by Sperry Gyroscope to maintain orientation. After the War, investigators in many countries developed numerous variants of these airborne magnetometers. Some were towed behind naval ships or airplanes and contributed to military purposes, but these instruments also led ultimately to the discovery of mid-ocean, seafloor spreading and to the mapping of mineral deposits. Other versions of fluxgates gradually replaced classic variometers (Forbes, 1987, p. 111) in magnetic observatories, or took their place in satellites (see Magsat and Ørsted) and planetary probes.

Other new types of magnetometers were introduced in the late 20th century, including proton precession, Superconducting Quantum Interference Devices (SQUIDs), optically pumped sensors, and others (see *Magnetometers*). The use of these newer instruments is discussed in other articles in this volume (see *Aeromagnetic surveying*; *Archaeology, magnetic methods*; *Magnetic surveys, marine*; and *Repeat stations*). The most important change in instrumentation in the last half-century, however, may have been the automation of observational facilities (see *Observatories, automation; Observatories, instrumenta-tion*). But perhaps it is too early to have historical perspective on these events. (See also Campbell, 2003, Chapter 4 for a current discussion of "Measurement methods," pp. 189–227.)

## Introduction and background

The planets and satellites (or moons) of our solar system are of several types. The terrestrial planets and moons are bodies like the Earth, which are made mainly of rocks and metals like iron. The inner planets, Mercury, Venus, Earth, and Mars are terrestrial planets. The Moon and some of the satellites of the planets in the outer solar system are terrestrial type bodies. The outer solar system planets are the gaseous giants Jupiter and Saturn and the icy giants Uranus and Neptune. The gaseous giants are made mainly of hydrogen while the icy giants are built mainly from things like water and methane. The substances in

the gaseous and icy giants are under enormous pressures and temperatures, so their physical states are very different from those that we encounter on Earth. At the very centers of Jupiter and Saturn there may be cores that resemble the terrestrial planets of the inner solar system. The satellites of the solar system reside mostly in orbits around the outer planets. Only Earth's moon and the small moons of Mars, Phobos and Deimos, circle the inner terrestrial planets. The outer solar system satellites are either terrestrial type bodies, like Jupiter's moon Io, or icy moons like Jupiter's moons Ganymede and Callisto, Saturn's moon Titan, and Neptune's moon Triton. As the name implies, the icy satellites are made mainly of a mixture of water ice, rock, and metal, with the ice making up typically around 50% of the moon by mass. Pluto and its moon Charon are icy bodies much like the icy satellites of the large outer planets. The interiors of many of the planets and moons of the solar system are depicted in Figure I23/Plate 12. The internal structures of all these bodies are based on theoretical models strongly constrained by observations, as discussed in the remainder of this article.

## Density and the interior of a planet

How do we know what the planets and moons are made of? There are clues from what we can identify either on the surfaces of these bodies or in their gaseous envelopes (elemental atmospheric compositions,

**Figure 123/Plate 12** Cutaway views of what lies beneath the surfaces of many of the planets and moons of the solar system. These models of the planetary interiors are based on a variety of geophysical observations as discussed in this article. Starting at the top and proceeding down to the right and then to the left are Neptune, Uranus, Saturn, Jupiter, Mars, Earth, Venus, and Mercury. Jupiter's four Galilean moons are arranged in line to the left of the planet (in order from right to left are Io, Europa, Ganymede, and Callisto). Earth's moon lies to its lower right. The bodies are not shown to proper relative scale. The figure was prepared by Calvin J. Hamilton and included here with permission.

chemical compositions and mineralogy of surface materials, surface geology), but one of the main indicators of overall composition is the density of the body, the ratio of its mass to volume. The sizes and masses of almost all planets and moons have been known for some time from astronomical observations, but the most current and accurate values are based on measurements by spacecraft that have landed on, orbited, or flown close by the bodies. The orbits of spacecraft are determined by the gravitational fields of the planets and moons, especially the fields of those bodies that are close to the spacecraft. The gravitational field of a body is the result of its mass and the way the mass is distributed inside the body. Therefore, tracking a spacecraft using its radio communication signal determines its orbit or trajectory from which the gravitational field and mass of a body can be inferred. The size and shape of a planet or moon can be obtained from images of the body acquired telescopically or by cameras onboard spacecraft. Detailed topographic maps of several bodies, e.g., Venus, Moon, and Mars, have been made by radar and laser altimeters on orbiting spacecraft. The volumes of planetary bodies follow directly from these types of measurements. Planets and moons are nearly spherical in shape and often the specification of a single average radius suffices to characterize the size of the body. Table I4 lists the masses, radii, and densities of the planets and major moons of the solar system.

The density of a planet or moon immediately tells us something about its interior because the materials from which planets are formed have characteristic densities. Rocks typically have densities about  $3000 \text{ kg m}^{-3}$ , metals have densities higher than about  $5000 \text{ kg m}^{-3}$ , and ices have densities of about 1000 kg m<sup>-3</sup>. The density of any material depends on pressure and temperature, variables that take on extreme values deep inside large planets. Accordingly, the significance of a planet's density also depends on its size. The inner terrestrial planets and the Moon have densities between about 3300 and 5500 kg m<sup>-3</sup> (Table I4). These bodies are mostly made of metal (iron) and rock. The Moon is relatively small, and its density reveals that it must be predominantly rock. Mercury's radius is only about 50% larger than the Moon's radius, but Mercury's much higher density requires that it be mostly metal compared to the mostly rocky Moon. The moons Ganymede and Titan are somewhat larger than the planet Mercury (Some moons are larger than some planets!), but they have densities of only about 2000 kg m<sup>-3</sup>. Ice must be a major component of these moons to explain such a low density. Triton, Pluto, and Charon are similar icy bodies.

#### Two-layer model of planetary interiors

The inference of interior composition and structure from density can be made more quantitative by constructing a model of a planet or moon. One of the simplest models of a planet is the so-called twolayer model in which the planet is represented by a spherical core of radius  $r_c$  and density  $\rho_c$  surrounded by a spherical shell of outer radius *R* and density  $\rho_c$ . The average density  $\overline{\rho}$  of such a model planet is

$$\overline{\rho} = \rho_{\rm c} \left(\frac{r_{\rm c}}{R}\right)^3 + \rho_{\rm s} \left(1 - \frac{r_{\rm c}^3}{R^3}\right) \tag{Eq. 1}$$

The average density  $\overline{\rho}$  is an observed quantity and is known. The quantities on the right-hand side of the equation  $\rho_c$ ,  $\rho_s$ , and  $r_c/R$  are model parameters and are unknown and to be determined. There are three unknowns in this simple model, core and shell densities and fractional core radius  $(r_c/R)$  and only one equation to constrain their values, so it is not possible to obtain a unique model of the planet. However, if, for example, reasonable values of the model densities can be assumed, then the fractional core radius can be determined. Of course, the model can be made more deterministic by adding additional observational constraints (equations) as we discuss later.

The simple two-layer model is in fact a reasonable first-order representation of the interiors of many planets and satellites. This is because many planets and moons are differentiated, i.e., the rock and metal have separated into a metallic core surrounded by a rocky shell or mantle. This likely happens during the early evolution of a planet when temperatures in its interior are high enough to melt the heavy metal (iron) which subsequently sinks and accumulates into a core at the center of the planet. We know this has happened for the Earth because seismological observations of the Earth's interior have detected the Earth's metallic core and have measured its density and radius. The Earth occupies a special position in the discussion of planetary interiors because we have observations of the Earth's interior. mainly from seismology, that are unavailable for other planets and moons. The one exception to this is the Moon; we also have seismic observations of the lunar interior from seismic stations placed on the Moon's surface during the Apollo exploration era. However, these data are not as informative about the Moon's interior as are the seismic data sets collected on Earth. For example, the lunar seismic data are unable to confirm the presence or absence of a small metallic core in the Moon. Seismic instruments placed on the surface of Mars by the

Viking spacecraft did not provide data that could be used to determine the planet's internal structure. For Earth, seismology has not only revealed the metallic core and the rocky mantle around it, but it has also shown that the core consists of a solid inner part and a liquid outer shell. Thus we talk about the inner core and the outer core of the Earth (Figure 123/Plate 12).

## Two-layer model of Mercury

Mercury, Venus, Mars, and the Galilean satellite Io are all believed to have metallic cores made mostly of iron surrounded by rocky shells or mantles (Figure I23/Plate 12). The first-order interiors of these bodies can be represented by a two-layer model. In the case of Mercury, the existence of a metallic core is based almost entirely on its density. Mercury's high density (Table I4) requires that it consist of more than 50% iron by mass, and it is likely that the iron has concentrated into a central core. If we assume that the density of Mercury's core is  $8000 \text{ kg m}^{-3}$  (a reasonable value for a mostly iron core) and that the density of its mantle is 3000 kg m<sup>-3</sup> (a representative value for rock) then according to (Eq. 1), the radius of Mercury's core would be nearly 80% of the planet's radius. Mercury can be thought of as a ball of iron with a relatively thin coating of rock (Figure I23/Plate 12). This result can also be seen in Figure I24, a graphical representation of (Eq. 1). Figure I24 plots  $\rho_c/\overline{\rho}$  against  $r_c/R$  for different values of  $\rho_s/\overline{\rho}$ . With the above values of  $\rho_c, \rho_s$ , and  $\overline{\rho}, \rho_c/\overline{\rho}$  is about 1.5,  $\rho_s/\overline{\rho}$ is about 0.55, and the position of Mercury on the plot would correspond to  $r_{\rm c}/R$  almost equal to 0.8. For the Moon, on the other hand,  $\rho_{\rm c}/\overline{\rho}$  would be in excess of 2,  $\rho_{\rm s}/\overline{\rho}$  would be nearly 1 (Table I4), and the position of the Moon on the plot would correspond to small values of  $r_{\rm c}/R$ .

Mercury is also known to have a magnetic field that is believed to be generated by a dynamo in its metallic core. The existence of Mercury's magnetic field supports the existence of its metallic core if the magnetic field is indeed generated in the way the Earth's magnetic field is produced, by convective motions of the highly electrically conducting core metallic fluid, i.e., by a core dynamo. Dynamo action requires a core to be at least partially fluid, so if Mercury's magnetic

**Figure 124** Normalized core density  $\rho_c/\overline{\rho}$  versus normalized core radius  $r_c/R$  for different values of normalized mantle density  $\rho_s/\overline{\rho}$  in a two-layer model of a planet.

field is produced by a dynamo, then not only must Mercury have a metallic core, but its core must also have a substantial liquid portion. Earth's metallic core is partially solidified, a result of the cooling of the core over geologic time. Dynamo action in the Earth occurs in its molten outer core. Mercury's core could also be solidifying from the inside out, similar to Earth's core, but the present operation of a dynamo in Mercury means that the planet, like Earth, has a liquid outer core sufficiently thick for a dynamo to operate. We will learn much more about the interior of Mercury with the successful completion of the Messenger mission. The spacecraft is presently on its way to orbit the planet; it is planned to make detailed measurements of Mercury's gravitational and magnetic fields and Mercury's rotational state, observations that can reveal a great deal about the interior of the body.

## Two-layer model of Venus

Like Mercury, the main constraint on the interior of Venus is its density. Venus is slightly smaller than Earth and its density is about 5% less than the density of the Earth (Table I4). Based on these similar properties, it is generally believed that the interior of Venus is like the interior of Earth, i.e., that Venus has a metallic, mainly iron core with a radius about half the planet's radius surrounded by a rocky mantle (Figure I23/Plate 12). Many spacecraft have orbited and landed on Venus, and we are quite certain that the planet does not have a magnetic field. So, unlike Mercury, we cannot use the existence of a magnetic field to support the existence of a metallic core inside Venus. Instead, we must explain why, if Venus is like Earth in its interior, Venus does not have a magnetic field like Earth does. There are several possible explanations for this, including the absence of a solid inner core in Venus. Because Venus is somewhat smaller than Earth and the pressure at its center is less than at the center of the Earth. Venus' core, though cooling over geologic time, may not have yet cooled sufficiently to freeze out an inner core. Inner core solidification might be necessary to drive a dynamo in the outer liquid core of a planet because the freezing of the inner core releases energy to drive the dynamo in the form of the latent heat of solidification and gravitational potential energy. Solidification of the Earth's inner core might play an essential role in driving the geodynamo. It might also be that Venus' core is simply not cooling fast enough to have a thermally driven dynamo because the planet's mantle cannot convect efficiently enough to remove a lot of heat from the core. Venus has no plate tectonics, an indication that its mantle convects sluggishly. Only when we can determine the extent of solidification of Venus' core through seismic exploration of the planet will we be able to identify the reason for the planet's lack of a magnetic field.

# Moment of inertia and interior of a planet, Mars and the Moon

When we come to discuss Mars and the Moon we are fortunate to have a crucial piece of information in addition to density that tells us a great deal about the distribution of mass inside a body. This is the moment of inertia C of the body about its rotation axis. The moment of inertia of a point mass about a rotation axis is the product of the mass and the square of the perpendicular distance of the mass to the axis. Planets and moons are not point masses, so their moments of inertia represent a summation or integral of contributions to the total moment of inertia from all the elements of mass within the body. It is easy to calculate the moments of inertia of idealized bodies. For example, the moment of inertia of a constant density sphere of radius R and total mass Mis  $0.4MR^2$ . Since the actual moment of inertia of a planetary body is some huge number, it is convenient to describe a planet's moment of inertia by scaling it to  $MR^2$ . The moment of inertia factor of a constant density sphere is then  $C/MR^2 = 0.4$ . The moment of inertia factors of planets and moons are less than 0.4 because these bodies are denser at depth than they are near the surface. The more a planet's mass is concentrated near its center the smaller is its moment of inertia. Planets and moons with metallic cores are obviously denser at their centers since iron is much denser than rock. Density also increases with depth in a planet because of the increase in pressure with depth. Extraordinary pressures experienced deep within planets compress rock and make it denser. The extreme pressures can even rearrange the minerals of the rock to create denser phases of the minerals. The tendency of pressure to increase density at depth in a planet occurs despite the effect of enhanced temperature deep within a planet. Most materials including rocks decrease in density with increasing temperature. Pressure overwhelms temperature as far as density is concerned. The moment of inertia factors of Earth, Moon, and Mars are given in Table I4. These are the only planets in the solar system for which we have direct measurements of the moment of inertia.

#### Moment of inertia and two-layer models, Mars

We will discuss how the moment of inertia of a planet can be determined, but let us first see how this property can be used to learn more about a planet's internal distribution of mass than could be deduced from density alone. The simple two-layer model of a planet provides an illustrative tool for this purpose. As discussed above, the two-layer model has three unknown quantities we would like to determine,  $\rho_c$ ,  $\rho_s$ , and  $r_c/R$ . Equation (1) and the known density provide one constraint on the three unknowns. The equation for the moment of inertia of a two-layer spherical body and the value of the moment of inertia provide a second constraint. The equation is

$$\frac{C}{MR^2} = 0.4 \left[ \frac{\rho_{\rm s}}{\overline{\rho}} + \frac{(\rho_{\rm c} - \rho_{\rm s})}{\overline{\rho}} \left( \frac{r_{\rm c}}{R} \right)^5 \right]$$
(Eq. 2)

and the left-hand side is known. There are now two equations for three unknowns, and we can construct a suite of models for a planet by considering, for example, a range of plausible values of  $r_c/R$ . Figure 125 shows the results of using (Eqs. 1 and 2) together with the known values of density and moment of inertia factor for the planet Mars (Table I4). The figure plots core density against  $r_c/R$  and represents the equation

**Figure 125** Core density as a function of normalized core radius  $r_c/R$  for a two-layer model of Mars constrained by the values of average density and axial moment of inertia.

$$\rho_{\rm c} \, (\rm kg \, m^{-3}) = 3\,935.0 \left[ \frac{\left( \frac{0.365}{0.4} \right) \left( 1 - \left( \frac{r_{\rm c}}{R} \right)^3 \right) - 1 + \left( \frac{r_{\rm c}}{R} \right)^5}{\left( \frac{r_{\rm c}}{R} \right)^5 - \left( \frac{r_{\rm c}}{R} \right)^3} \right]$$
(Eq. 3)

For plausible core densities corresponding to densities of iron or iron mixed with lighter elements like sulfur, values of  $r_c/R$  range from about 0.45 to 0.60. If the normalized core radius is about 0.45, then the density of the core is about 8250 kg m<sup>-3</sup> typical of the density of a pure Fe core. If the normalized core radius is 0.60, then the density of the core is about 5900 kg m<sup>-3</sup> typical of the density of a core containing both iron and sulfur as FeS. While the cores of terrestrial planets are composed mainly of metals like iron and nickel, the cores can also contain other lighter elements such as S or O. Indeed, based on the seismically determined density of the Earth's core and the measured density of iron at high temperature and pressure, it is certain that light elements are in the Earth's core in addition to Fe and Ni. The density and moment of inertia of Mars leave no doubt that Mars has a metallic core and rocky mantle (Figure I23/Plate 12). For plausible core densities the core radius is between about 1530 (0.45R) and 2040 km (0.6R) depending on core composition; the more iron-rich the core, the smaller it is. The mantle density is about 3400-3500 kg m<sup>-3</sup> depending on core size; smaller mantle densities correspond to larger cores. The results we find for Mars show that even simple twolayer models can provide strong constraints on certain global properties of planets and moons.

### Measuring moment of inertia from a planet's rotation

How do we determine the moment of inertia of a planet like Mars? Basically, we must be able to observe how a planet's state of rotation responds to external torques exerted on the planet. The rotation of a body is determined by an equation analogous to Newton's second law of motion for the linear movement of a body. Newton's second law states that the force applied to a body equals the product of its mass and acceleration. The analogous principle for angular motion states that the torque applied to a body equals the product of its moment of inertia and angular acceleration. The torque about an axis is the product of a force with the perpendicular distance between the force and the axis. Torques on planets arise from the gravitational pull of the Sun or the gravitational attraction of a planet's satellite. The torque applied to the Earth by the Moon significantly affects the Earth's rotation. Mercury and Venus have no satellites to influence their rotational states. Phobos and Deimos exert torques on Mars, but their combined effect is much less than the torque exerted on Mars by the Sun. The rotation or spin axes of Earth and Mars are tilted about axes normal to their orbital planes (the obliquities of Earth and Mars are 23.45° and 25.19°, respectively), and the gravitational torques on them cause their spin axes to precess about the orbit normals. Measurement of the precession rate together with knowledge of the forcing gravitational torque allows the determination of the axial moment of inertia from the form of Newton's law for angular motion. Astronomical observations have revealed the precession rate of the Earth's spin axis and in turn the Earth's moment of inertia. Radio tracking of the Mars Pathfinder Lander has yielded similar information for Mars. Laser ranging observations of the Moon made possible by reflectors placed on the lunar surface during the Apollo program have determined the Moon's rotational state and its moment of inertia. Moments of inertia of planets and satellites are summarized in Table I4. The table includes the direct measurements and values inferred indirectly by other means as discussed below.

#### Moment of inertia and interior of the Moon

The moment of inertia factor of the Moon ( $C/MR^2 = 0.3935$ , Table I4) is sufficiently close to 0.4 that the interior could be rock with an almost

constant density. Density would increase slightly with depth in such a body due to the increase of pressure with depth and the small increase of density could account for the small decrease in the moment of inertia factor below 0.4. Alternatively, the moment of inertia factor of the Moon is also consistent with it having a small iron core a few hundred kilometers in radius at its center (Figure I23/Plate 12). Though we do have seismic data for the Moon, these data do not constrain the possible existence of a metallic core. However, magnetic data for the Moon indicate the likelihood that it has an iron core. Magnetometers were placed on the lunar surface and in orbit around the Moon during the Apollo exploration program, and these instruments showed that while the Moon has no large-scale magnetic field at present, the lunar crust is magnetized. It is generally believed that the crust was magnetized at a time in the past when the Moon had an active dynamo, and the crustal rocks cooled through the Curie temperature in the presence of a lunar magnetic field. If the remanent magnetization of the Moon's crust was created in this way, then the Moon must have a metallic core that supported a dynamo in the past. The lack of a magnetic field at present could be due to the cooling of the Moon over geologic time, which has left it with a nearly solidified core in which dynamo action can no longer occur. Other explanations are also possible, but the cooling of a relatively small body like the Moon is expected to have substantially solidified its core. The lunar core may not be entirely solidified, or even partially frozen, according to an interpretation of the lunar rotational data from the laser ranging observations.

#### Mars crustal magnetization

A magnetometer on the Mars Global Surveyor spacecraft discovered that the southern highlands crust of Mars is also magnetized, and, in certain regions of Mars, even more strongly magnetized than Earth's most magnetic rocks (see Magnetic field of Mars). The southern highlands crust of Mars dates from the earliest phase of Martian evolution, the so-called Noachian, and its magnetization suggests that Mars had a magnetic field generated by an internal core dynamo in the distant past. The existence of a metallic core in Mars, as deduced from its density and moment of inertia, is consistent with the inference of a core from the magnetization of the Martian crust. The absence of a Martian dynamo at present could be explained in ways similar to those that offer explanations for the lack of present magnetic fields on Venus and the Moon. These include solidification of the core to the point where a dynamo cannot operate in the remaining liquid outer core or the inability of the mantle to cool the core at a rate large enough to drive a dynamo through thermal convection in the core. The detection of the solar gravitational tide on Mars through radio tracking of the orbiting Mars Global Surveyor has led to the conclusion that at least some outer portion of the Martian core is not solidified.

## Gravitational field and a planet's interior

Much can be learned about a planet's interior from measurements of its external gravitational field since the gravitational field of a body arises directly from the mass inside it. Each element of mass in a planet or satellite contributes to the external gravitational field according to Newton's law of gravitation, which states that the gravitational force exerted by an element of mass is directly proportional to the element's mass and inversely proportional to the square of the distance between the mass element and the point at which the force acts. The net gravitational force at a point outside a planet is obtained by summing the forces exerted by each mass element over the entire distribution of mass inside the body, taking proper account of the directional nature of the gravitational force. When a planet is in hydrostatic equilibrium (see below), its moment of inertia and internal structure can be deduced directly from the gravitational field measurements. The Earth is reasonably close to this state, but Mars is not, due to the uncompensated portion of the Tharsis uplift. The Moon is not in hydrostatic equilibrium, and it is not known to what extent Mercury and Venus might depart from this state. Thus, though we know the gravitational field of Venus quite well, we cannot use this knowledge to determine its moment of inertia and deep internal structure and, in particular, to verify that it has a metallic core like Earth. There are other bodies in the solar system that we think are in hydrostatic equilibrium. These include the outer planets with fluidlike interiors and the Galilean moons of Jupiter, Io, Europa, Ganymede, and Callisto. Measurements of the gravitational fields of these moons by the Galileo spacecraft have been used to deduce their internal structures.

The gravitational field of any planet is generally represented mathematically by a function known as the gravitational potential V; the gravitational force on a unit mass is the gradient or directional derivative of V. The potential is, in turn, given by a series of terms known as a spherical harmonic expansion. Spherical harmonics (q.v.) are functions of latitude and longitude that provide a basis for the representation of potential functions like the gravitational field external to a distribution of mass. These potential fields are solutions of Laplace's equation. The terms in the spherical harmonic expansion of the external gravitational field depend not only on latitude and longitude, but they also include a dependence on the radial distance r to the center of mass of the planet; the terms are inversely proportional to powers of r. The leading term in the spherical harmonic expansion of the external gravitational field is GM/r (where G is the universal gravitational constant and M is the mass of the planet). This is the gravitational field that would exist if all the mass of the planet were concentrated in a point at its center of mass. The next terms, there are five of them, are all proportional to  $r^{-3}$ . These terms can be thought of as arising from the ellipsoidal distortion of the planet's mass distribution. One of these terms,  $(GM/r)(R/r)^2 C_{20} (3 \sin^2 \phi - 1/2)$ , is of particular importance because the coefficient  $C_{20}$  (sometimes denoted by  $-J_2$ ) can be used, under certain circumstances, to determine the planet's axial moment of inertia. There is no term in the external gravitational potential proportional to  $r^{-2}$  because the origin of the coordinate system is fixed at the planet's center of mass (the center of mass is the point inside a mass distribution about which the mass distribution has no net moment).

# Hydrostatic equilibrium: determining *C* from the gravitational field

The gravitational coefficient  $C_{20}$  can be used to determine  $C/MR^2$ when a planet is in a state of hydrostatic equilibrium. A planet in hydrostatic equilibrium behaves like a fluid in response to forces exerted on the planet. Over geologically long times, rocks can behave like fluids and flow in response to forces exerted on them. The motions are very slow, but over geologic time the rocks in a planet can deform and move over large distances. This is the process that enables plate tectonics and mantle convection on Earth and allows the Earth, for example, to adjust to changes in the mass loading of its surface by postglacial rebound.. Fluidlike deformation of rock is facilitated by high temperature so that subsolidus creep generally occurs beneath a relatively cold and strong outer shell of a planet called the lithosphere. If the lithosphere is thick enough and strong enough to support the stresses associated with surface or subsurface mass anomalies, then the planet will not be in hydrostatic equilibrium. This is probably why the Moon is not in hydrostatic equilibrium, and a similar explanation might apply to the small planet Mercury if we find that it is also not in hydrostatic equilibrium. We are not safe in using  $C_{20}$  to determine  $C/MR^2$  for Mercury or Venus, but the procedure can be applied to the Galilean satellites of Jupiter.

For a body in hydrostatic equilibrium that is distorted by rotation and tides, it can be shown that  $C/MR^2$  is related to  $C_{20}$  by the Radau equation

$$\frac{C}{MR^2} = \frac{2}{3} - \frac{4}{15} \left[ \frac{4 - k_{\rm f}}{1 + k_{\rm f}} \right]^{1/2}$$
(Eq. 4)
where  $k_{\rm f}$  is the fluid Love number of the planet, which depends on its internal mass distribution and is given in terms of  $C_{20}$  by

$$k_{\rm f} = \frac{6}{5q_{\rm r}} (-C_{20}) \tag{Eq. 5}$$

for a tidally and rotationally distorted satellite in synchronous rotation about a planet (e.g., one of the Galilean moons orbiting Jupiter), or by

$$k_{\rm f} = \frac{3}{q_{\rm r}}(-C_{20})$$
 (Eq. 6)

for a planet distorted by rotation only (e.g., Earth or Mars), where

$$q_{\rm r} = \frac{\omega^2 R^3}{GM} \tag{Eq. 7}$$

and  $\omega$  is the rotational angular velocity of the body.

For Earth and Mars it is unnecessary to try to estimate  $C/MR^2$  from  $C_{20}$  using the Radau equation because  $C/MR^2$  has been determined directly from the observed rates of precession of the planets' rotation axes. However, it is useful to carry out the exercise to see how the approach works for these planets and to assess how far these planets are out of hydrostatic equilibrium. For bodies like the Galilean satellites of Jupiter, the only way we can estimate  $C/MR^2$  is to deduce it from the gravitational fields  $(C_{20})$  measured by radio tracking the Galileo spacecraft as it made multiple flybys of the moons. For Earth,  $q_{\rm r} = 0.0034498$  and  $C_{20} = -0.0010826$ , and the Radau equation yields  $C/MR^2 = 0.332$ , very close to the value of  $C/MR^2 = 0.3308$ deduced from precession of the Earth's rotation axis. For Mars,  $q_{\rm r} = 0.0045702$  and  $C_{20} = -0.001964$ , and the Radau equation yields  $C/MR^2 = 0.376$ , not close enough to the value of  $C/MR^2 = 0.365$ deduced from observations of the precession rate of the rotation axis of Mars (by radio tracking of the Mars Pathfinder Lander and Mars Global Surveyor orbiter) to yield reliable models of the Martian interior. The reason, as noted above, is that Mars is not in hydrostatic equilibrium because the Tharsis highland is a major mass load that is partially supported by the strength of the Martian lithosphere.

#### Galilean moons of Jupiter

A strong case can be made that the Galilean moons of Jupiter, Io, Europa, Ganymede, and Callisto are sufficiently close to hydrostatic equilibrium for their axial moments of inertia and internal structures to be inferred from their gravitational field coefficients  $C_{20}$ . These satellites are distorted by the tidal forces from the massive Jupiter and by the centrifugal forces of their rotations. The Galilean moons are in synchronous rotation about Jupiter (they keep the same face to Jupiter as they rotate about it) with periods of days (Table 15); the satellites are reasonably rapid rotators. Because they do not have the strength to resist the large tidal and rotational forces over geological time, their internal masses flow and adopt an equilibrium ellipsoidal fluid shape. Rotation flattens the moons along their rotational axes

Table 15 Orbital parameters of moons

Body	Average distance from planet (km)	Orbital period (days)
Io	$4.22 \times 10^5$	1.77
Europa	$6.71 \times 10^{5}$	3.55
Ganymede	$10.70 \times 10^{5}$	7.15
Callisto	$18.83 \times 10^{5}$	16.7
Titan	$1.222 \times 10^{6}$	15.94
Triton	$3.55  imes 10^5$	5.88

and produces equatorial bulges perpendicular to the axes of rotation. Each moon is also elongated by tidal forces along an axis that passes from its center of mass to the center of mass of Jupiter. The redistribution of mass into an ellipsoidal shape is the source of the contributions to the gravitational field represented by coefficients like  $C_{20}$ .

The gravitational fields of all the Galilean satellites have been measured by radio tracking the trajectory of the Galileo spacecraft as it repeatedly orbited Jupiter and flew by the moons. The subtle deflection of the spacecraft trajectory as it passes close to a moon and feels the pull of the moon's gravitational field provides a direct measure of the field. The Galileo spacecraft arrived at Jupiter in December of 1995 and explored the Jovian system until it was targeted to crash into Jupiter on September 21, 2003. The many flybys of the Galilean moons by the spacecraft over this nearly 8-year period provided all the gravitational data on which present models of the satellite interiors are based. Multiple flybys of Io were particularly useful in establishing that it is in hydrostatic equilibrium. A polar flyby of Io at an altitude of 300 km and equatorial flybys at altitudes between 100 and 200 km enabled independent determination of rotational and tidal contributions to the gravitational field. These separately determined gravitational field components are in a ratio consistent with the equilibrium ellipsoidal distortion of Io under Jovian tidal forces and rotation of Io. Io's actual shape, as determined from spacecraft images of the satellite, is also consistent with the equilibrium ellipsoid. Io is certainly in hydrostatic equilibrium, a condition expected for a body so hot in its interior that its mantle might be substantially partially molten. Even without melting, the rocks should be so hot that they should easily flow over geologic time. Io's high-temperature internal state is revealed by its active volcanism: Io is the most volcanically active body in the solar system. The energy for all this volcanic activity comes from the dissipation of tidally forced distortions of the body. The time-varying tidal distortions giving rise to heating are deformations in addition to the steady tidal distortion that gives rise to Io's quadrupole gravitational field. These additional tidal deformations are caused by the eccentricity of Io's orbit around Jupiter. There are no similar data to more rigorously establish the hydrostaticity of the other Galilean satellites.

# ю

Table I4 summarizes the physical characteristics of the Galilean satellites of Jupiter including, in particular, the densities and moments of inertia that are used to construct models of the moons' interiors. These properties are based mainly on the data acquired by the Galileo spacecraft. Two- and three-layer models of the interiors of the moons, based on these properties and the modeling approach discussed above, are shown in Figure I23/Plate 12. Io, about the size of the Moon, is differentiated into a metallic core and rocky mantle. If Io's core is pure iron with a density of about 8 090 kg m<sup>-3</sup> then its radius is 650 km or about 36% of Io's outer radius. The mass of this Fe core is about 10% of Io's total mass. If the core consists of a eutectic Fe-FeS alloy with a density of about 5150 kg m<sup>-3</sup>, then its radius is about 950 km or about 36% of Io's outer radius. The mass of this Fe-FeS core is about 20% of Io's total mass. The magnetometer on the Galileo spacecraft did not detect an Ionian magnetic field on its flybys of the satellite. The lack of an operative dynamo in Io's metallic core might be explained by the inability of the hot mantle to cool the core. If the heat flow from the core is too small, the core would not convect and there would be no core motions to drive a dynamo. It seems unlikely, given the volcanic activity of the satellite and the large amount of heat it radiates, that Io's core could have solidified to the point where dynamo action would not be possible. It is more likely that Io's core is completely molten but not convecting.

#### Europa

Europa is somewhat smaller than Io and the Moon. Like Io, Europa has a metallic core surrounded by a rocky mantle (Figure 123/Plate 12).

In addition, it has a layer of water about 100 km thick that covers the rock mantle. At the surface, the water is frozen, but beneath the surface the water may be liquid, i.e., Europa might have an internal ocean. The ocean could be extremely deep and extend all the way down to the silicate mantle. The ocean could also be a relatively thin layer of liquid water within a largely ice shell. The average density and the moment of inertia of a planet or satellite provide information on the internal density distribution. We cannot infer from these data whether an iron core is solid or liquid or whether a water shell is ice or liquid. This is because the density changes associated with freezing of water or molten iron are too small to be distinguished in simple models of planetary interiors based on only mean density and moment of inertia. Europa is not volcanically active like Io, but its icy surface is disrupted by fractures and ridges indicative of internal activity in the moon. In fact, the appearance of the surface, with some regions so broken apart that they resemble the tops of floating icebergs, is one of the reasons, it is believed, that Europa has a liquid water ocean beneath its surface. A second reason to suspect the existence of an internal liquid water ocean in Europa is the detection of electrical currents inside Europa by the magnetometer on the Galileo spacecraft. The currents are driven by magnetic field changes felt in the moon as it orbits Jupiter and senses the planet's magnetic field. The currents in turn produce magnetic fields that are detected by the Galileo spacecraft. Rocks and ice are not good enough conductors of electricity to support the currents, but salty water, like the Earth's ocean, is conductive enough. So, the evidence for a subsurface ocean in Europa is all indirect, but the possibility that the ocean really exists is so important (an internal ocean would provide an environment conducive to life) that Europa will undoubtedly be a focus of future planetary exploration. The Galileo magnetometer did not detect an Europan magnetic field (a steady global magnetic field produced by a dynamo), so like Io, there is no dynamo operating in Europa's core. The reason for lack of dynamo action in Europa's core is probably different from the explanation for Io because Europa is not intensely heated by tidal dissipation as is Io. Europa may not have a dynamo for the same reason the Moon lacks a dynamo at present; these small moons may have cooled sufficiently that their cores are largely solidified and unable to support a dynamo. Other explanations are also possible. Europa's core could vary in radius from about 13% to 45% of Europa's full radius, depending on the composition of the core.

# Ganymede

Ganymede is the largest moon in the solar system. It is even larger than the planet Mercury (Tables I4 and I5). It is also the only moon in the solar system known to have a magnetic field. Its magnetic field is larger than Mercury's magnetic field. Ganymede's moment of inertia is smaller than that of any of the terrestrial planets or other Galilean satellites (Tables I4 and I5). Its density (about 2000 kg m<sup>-3</sup>) is intermediate between that of water (about 1000 kg  $m^{-3}$ ) and rock (about 3000 kg m<sup>-3</sup>), and accordingly it consists of about half rock (+ metal) and half water by mass. Ganymede is therefore known as an icy satellite. Like Europa, Ganymede consists of a metallic core surrounded by a rock mantle and a water-ice shell (Figure I23/Plate 12). However, unlike Europa, the outer ice shell is enormously thick (as thick as about 800 km). The small moment of inertia ( $C/MR^2 = 0.3115$ ) requires a large density difference between the core and the outer shell; this is provided by the density difference between water and iron. The detection of induced magnetic fields by the Galileo magnetometer, similar to the induced fields found around Europa, supports the possibility that Ganymede, like Europa, has an internal liquid water ocean embedded in its largely frozen outer shell of ice. The internal ocean on Ganymede would be buried deeper below the surface than it is on Europa. Though Ganymede's surface has been modified by internal dynamical processes (endogenic modification of the surface), it does not display the features found on Europa that suggest an ocean just below the surface. The core is the site of the dynamo that creates Ganymede's magnetic field; the existence of the magnetic field is indirect proof of the existence of Ganymede's metallic core. Moreover, we know that Ganymede's core is either entirely molten or liquid in an outer shell thick enough to sustain a convectively-driven dynamo. The possibility that Ganymede's magnetic field is produced by the global magnetization of a shell of rock in its interior cannot be completely ruled out, but it is considered less likely than a core dynamo. Even in this case, Ganymede would have to have had a dynamo operating in a metallic core in the past to create the magnetic field in which the crust was magnetized. Curiously, perhaps, the interior of Ganymede looks very much like Io with the addition of a thick ice shell. However, tidal dissipation does not presently heat the interior of Ganymede.

#### Callisto

Callisto is another icy satellite, just slightly smaller and slightly less dense than Ganymede. However, both its interior and surface are very different from Ganymede. Though Callisto is also about half rock and half water by mass, its  $C/MR^2$  is only slightly smaller than 0.4 (Table I4), implying that its interior is not too different from a uniform mixture of ice and rock with nearly constant density. The reduction of  $C/MR^2$  from 0.4 is due in part to the densification of ice with depth inside Callisto (ice transforms to higher density phases at sufficiently high pressures) and the partial separation of rock from ice in the relatively shallow subsurface layers of Callisto. However, in the bulk of Callisto at depth, ice and rock are still intimately mixed as they are in the material which accreted to form Callisto (Figure I23/Plate 12). In particular, Callisto does not have a metallic core as do the other Galilean satellites. The lack of a magnetic field associated with Callisto (based on observations by the Galileo spacecraft) is consistent with the absence of a core. Callisto is said to be only partially differentiated, where in this context, differentiation is the process that separates ice from rock and usually would involve the melting of the ice of an ice-rock mixture. Ganymede is differentiated not only in the sense that its ice and rock have separated, but its metal and rock have also separated through the melting of the primordial rock component early in the formation of the satellite. The term differentiation, as traditionally applied to terrestrial planets, usually refers to the melting of rock and the separation of molten iron into a central core. Why Ganymede got hot enough inside to fully differentiate and separate ice from rock and also form a metal core while similarly sized Callisto failed to get hot enough to even melt most of the ice in the primordial ice-rock mixture from which it formed is still an unsolved problem. The answer might lie in the orbital-dynamical history of the satellites; Ganymede might have been intensely tidally heated in the past, while Callisto would have escaped such a fate since Callisto is much farther from Jupiter and not involved in orbital resonances with the other Galilean satellites. Electromagnetic induction signals have been detected in several flybys of Callisto by the Galileo spacecraft, indicating that Callisto, like Europa and Ganymede, has an internal liquid water ocean buried deep beneath its surface. How such a global ocean could exist in a largely undifferentiated satellite is not understood.

# Titan

Saturn's large satellite Titan is an icy satellite with a density of about  $1880 \text{ kg m}^{-3}$  (Table I4). It is in synchronous rotation about Saturn at an average orbital distance of about 1.2 million km (Table I5). There are no rotational or gravitational data to constrain interior models of Titan, so present ideas about the moon are based on its density. It is generally thought that ice and rock are separated in Titan as they are in Ganymede. However, unlike Ganymede, Titan does not have a magnetic field, a fact confirmed by magnetometer data from a recent flyby of Titan by the Cassini spacecraft. The absence of a magnetic field is only a weak constraint on whether or not Titan has a metallic core; either Titan does not have an iron core, or it has a core, but not an operative dynamo in the core. Future flybys of Titan by the Cassini spacecraft should provide information about Titan's gravitational field that will

446

help us infer its internal structure similar to the inferences about the interiors of the icy Galilean satellites made from measurements of their gravitational fields by the Galileo spacecraft. Titan is distinguished by its massive atmosphere of nitrogen (95%) and methane (5%). The surface pressure on Titan is about 1.5 times the pressure at Earth's surface. Titan is the only moon in the solar system with such a substantial atmosphere whose existence holds clues to the formation and evolution of the satellite and the nature of its interior.

#### Pluto, Charon, and Triton

The small minor planet Pluto and its comparably sized moon Charon are additional examples of icy solar system bodies. Their densities are somewhat uncertain; Pluto's density lies between about 1750 and 2150 kg m<sup>-3</sup>, and Charon's density lies in the range 1300-2200 kg m<sup>-3</sup> (Table I4). We have little other information about these bodies, so it is impossible to conclude one way or another about the separation of ice from rock in their interiors. In addition to ice and rock, Pluto and Charon may contain organic material in their interiors. Pluto and Charon are likely to be typical of many other icy objects orbiting at the edge of the solar system in the so-called Kuiper belt. Pluto is very similar in size and density and surface composition to Neptune's icy moon Triton (Table I4). Nitrogen and methane ices (in addition to water ice) have been detected on the surfaces of Pluto and Triton, and both bodies have thin predominantly nitrogen atmospheres. Triton is in an unusual orbit around Neptune; the orbit is highly inclined and is retrograde (the inclination of the orbit is about 157°). Triton's orbit suggests that it formed elsewhere in the outer solar system and was captured from heliocentric orbit by Neptune. Triton was likely strongly heated during this capture event, and it is therefore expected to have differentiated into a rock core surrounded by an ice mantle. Theoretical considerations suggest that Pluto might also be differentiated, though not by heating during capture.

#### Giant planets in the outer solar system

#### Jupiter

The outer planets are large, fluidlike bodies with low densities compared to the densities of the terrestrial planets (Table I4). Jupiter, the largest planet in the solar system, is composed largely of hydrogen and helium (Figure 123/Plate 12). Hydrogen and helium are gases in the outer layers of Jupiter (H2 and He are 86.4% and 13.6%, respectively, by number, in Jupiter's atmosphere), but pressures are so large in the deep interior of Jupiter that its hydrogen and helium are more like dense liquids than gases at large depths. Hydrogen transforms to a metallic, highly electrically conducting phase at a depth perhaps as shallow as 20% of Jupiter's radius. The dynamo that produces Jupiter's magnetic field could reside in this metallic hydrogen region of the planet's interior. The molecular hydrogen envelope could be electrically conducting enough near the base of the layer to support dynamo action. There may be a relatively small core at the center of Jupiter as large as several Earth masses (up to about 10 Earth masses) and made of rock, metal, and ices (water, ammonia, and methane). Jupiter is so massive that it is contracting under its own gravitation, a process that releases gravitational potential energy in the form of heat. This heat is radiated from Jupiter's atmosphere; it has been measured and has been found to be comparable to the amount of heat Jupiter receives from the Sun and reradiates to space. Models of Jupiter's interior are based on theoretical considerations and are constrained by its density and spacecraft observations of the planet's gravitational field described by gravitational coefficients such as  $C_{20} = -J_2$  (and higher degree coefficients like  $J_4$  and  $J_6$ ).

#### Saturn

Saturn is similar to Jupiter in its interior (Figure 123/Plate 12). It is a smaller planet (Table 14) and contains relatively more helium. The

molecular to metallic phase transition in Saturn occurs deeper within the planet (at a depth of about 0.5 Saturn radius) as compared to Jupiter. This is because the pressure at which the phase change occurs is found deeper within Saturn as a consequence of the planet's smaller size and gravity. Like Jupiter, Saturn also has a magnetic field likely generated by a dynamo in the metallic hydrogen part of its interior. Saturn might also have a rock, metal, ice core at its center.

#### Uranus and Neptune

Uranus and Neptune are known as icy giants (Figure 123/Plate 12). They are similar to each other in mass and size but smaller than Jupiter and Saturn (Table 14). Their densities are about the same as that of Jupiter but about twice as large as that of Saturn. They are believed to have outer envelopes of hydrogen and helium, but deep interiors consisting mostly of ices such as water, methane, and ammonia. They might also have rock, metal, ice cores of about an Earth mass at their centers. Uranus and Neptune have magnetic fields that must be generated in highly electrically conducting regions of their icy interiors.

#### **Crusts of terrestrial planets**

The discussion above has emphasized the deep interiors of planets and moons. The outer layers of the terrestrial planets all have rocky crusts, and the outer regions of the giant planets all have gaseous atmospheres. Of course, some terrestrial planets also have atmospheres. The rocky crusts of Mercury, Venus, Earth, Moon, and Mars are compositionally distinct from the rocks of the underlying mantles. The crusts of the terrestrial planets formed by differentiation from the primordial mantle rocks, i.e., they are formed by melting of the original mantle rocks and separation of the melt from the unmelted residuum (the present mantle rocks). Separation was achieved by the gradual upward migration of the lighter magma that later solidified to form the crust. This process is going on today at the mid-ocean ridges on Earth, the sites of seafloor spreading. We know a great deal about the Earth's crust because we have the rocks themselves (at least the rocks of the upper crust) and data from seismic, magnetic, and gravity studies that reveal values of crust density and thickness. We also have rock samples and seismic, magnetic, and gravity data that reveal the nature of the lunar crust. Meteorites, believed to be from Mars, the so-called SNC meteorites (Shergotty-Nakhla-Chassigny), provide information about the composition and mineralogy of the planet. For Venus, Mars, and the Moon there are considerable data about their crusts from gravity, topography, and geochemical observations by orbiting spacecraft. Landers on Venus and Mars have provided in situ analyses of the surface rocks. The crusts of the terrestrial planets are essentially basaltic in character, similar to the rocks that form the crust beneath the Earth's oceans. On Earth there are actually two distinct types of crust, oceanic and continental. The rocks of the continents are compositionally distinct from those of the ocean floor. Continental rocks are richer in silica and formed from multiple stages of melting and differentiation in the presence of water. The oceanic crust is about 5 km thick on average while the continental crust is much thicker, about 40 km thick. Because of the concentration of the crust in the northern hemisphere beneath Eurasia, there is a hemispheric dichotomy in the Earth's crustal thickness.

It is not known if there is crust on the other terrestrial planets similar to the continental crust of Earth. There are two crustal types on the Moon, the anorthositic crust of the lunar highlands (the light crystallization product of the lunar magma ocean) and the basaltic crust of the lunar maria (the infill of the lunar impact basins). There is a hemispheric dichotomy in crustal thickness on the Moon with the farside of the Moon having a substantially greater thickness than the nearside. The lunar crust has also been thinned beneath the South Pole Aitken basin. There may be two crustal types on Venus, one type forming the high-standing plateaus like Ishtar Terra, and the other forming the volcanic rises like Beta Regio. The *in situ* analyses by the Venera

Figure 126/Plate 13b Map of crust thickness of Mars based largely on gravitational and topographic data from the Mars Global Surveyor spacecraft (Neumann *et al.*, 2004).

landers have revealed basaltic compositions in the Venusian lowland plains. Mars also has a crustal dichotomy. The primordial crust of the southern hemisphere stands higher and is thicker than the primordial crust of the northern hemisphere which has been mantled with a thin covering of younger and compositionally distinct crust. (The average thickness of the crust of Mars is between about 50 and 100 km.) The crustal dichotomies of the terrestrial planets were likely formed by internal dynamical processes, although major impacts, particularly on the Moon (e.g., the large South Pole Aitken basin) could also have played a role. The crustal dichotomies are probably the cause of the offsets between the centers of mass and the centers of figure of the terrestrial planets.

Less is known about the crust of Mercury. Remote sensing observations indicate that Mercury has a basaltic crust. If the Messenger spacecraft successfully orbits Mercury and returns anticipated data, we will know as much about Mercury's crust as we do about the crusts of the other terrestrial planets.

The main source of information about the thicknesses of the crusts of the terrestrial planets (other than Earth) derives from the topography and gravity data obtained by orbiting spacecraft. These data have enabled the construction of global crust thickness maps of the Moon and Mars. The observed gravity variations are first modified to account for the effects of topography using the measured topography. The extra mass associated with elevated regions and the mass deficit associated with low areas contribute to the measured variations in gravity. The resulting gravity variations are known as Bouguer gravity anomalies. While the Bouger gravity map accounts for topography effects, it does not take account of the fact that variations in topography are generally isostatically compensated by variations in crust thickness. According to a geophysical principle known as Airy compensation, the masses of material columns above a certain depth of compensation are balanced; the crust is thicker beneath elevated topography compared to average crust so that the extra mass of the topography is balanced by an equal mass deficit associated with the replacement of heavy mantle rock by lighter thickened crust. Similarly, the crust is thinned beneath topographic depressions, so that the mass deficit of negative topography is balanced by an equal mass excess associated with the replacement of thinned crust by heavier mantle rock. By attributing the Bouguer gravity anomalies to crustal thickness variations, those variations can be determined. However, the depth of compensation or average crustal thickness must be assumed or constrained by some other observations. In this way, the crustal thickness map of Mars shown in Figure I26/Plate 13b has been derived from topography

and gravity measurements obtained by the Mars Global Surveyor spacecraft. The map assumes that the average crust thickness on Mars is 50 km. The crustal dichotomy between the northern lowlands and southern highlands is immediately apparent. The strongly magnetized region of the Martian crust lies in the southern highlands (see *Magnetic field of Mars*, chapter and figure), but not all of the southern hemisphere crust is magnetized. The principle of Airy compensation is well established for Earth where it can be tested against seismic measurements of crustal thickness. The thickest crust on Earth lies below its most mountainous regions.

# **Concluding remarks**

Seismic measurements directly probe a planet's interior, determining structure and providing constraints on composition and mineralogy. We have such observations for Earth, but the only other planet that has been seismically studied is the Moon. Nevertheless, we have learned a good deal about the interiors of other planets and moons in our solar system by observing how some of them respond dynamically to tidal torques and by measuring their densities and external gravitational and magnetic fields. Still other observations of the geology and composition of their surfaces provide additional clues about what lies inside them. Though we only have observed most of the bodies shown in Figure 123/Plate 12 from the Earth, or from orbiting and flyby spacecraft, it is rather remarkable that we can draw the cutaway views shown in the figure to reveal what these planets and moons are like inside.

Harmonics, Spherical Magnetic Field of Mars

# INTERNAL EXTERNAL FIELD SEPARATION

#### Introduction

The process of separation of the magnetic field can be applied to the main magnetic field or to the daily variation fields of solar and lunar origin, or to disturbance fields or disturbance daily variation fields. Each application has a different purpose. The results of the separation show that the Earth's main magnetic field is dominantly of internal origin, while the daily variation and disturbance fields have external fields that are greater than the internal fields and therefore originate above the Earth.

The results of the analyses provide the information needed for studies of dynamo processes in the Earth's interior, in the ionosphere, in the deep oceans, and for distributions of electrical conductivity within those regions. In studies of magnetic daily variations of solar and lunar origin, the amplitude ratio and phase angle differences of the internal and external fields are used as the electrical response function of the Earth.

The internal and external fields correspond to two independent vector spherical harmonics that are orthogonal under integration over the surface of a sphere. However, there is a third, independent vector spherical harmonic, orthogonal to the internal and external fields, referred to as the "nonpotential" field, which can be used to resolve the residual differences between horizontal components of the field that cannot be represented by "potential" fields, meaning internal and external fields. Coefficients of the nonpotential field determined from observatory data are not statistically significant, indicating that the electrical current system associated with the maintenance of the Earth's electrostatic charge, called the "global electrical circuit," cannot be determined from magnetic observatory data. With the availability of satellite magnetic data, and the possibility of field-aligned currents at low-Earth orbit altitudes, it is quite likely that satellite magnetic data will provide significant nonpotential field coefficients. Field separations can be done globally or regionally. Global analyses are usually done using spherical harmonics, but some analyses have been done using surface integral methods, (Price and Wilkins, 1963). A variety of methods are available for regional analyses, including spherical cap harmonic analysis (see *Harmonics, spherical cap*) and spectral methods. Global analyses using spherical harmonics and the method of least-squares are the simplest and most easily understood. Spherical cap harmonic analyses are useful for interpolation of field values, but do not separate the field accurately. Other methods have problems of implementation, as well as problems with aliasing or poor choice of spectral cut-off. In the study of magnetic daily variations, an estimate of the local direction and strength of the overhead current system is easily obtained by rotating the horizontal magnetic field variation components clockwise through 90°.

#### Spherical harmonic analysis

The first spherical harmonic analysis on a global scale was that of the Earth's main magnetic field by Gauss (1838). He assumed that the Earth was a sphere, and that all measurements of the field were made on the surface of the sphere. There is an implied assumption that there are no surface electrical currents on the surface of the sphere and that there are no electrical currents flowing with a radial component, e.g., Earth-air, or field-aligned. Thus, the electrical current density will be zero,  $\mathbf{J} = 0$ . With all these assumptions, together with the absence of displacement currents, Ampere's law for the magnetic field strength  $\mathbf{H}$  reduces to  $\nabla \times \mathbf{H} = 0$ . In regions of constant magnetic susceptibility, the equation for the magnetic flux density  $\mathbf{B}$  is therefore  $\nabla \times \mathbf{B} = 0$ , so that the magnetic flux density is the gradient of a scalar potential, that is,  $\mathbf{B} = -\nabla V$ , where the scalar potential function V is a function of the radius r of the sphere, the colatitude  $\theta$ , and the east longitude  $\phi$ .

The magnetic flux density has no divergence, because there are no free magnetic poles, quite in contrast to the existence of free electric charges. This condition is written  $\nabla \cdot \mathbf{B} = 0$ , and therefore, the scalar potential *V* satisfies Laplace's equation,  $\nabla^2 V = 0$ .

Solutions of Laplace's equations are called spherical harmonics (see *Harmonics, spherical*), and the solutions  $V(r, \theta, \phi)$  are called solid spherical harmonics, to distinguish them from surface spherical harmonics  $P_n^m(\cos \theta) \cos m\phi$  and  $P_n^m(\cos \theta) \sin m\phi$ , which do not satisfy Laplace's equation.

The functions  $V_{int}(r, \theta, \phi)$  and  $V_{ext}(r, \theta, \phi)$ , defined by

$$V_{\text{int}}(r,\theta,\phi) = a \sum_{n=1}^{N} \frac{a^{n+1}}{r^{n+1}} \sum_{m=0}^{n} \left( g_{ni}^{m} \cos m\phi + h_{ni}^{m} \sin m\phi \right)$$
$$\times P_{n}^{m} (\cos \theta), \quad r > a,$$
$$V_{\text{ext}}(r,\theta,\phi) = a \sum_{n=1}^{N} \frac{r^{n}}{a^{n}} \sum_{m=0}^{n} \left( g_{ne}^{m} \cos m\phi + h_{ne}^{m} \sin m\phi \right)$$
$$\times P_{n}^{m} (\cos \theta), \quad r < a, \tag{Eq. 1}$$

are the potential functions for sources internal to the reference sphere r = a and for sources external to the reference sphere, respectively. Subscripts *i* and *e* have been applied to coefficients  $g_n^m$  and  $h_n^m$  to indicate internal or external fields. The initial factor *a* in (Eq. 1) has been included so that the *g* and *h* coefficients will have the dimensions of magnetic flux density. Gauss's first analysis of the main field to degree and order N = 4 used only the term  $V_{int}(r, \theta, \phi)$ , on the assumption that the geomagnetic main field is a term of internal origin only. Analysis of the field gives no indication as to the location of the internal and external sources. Therefore, the potential of the main field, or its variations, is represented as a linear combination of the two types given in (Eq. 1), and applied to field measurements made in the region between the ground and the ionosphere, or, in the case of satellite magnetic data, between the ionosphere and the magnetopause.

#### The current function representation

The field of internal origin can be represented by a system of surface currents flowing over the surface of a sphere, concentric with and within the minimum sphere over which observations are made. A stream function  $\Psi(\theta, \phi)$ , with units of amperes, called the current function, gives the surface current density  $\mathbf{K}(\theta, \phi)$  (in amperes per meter) in the form

$$\mathbf{K}(\theta,\phi) = \frac{1}{R\sin\theta} \frac{\partial\Psi}{\partial\phi} \mathbf{e}_{\theta} - \frac{1}{R} \frac{\partial\Psi}{\partial\theta} \mathbf{e}_{\phi} = -\mathbf{e}_r \times \nabla\Psi = \nabla \times (\mathbf{e}_r \Psi)$$
(Eq. 2)

The vector  $\nabla \Psi$  is in the direction of  $\Psi(\theta, \phi)$  increasing, that is, directed toward maxima, and from (Eq. 2) the electrical current flow is counterclockwise around maxima when seen from above. Note however, that the maxima of  $\Psi(\theta, \phi)$  can be negative and the minima positive.

The current function is denoted  $\Psi(\theta, \phi)$ , with units of amperes, and has a spherical harmonic representation

$$\Psi(\theta,\phi) = \sum_{n=1}^{N} \sum_{m=0}^{n} (J_{nc}^{m} \cos m\phi + J_{ns}^{m} \sin m\phi) P_{n}^{m}(\cos\theta), \quad (\text{Eq. 3})$$

Subscripts *c* and *s* have been added to the coefficients  $J_n^m$  to indicate application to  $\cos m\phi$  and  $\sin m\phi$  respectively. For a current function in the ionosphere, of radius *R*, to represent the magnetic daily variations, whose coefficients have been determined relative to a sphere of radius *a*, the current function coefficients in amperes are given by

$$J_{nc}^{m} = -(a)_{km} \frac{10}{4\pi} \frac{2n+1}{n+1} \frac{R^{n}}{a^{n}} (g_{ne}^{m})_{nT}, \quad J_{ns}^{m} = -(a)_{km} \frac{10}{4\pi} \frac{2n+1}{n+1} \frac{R^{n}}{a^{n}} (h_{ne}^{m})_{nT}.$$
(Eq. 4)

For a current function within the Earth to represent main field coefficients that have been determined relative to a sphere of radius a, the current function coefficients in amperes are given by

$$J_{nc}^{m} = (a)_{\rm km} \frac{10}{4\pi} \frac{2n+1}{n} \frac{a^{n+1}}{R^{n+1}} (g_{ni}^{m})_{\rm nT}, \quad J_{ns}^{m} = (a)_{\rm km} \frac{10}{4\pi} \frac{2n+1}{n} \frac{a^{n+1}}{R^{n+1}} (h_{ni}^{m})_{\rm nT}.$$
(Eq. 5)

# Global magnetic field separation

In studies of the geomagnetic daily variations, current systems in the ionosphere are the basic source, and eddy currents are induced in the Earth by the ionospheric currents, with only a very small contribution from the magnetospheric current system. Therefore, for the study of the geomagnetic daily variations, the potential function must include terms of both internal and external origin, with the expectation that the terms of external origin will be the greater of the two, being the basic source of the phenomenon. The two types of potential can be separated by numerical calculations as follows, the process being the title of this article, "internal-external field separation."

### Magnetic flux density field components

The three components of the geomagnetic field are denoted X, Y, and Z. The northward component is X, the eastward component Y, and the vertically downward component Z. The components, X, Y, and Z in that order, form a right-handed orthogonal system.

The mathematical expressions for the field components over the reference sphere, r = a, are

$$X = \frac{1}{a} \frac{\partial V}{\partial \theta} \Big|_{r=a}, \quad Y = -\frac{1}{a \sin \theta} \frac{\partial V}{\partial \phi} \Big|_{r=a}, \quad Z = \frac{\partial V}{\partial r} \Big|_{r=a}, \quad (\text{Eq. 6})$$

and therefore in a region free of magnetic sources and electric currents, the ambient magnetic field can be derived from fields of internal and external origin, and the components will have the mathematical form

$$\begin{split} X(a,\theta,\phi) &= \sum_{n=1}^{N} \sum_{m=0}^{n} \left[ \left( g_{ni}^{m} + g_{ne}^{m} \right) \cos m\phi + \left( h_{ni}^{m} + h_{ne}^{m} \right) \sin m\phi \right] \frac{\mathrm{d}P_{n}^{m}(\cos\theta)}{\mathrm{d}\theta}, \\ Y(a,\theta,\phi) &= \sum_{n=1}^{N} \sum_{m=0}^{n} \left[ \left( g_{ni}^{m} + g_{ne}^{m} \right) \sin m\phi - \left( h_{ni}^{m} + h_{ne}^{m} \right) \cos m\phi \right] \frac{m}{\sin\theta} P_{n}^{m}(\cos\theta), \\ Z(a,\theta,\phi) &= \sum_{n=1}^{N} \sum_{m=0}^{n} \left\{ \left[ -(n+1)g_{ni}^{m} + ng_{ne}^{m} \right] \cos m\phi \right. \\ &+ \left[ -(n+1)h_{ni}^{m} + nh_{ne}^{m} \right] \sin m\phi \right\} P_{n}^{m}(\cos\theta). \end{split}$$
(Eq. 7)

Because the radial dependence of the internal and external fields is known, (Eq. 7) can be easily adapted for calculations using magnetic field measurements which are not made over the surface of a sphere, and where the coordinates of the point at which each measurement is made is given in terms of geocentric coordinates,  $r, \theta, \phi$ . From the equations for the horizontal components of the field, namely X and Y, it will be seen that the coefficients involve only  $(g_{ni}^m + g_{ne}^m)$  and  $(h_{ni}^m + h_{ne}^m)$ , so that from the X component only, it is possible to determine the Y components. However, from these two elements only, it is not possible to separate the coefficients into internal and external parts, meaning it is not possible to determine  $g_{ni}^m$  and  $g_{ne}^m$  separately. However, the coefficients  $[-(n + 1)g_{ni}^m + ng_{ne}^m]$  and  $[-(n + 1)h_{ni}^m + nh_{ne}^m]$ as determined from the radial or vertical component Z, will allow the separation of the coefficients and therefore allow separation of the field into parts of internal and external origin, respectively.

#### The nonpotential field

It will be seen from (Eq. 7), that the coefficients from the northward component of the field X, obtained in the form  $(g_{ni}^m + g_{ne}^m)$  and  $(h_{ni}^m + h_{ne}^m)$ , can be used to estimate the values of the eastward component Y. Should the estimated values of Y not be in agreement with the observed values of Y, then to resolve the situation, a nonpotential field is introduced, as shown below by coefficients  $g_{nv}^m$  and  $h_{nv}^m$ . The radial dependence required for the internal and external fields is quite definite, but the radial dependence of the nonpotential field depends upon the hypothesis chosen for the origin of the fields; for example, Earthair currents, or field-aligned currents.

The nonpotential field  $\mathbf{B}_{v}(r, \theta, \phi)$  is

$$\mathbf{B}_{\nu}(r,\theta,\phi) = \frac{1}{\sin\theta} \frac{\partial V_{\nu}}{\partial \phi} \mathbf{e}_{\theta} - \frac{\partial V_{\nu}}{\partial \theta} \mathbf{e}_{\phi} \\
= -\mathbf{r} \times \nabla V_{\nu}(r,\theta,\phi), \\
= \nabla \times [\mathbf{r}V_{\nu}(r,\theta,\phi)], \quad (\text{Eq. 8})$$

and has no radial component. The scalar function  $V_{\nu}(r, \theta, \phi)$  (with units of magnetic flux density) is given by

$$V_{\nu}(r,\theta,\phi) = \sum_{n=1}^{N} \sum_{m=0}^{n} \frac{q_{n}^{m}(r)}{q_{n}^{m}(a)} (g_{n\nu}^{m} \cos m\phi + h_{n\nu}^{m} \sin m\phi) P_{n}^{m}(\cos\theta).$$
(Eq. 9)

The function  $q_n^m(r)$  cannot be determined from analysis of theory or data alone, but requires a hypothesis to be made on the form of the electrical current system.

The field components of the magnetic field over the reference sphere, r = a, are

$$X(a,\theta,\phi) = \sum_{n=1}^{N} \sum_{m=0}^{n} \left[ (g_{ni}^{m} + g_{ne}^{m}) \cos m\phi + (h_{ni}^{m} + h_{ne}^{m}) \sin m\phi \right] \frac{\mathrm{d}P_{n}^{m}}{d\theta} + (g_{nv}^{m} \sin m\phi - h_{nv}^{m} \cos m\phi) \frac{m}{\sin \theta} P_{n}^{m}, \qquad (\text{Eq. 10})$$

$$Y(a, \theta, \phi) = \sum_{n=1}^{N} \sum_{m=0}^{n} \left[ (g_{ni}^{m} + g_{ne}^{m}) \sin m\phi - (h_{ni}^{m} + h_{ne}^{m}) \cos m\phi \right] \\ \times \frac{m}{\sin \theta} P_{n}^{m} - (g_{nv}^{m} \cos m\phi + h_{nv}^{m} \sin m\phi) \frac{dP_{n}^{m}}{d\theta},$$
(Eq. 11)

$$Z(a,\theta,\phi) = \sum_{n=1}^{N} \sum_{m=0}^{n} \left\{ \left[ -(n+1)g_{ni}^{m} + ng_{ne}^{m} \right] \cos m\phi + \left[ -(n+1)h_{ni}^{m} + nh_{ne}^{m} \right] \sin m\phi \right\} P_{n}^{m}(\cos\theta).$$
 (Eq. 12)

The electrical current system comes only from the nonpotential field as

$$\begin{aligned} \mathbf{J}_{\nu}(r,\theta,\phi) &= \frac{1}{\mu_{0}} \nabla \times \mathbf{B}_{\nu}(r,\theta,\phi) \\ &= \frac{1}{\mu_{0}r} \sum_{n=0}^{N} \sum_{m=0}^{n} \frac{1}{q_{n}^{m}(a)} \bigg\{ q_{n}^{m}(r)n(n+1) \, \mathbf{e}_{r} + \frac{\mathbf{d}}{\mathbf{d}r} \big[ r q_{n}^{m}(r) \big] \\ &\times \bigg( \mathbf{e}_{\theta} \frac{\partial}{\partial \theta} + \frac{\mathbf{e}_{\phi}}{\sin \theta} \frac{\partial}{\partial \phi} \bigg) \big( g_{n\nu}^{m} \cos m\phi + h_{n\nu}^{m} \sin m\phi \big) P_{n}^{m}(\cos \theta) \bigg\} \end{aligned}$$

$$(Eq. 13)$$

The hypothesis of Earth-air currents requires  $q_n^m(r) = 1/r$  when the current system of (Eq. 13) reduces to a radial term only. An expression for a field of internal origin, along whose field lines the electrical current system travels, can also be found (Winch *et al.*, 2005).

The representation of (Eqs. 10–12) can be interpreted as a representation of the magnetic field over a sphere in terms of the three independent and orthogonal vector spherical harmonics, usually given in complex form as  $\mathbf{Y}_{n,n+1}^m(\theta,\phi)$ ,  $\mathbf{Y}_{n,n}^m(\theta,\phi)$ ,  $\mathbf{Y}_{n,n-1}^m(\theta,\phi)$ .

# Magnetic daily variations

The magnetic daily variations of solar and lunar type originate in the ionosphere by a dynamo process, so that in contrast to the main magnetic field in which the internal coefficients are almost the only significant terms, the magnetic daily variations are dominantly of external origin. The extra complication of dependence on time adds an extra dimension to the complexity of the analysis. A very basic assumption of local time  $t^*$  dependence on time, where  $t^* = t + \phi$ , and t is universal time, can reduce the complexity, but ignores significant nonlocal time terms that arise because of the inclination of the Earth's geomagnetic and geographic axes. A less restrictive assumption is that of westward movement only, since the solar and lunar magnetic variations are driven by the Sun, one can expect that eastward moving variations will be mostly insignificant.

The analysis begins with Fourier analysis of the elements X, Y, Z, at each observatory. Thus

$$X(a,\theta,\phi,t) = \sum_{M=1}^{4} [A_{XM}(a,\theta,\phi)\cos Mt + B_{XM}(a,\theta,\phi)\sin Mt],$$
  

$$Y(a,\theta,\phi,t) = \sum_{M=1}^{4} [A_{YM}(a,\theta,\phi)\cos Mt + B_{YM}(a,\theta,\phi)\sin Mt],$$
  

$$Z(a,\theta,\phi,t) = \sum_{M=1}^{4} [A_{ZM}(a,\theta,\phi)\cos Mt + B_{ZM}(a,\theta,\phi)\sin Mt].$$
  
(Eq. 14)

It is the standard practice to do separate spherical harmonic analyses of the A and B coefficients, to obtain internal and external coefficients

$$g_{nAi}^{mM}$$
,  $h_{nAi}^{mM}$  and  $g_{nAe}^{mM}$ ,  $h_{nAe}^{mM}$ ,  $g_{nBi}^{mM}$ ,  $h_{nBi}^{mM}$  and  $g_{nBe}^{mM}$ ,  $h_{nBe}^{mM}$ .

of the potential functions  $V_A^M(r, \theta, \phi)$  and  $V_B^M(r, \theta, \phi)$ , where

$$V_A^M(r,\theta,\phi) = a \sum_{n=1}^N \sum_{m=0}^n \left[ \left(\frac{a}{r}\right)^{n+1} \left(g_{nAi}^{mM} \cos m\phi + h_{nAi}^{mM} \sin m\phi\right) + \left(\frac{r}{a}\right)^n \left(g_{nAe}^{mM} \cos m\phi + h_{nAe}^{mM} \sin m\phi\right) \right] P_n^m(\cos\theta),$$
(Eq. 15)

$$V_B^M(r,\theta,\phi) = a \sum_{m=1}^N \sum_{n=0}^m \left[ \left(\frac{a}{r}\right)^{n+1} \left(g_{nBi}^{mM} \cos m\phi + h_{nBi}^{mM} \sin m\phi\right) + \left(\frac{r}{a}\right)^n \left(g_{nBe}^{mM} \cos m\phi + h_{nBe}^{mM} \sin m\phi\right) \right] P_n^m(\cos\theta),$$
(Eq. 16)

where only a limited range of m is used, for example, m = M - 1, M, and M + 1.

However, if one were to include the following expression for  $V_B^M(r, \theta, \phi)$ , which contains only the g and h coefficients appearing in  $V_A^M(r, \theta, \phi)$ , along with the least-squares analysis of  $V_A^M(r, \theta, \phi)$ ,

$$V_B^M(r,\theta,\phi) = a \sum_n \sum_n \left[ \left(\frac{a}{r}\right)^{n+1} \left( h_{nAi}^{mM} \cos m\phi - g_{nAi}^{mM} \sin m\phi \right) + \left(\frac{r}{a}\right)^n \left( h_{nAe}^{mM} \cos m\phi - g_{nAe}^{mM} \sin m\phi \right) \right] P_n^m(\cos\theta),$$
(Eq. 17)

then the combination

$$V_{A}^{M}(r,\theta,\phi)\cos Mt + V_{B}^{M}(r,\theta,\phi)\sin Mt$$
  
=  $a\sum_{n=1}^{N}\sum_{m=0}^{n} \left(\frac{a}{r}\right)^{n+1} \left[g_{nAi}^{mM}\cos(m\phi+Mt) + h_{nAi}^{mM}\sin(m\phi+Mt)\right]P_{n}^{m}(\cos\theta)$   
+  $a\sum_{n=1}^{N}\sum_{m=0}^{n} \left(\frac{r}{a}\right)^{n} \left[g_{nAe}^{mM}\cos(m\phi+Mt) + h_{nAe}^{mM}\sin(m\phi+Mt)\right]P_{n}^{m}(\cos\theta).$   
(Eq. 18)

consists only of terms with argument  $m\phi + Mt$ , which are westward moving. In the special case that m = M, the terms with argument  $m\phi + Mt$  reduce to local time  $t^*$ , and  $mt^* = m(t + \phi)$ .

The use of (Eqs. 15 and 17) together doubles the number of equations of condition for the westward moving terms. Because the magnetic variation "follows the Sun" and moves westward, the eastward moving terms are therefore much smaller, and in the first instance, can be regarded as random noise. Analysis of residuals after removing the westward moving part can be done by using an expression for  $-V_B^M(r, \theta, \phi)$  in place of (Eq. 17) for  $V_B^M(r, \theta, \phi)$ .

#### Separation using Cartesian components

For a Cartesian coordinate system at the center of the Earth, the *x*-axis directed toward the intersection of the equator and the Greenwich meridian, the *y*-axis at the intersection of the equator and the 90°E meridian, and the *z*-axis directed toward the North Pole. If  $\Pi, \Gamma, \Xi$ , denote field components parallel to the *x*-, *y*- and *z*- axes, then

$$\Pi = -Z\sin\theta\cos\phi - X\cos\theta\cos\phi - Y\sin\phi,$$
  

$$\Gamma = -Z\sin\theta\sin\phi - X\cos\theta\sin\phi + Y\cos\phi,$$
  

$$\Xi = -Z\cos\theta + X\sin\theta.$$
(Eq. 19)

The method requires the *surface* spherical harmonic analysis of the Cartesian field elements,  $\Pi, \Gamma, \Xi$ . Coefficients  $a_n^m, b_n^m, c_n^m, d_n^m, e_n^m, f_n^m$ , are determined using

$$\Pi = \sum_{n=0}^{N+1} \sum_{m=0}^{n} (a_n^m \cos m\phi + b_n^m \sin m\phi) P_n^m (\cos \theta),$$
  

$$\Gamma = \sum_{n=0}^{N+1} \sum_{m=0}^{n} (c_n^m \cos m\phi + d_n^m \sin m\phi) P_n^m (\cos \theta),$$
  

$$\Xi = \sum_{n=0}^{N+1} \sum_{m=0}^{n} (e_n^m \cos m\phi + f_n^m \sin m\phi) P_n^m (\cos \theta).$$
 (Eq. 20)

By forming specified orthogonal combinations of the computed coefficients, the internal, external, and nonpotential coefficients are determined independently, so that, for example, if one decided to have only internal terms in the model, there is no need to repeat the calculation (see Winch, 1968 for the necessary details).

#### Surface integral method

Kahle and Vestine (1963) put forward a method of surface integrals for separating a potential function  $V(\theta, \phi)$ , calculated as a set of numerical values over the globe, into its terms of internal and external origin. The method first requires the determination of the numerical values of  $V(\theta, \phi)$  by integration of the given X values with respect to colatitude  $\theta$  and integration of Y values with respect to east longitude  $\phi$ . The reconciliation of values of potential from the two different elements is discussed by Price and Wilkins (1963), and the method applied to the analysis of Sq variations for the International Polar Year.

Using the known potential function V, the internal and external components of V are determined from a form of Green's third identity,

$$V_{\text{ext}} - V_{\text{int}} = \frac{1}{2\pi} \int_{s} (V + 2aZ) \frac{dS}{r}.$$
 (Eq. 21)

The separation into internal and external parts is done using the numerical arrays determined by (Eq. 21) and the known array

$$V(\theta, \phi) = V_{\text{ext}}(\theta, \phi) + V_{\text{int}}(\theta, \phi).$$
(Eq. 22)

Weaver (1964) describes a method for separating a local geomagnetic field into its external and internal parts using two-dimensional Fourier analyses of the X, Y, and Z components. The formulae for separating the X field are

$$X_{\rm e} = \frac{1}{2}(X + M_1Z), \quad X_i = \frac{1}{2}(X - M_1Z),$$

where

$$M_1 Z = \frac{1}{2\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} Z(u, v) \frac{x - u}{\left[ (x - u)^2 + (y - v)^2 \right]^{3/2}} du dv$$

## A simple method

In order to determine the direction and strength of the external field in magnetic daily variation studies, without the need for any analysis at all, the horizontal components can be rotated clockwise through 90°. For the Sq field, it can be shown that the method is accurate to within 10% of the maximum overhead current circulation, with largest errors occurring in middle and equatorial latitudes, e.g., Winch (1966). The method is useful for checking results of other more complicated forms of analysis and interpolation.

# IONOSPHERE

The ionosphere is the weakly ionized region of the upper atmosphere above 60 km altitude where free electrons and ions form a plasma that influences radio wave propagation and conducts electrical currents. The plasma is created by solar extreme-ultraviolet and X-ray radiation impinging on the atmosphere and at high latitudes in the northern and southern *auroral ovals* (q.v.), by energetic particles precipitating from the *magnetosphere* (q.v.). Plasma is destroyed through chemical reactions that lead to electron-ion recombination. The ionizing solar radiation varies by about a factor of two over the 11-year solar sunspot cycle, which results in significant solar-cycle variations in the plasma density. Figure 127 shows typical altitude profiles of the mid-latitude electron density at day and night for years of minimum and maximum solar activity. For historical reasons relating to radio sounding of the ionosphere, the region of maximum density above 150 km is called the *F*-region (or layer), the region around the secondary maximum density at about 110 km is called the *E* region, and the region below about 90 km is called the *D* region.

The ionosphere refracts, reflects, retards, scatters, and absorbs radio waves in a manner that depends on the radio wave frequency. Aroundthe-Earth communications are possible by utilizing ionospheric and ground reflections of waves at frequencies below about 3-30 MHz (100 to 10 m wavelength), depending on the peak electron density. However, frequent collisions between electrons and air molecules in the D region remove energy from the radio waves, leading to partial or even complete absorption, depending on the electron density. At higher frequencies, radio waves penetrate entirely through the ionosphere, allowing radio astronomy and communications with spacecraft. Nevertheless, such signals can still be degraded by refraction and scattering off of small-scale density irregularities. In the case of geolocation signals like those of the Global Positioning System (GPS), variable and uncertain ranging errors can be introduced by ionospheric signal retardation. The retardation is proportional to the total electron content (TEC), or height-integrated electron density. A typical global pattern of TEC is shown in Figure I28. The TEC tends to be larger in winter than in summer, because of slower chemical loss in winter.

The ionospheric electrons and ions are strongly influenced by the geomagnetic field, and tend to move in spirals along geomagnetic-field lines. In the F-region, where collisions with air molecules are infrequent, the plasma diffuses rapidly along the magnetic field, but not across it. Winds in the upper atmosphere can also push the ions along the field lines. Plasma motion across magnetic field lines, on the other hand, is produced by electric fields. In the presence of an electric field E and a magnetic field B, electrons and ions drift perpendicular to both fields at the velocity  $\mathbf{E} \times \mathbf{B}/B^2$ . In the upper *F*-region, where ion lifetimes are long, the ions and electrons can be transported vertically and horizontally over significant distances between the times they are produced and lost, giving rise to a pattern of plasma density that depends on the geomagnetic-field configuration. As seen in Figure 128, a relative minimum in TEC tends to form along the magnetic equator in the afternoon and evening. It is created by an upward  $\mathbf{E} \times \mathbf{B}/B^2$  plasma drift during the day, with subsequent rapid plasma diffusion along the magnetic field, driven downward and away from the magnetic equator by gravity and plasma pressure gradients. Maxima in

the F-region ion density build up about 1500 km on either side of the magnetic equator.

The geomagnetic influence on ion and electron mobility makes the electrical conductivity of the ionosphere highly anisotropic. The relatively free motion of electrons along the magnetic-field direction gives rise to large conductivity in that direction. In fact, the large parallel conductivity extends far into space, out to many Earth radii, and permits electric currents to flow relatively easily along geomagnetic-field lines from one hemisphere of the Earth to the opposite hemisphere.

In the direction perpendicular to the geomagnetic field, current can flow in response to an electric field only when the electrons and positive ions move at different velocities. Their common drift at the velocity  $\mathbf{E} \times \mathbf{B}/B^2$  in the upper *F*-region does not produce current. However, at lower altitudes, ion-neutral collisions deflect the ion motion away from the velocity  $\mathbf{E} \times \mathbf{B}/B^2$ , while the electrons continue to drift at that velocity so that current flows perpendicular to the magnetic field. Part of this current, called Pedersen current, is in the direction of E, and is associated with a Pedersen conductivity. Another part of the current, called Hall current, flows in the  $\mathbf{B} \times \mathbf{E}$  direction, opposite to the electron velocity, and is associated with a Hall conductivity. Figure I29 shows typical daytime altitude profiles of the parallel, Hall, and Pedersen conductivities. In the E-region the conductivities vary by about 40% over the solar cycle, but in the F-region the percentage variation is much greater. Unlike the TEC, which represents primarily F-region plasma, the height-integrated Pedersen and Hall conductivities vary mainly with the E-region plasma densities, which have short lifetimes and therefore depend directly on the solar and auroral ionization. They maximize during daylight, and at night in the auroral zone.

The electric field that drives current in the conductive medium is the field present in the reference frame moving with the air,  $\mathbf{E} + v \times \mathbf{B}$ , where *v* is the wind velocity. Upper atmospheric winds drive electric current by moving the conductive medium through the geomagnetic field, thereby driving an ionospheric dynamo. Convergent or divergent wind-driven currents create space charge and an electrostatic field  $\mathbf{E}$  that drives offsetting divergent or convergent current. The ionospheric dynamo is the main source of quiet-day ionospheric electric fields

and currents, and of their associated geomagnetic daily variations, at middle and low latitudes (see *Periodic external fields*). At high magnetic latitudes, electric fields and currents connect along geomagnetic-field lines with sources in the outer magnetosphere. They intensify greatly during magnetic storms (see *Storms and substorms*), and can produce strong heating and dynamical changes in the upper atmosphere and ionosphere.

# **IRON SULFIDES**

#### General

Iron sulfides are generally quoted as minor magnetic minerals and the interest of paleomagnetists for this family of minerals progressively developed only during the last 10-15 years. This was due partly to the fact that their occurrence was originally believed to be restricted to peculiar geological environments (i.e., sulfidic ores, anoxic sulfatereducing sedimentary environments) and partly to their metastability with respect to pyrite (FeS<sub>2</sub>), which is paramagnetic. Magnetic iron sulfides were therefore not expected to carry a stable remanent magnetization and to survive over long periods of geological time in sedimentary environments. However, their occurrence as main carriers of a remanent magnetization stable through geological times has been increasingly reported in recent years from a large variety of rock types, primarily as a result of more frequent application of magnetic methods to characterize the magnetic mineralogy in paleomagnetic samples. The recognition of the widespread occurrence of magnetic iron sulfides as stable carriers of natural remanent magnetizations (NRMs) in rocks propelled specific researches on their fundamental magnetic properties.

# **Pyrrhotite: magnetic properties**

Among magnetic iron sulfides, the pyrrhotite solid solution series (Fe<sub>1-x</sub>S; with x varying between 0 and 0.13) exhibits a wide range of magnetic behaviors. Stochiometric pyrrhotite FeS (troilite) shows

a hexagonal crystal structure based upon the NiAs structure, with alternating *c*-planes of Fe and S (Figure 130). In each Fe-layer the Fe<sup>2+</sup> ions are ferromagnetically coupled, while neighboring Fe-layers are coupled antiferromagnetically to each other via intervening S<sup>2-</sup> ions. The nonstoichiometric pyrrhotites are cation deficient. The increase of Fe deficiency affects both the crystallographic and magnetic structures: ordering of Fe vacancies leads to an alternation of partially and fully filled Fe layers, the hexagonal structure distorts to monoclinic and the magnetic ordering turns from antiferromagnetic to ferrimagnetic. Pyrrhotite shows strong magnetocrystalline anisotropy, with the easy directions of magnetization confined in the crystallographic basal plane (the magnetic crystalline anisotropy constant  $K_1$  is positive and estimated at ca.  $10^4$  J m<sup>-3</sup>, see Dunlop and Özdemir, 1997). The crystallographic *c*-axis perpendicular to the basal plane is the axis of very hard magnetization.

The more Fe-rich, hexagonal, pyrrhotites (F<sub>9</sub>S<sub>10</sub>, and possible F<sub>10</sub>S<sub>11</sub>, F<sub>11</sub>S<sub>12</sub>) are antiferromagnetic at room temperature and are characterized by a  $\lambda$  transition at temperatures between ca. 180°C and 220°C, depending on composition, above which they exhibit ferrimagnetism. The  $\lambda$  transition represents a change in the vacancy-ordering pattern of the crystal structure and is distinctive and diagnostic of hexagonal (Fe-rich) pyrrhotites. The Curie temperature for the different compositions of hexagonal pyrrhotites varies between 210°C and 270°C.

The most Fe-deficient pyrrhotite ( $F_7S_8$ ) is monoclinic and ferrimagnetic at room temperature, with a Curie temperature of ca. 325 °C. It has no  $\lambda$  transition, but it shows a diagnostic low-temperature transition in remanence and coercivity at 30–35 K (Rochette *et al.*, 1990).

Natural pyrrhotite usually occurs as a mixture of superstructures of monoclinic and hexagonal types, which results in an intermediate overall composition. Magnetic properties of pyrrhotite and their dependence from grain size and temperature have been investigated in detail in a number of specific studies (e.g., Clark, 1984; Dekkers, 1988, 1989, 1990; Menyeh and O'Reilly, 1991, 1995, 1996; Worm *et al.*, 1993; O'Reilly *et al.*, 2000). Monoclinic ferrimagnetic pyrrhotite ( $F_7S_8$ ) has a saturation magnetization ( $J_s$ ) of 18 A m<sup>2</sup> kg<sup>-1</sup> at room temperature. The magnetic susceptibility of pyrrhotites is field independent in grains smaller than 30  $\mu$ m, however for larger grains the magnetic susceptibility ( $\chi$ ) and its field dependence increase with increasing grain size ( $1 \times 10^{-5}-7 \times 10^{-5} \text{ m}^3 \text{ kg}^{-1}$ ). Conversely, the coercivity parameters all increase with decreasing grain size. The room temperature coercive force ( $H_c$ ) ranges from 10 to 70 kA m<sup>-1</sup> (i.e., 12–88 mT for coercive force expressed as magnetic induction  $B_c$ )

**Figure 130** Sketch of the crystalline structure of stoichiometric troilite (FeS). The structure is basically hexagonal, with alternating layers of  $Fe^{2+}$  and  $S^{2-}$  ions. The *c*-axis of hexagonal symmetry is the axis of very hard magnetization and is perpendicular to the basal planes. Elemental magnetic moments are parallel within a particular cation basal plane. The alternating  $Fe^{2+}$  layers define the two magnetic sublattices with oppositely directed magnetic moments. In nonstoichiometric monoclinic pyrrhotite  $Fe_7S_8$ , the cation vacancies are preferentially located on one of the two magnetic sublattices, giving rise to ferrimagnetism.

and for synthetic powders with grain size in the range  $1-24 \ \mu m$ , it could be fitted by a power-law dependence of the form  $H_c \propto L^n$ , where L is the particle size and n = -0.38 (O'Reilly *et al.*, 2000). During hysteresis measurements and isothermal remanent magnetization (IRM) acquisition experiments pyrrhotite powders approach complete saturation only in fields greater than 1 T, with the magnetic hardness increasing with decreasing grain sizes (O'Reilly *et al.*, 2000).

In synthetic monoclinic pyrrhotites the critical size for the transition from the single-domain (SD) to the multidomain (MD) state, with typical lamellar domains normal to the *c*-axis, is estimated at a mean value of ca. 1  $\mu$ m. The micromagnetic structures of hexagonal synthetic pyrrhotites are far more complex than that of monoclinic pyrrhotites, with typical wavy walls and a significantly smaller size of the individual magnetic domains (O'Reilly *et al.*, 2000).

The remanent magnetization carried by pyrrhotites can be of prime importance for paleomagnetic studies, but various factors may complicate the paleomagnetic interpretation of the data obtained from the classical demagnetization treatments. During alternating field (AF) demagnetization pyrrhotite-bearing samples were reported to acquire significant gyromagnetic and rotational remanent magnetization (RRM) in fields higher than 20 mT (Thomson, 1990) and upon heating at temperatures greater than 500°C during thermal demagnetization pyrrhotite transforms irreversibly to magnetite and, via subsequent further oxidation and heating, to hematite (Dekkers, 1990), producing new magnetic phases that may acquire new remanent magnetizations in the laboratory. Furthermore, self-reversal phenomena of pyrrhotite have been earlier reported under various laboratory experiments (Everitt, 1962; Bhimasankaram, 1964; Bhimasankaram and Lewis, 1966). Recent studies linked such phenomena to crystal twinning (Zapletal, 1992) and/or to a close coexistence of pyrrhotite and magnetite crystals, the latter being nucleated from direct oxidation of the pyrrhotite grains during heating (Bina and Daly, 1994).

# Greigite: magnetic properties

The iron sulfide greigite (Fe<sub>3</sub>S<sub>4</sub>) is the ferrimagnetic inverse thiospinel of iron and its crystalline structure is comparable to that of magnetite (Fe<sub>3</sub>O<sub>4</sub>) in which sulfur replace oxygen atoms. In the cubic close-packed crystal structure of greigite, the tetrahedral A-sites are filled by Fe<sup>3+</sup> ions and the octahedral B-sites are filled half by Fe<sup>3+</sup> ions and half by Fe<sup>2+</sup> ions (Figure 131).

Greigite is characterized by a high magnetocrystalline anisotropy (with a positive magnetic crystalline anisotropy constant  $K_1$  estimated at ca. 10<sup>3</sup> J m<sup>-3</sup>, see Diaz Ricci and Kirschvink, 1992; Dunlop and Özdemir, 1997) and its magnetic easy axis is aligned along the <100> crystallographic direction. Basic magnetic properties at room temperature in synthetic greigite powders were systematically investigated by Dekkers and Schoonen (1996), indicating a minimum lower bound for the saturation magnetization ( $J_s$ ) of 29 A m<sup>2</sup> kg<sup>-1</sup>, a magnetic susceptibility ( $\chi$ ) between ca. 5 × 10<sup>-5</sup> and 20 × 10<sup>-5</sup> m<sup>3</sup> kg<sup>-1</sup> and intermediate coercivities (i.e., IRM acquisition curves saturate after application of fields  $\geq$ 0.7–1 T).

Greigite is unstable during heating to temperature higher than ca. 200 °C. As a consequence of such instability the magnetic susceptibility and the magnetization in greigite-bearing sediments both undergo significant changes during heating (see Krs *et al.*, 1990, 1992; Reynolds *et al.*, 1994; Roberts, 1995; Horng *et al.*, 1998; Sagnotti and Winkler, 1999; Dekkers *et al.*, 2000): a major drop is generally observed between ca. 250 °C and 350 °C, reflecting decomposition of greigite in nonmagnetic sulfur, pyrite, and marcasite, followed by a dramatic increase above 350–380 °C and a subsequent decrease above 400–450 °C, indicating progressive production of new magnetic phases (pyrrhotite, then magnetite/maghemite, and finally hematite). Thermal decomposition of greigite precludes direct determination of its Curie temperature.

Greigite does not show any low temperature (5–300 K) phase transition (Roberts, 1995; Torii *et al.*, 1996; Dekkers *et al.*, 2000), though

<100> axis

**Figure 131** Sketch of the  $\frac{1}{2}$  of a unit cell of greigite (Fe<sub>3</sub>S<sub>4</sub>). The crystalline structure of greigite is basically the same inverse spinel structure typical for magnetite (Fe<sub>3</sub>O<sub>4</sub>) in which S<sup>2-</sup> ions substitute O<sup>2-</sup> ions. Cations are both in tetrahedral (A-site) and octahedral (B-site) coordination with S<sup>2-</sup> ions. In greigite the easy axis of magnetization is the <100> crystallographic axis.

a broad  $J_{\rm s}$  maximum peak value was observed at 10 K during cooling from 300 to 4 K (Dekkers *et al.*, 2000).

Typical for greigite are: low to intermediate coercivities, with spectra that partly overlap those of magnetite and pyrrhotite (i.e., for natural greigite-bearing sediments and synthetics greigite the published values for the coercivity of remanence  $(B_{cr})$  ranges from 20 to 100 mT, while for the coercivity  $(B_c)$  varies from 13 to 67 mT), maximum unblocking temperatures in the range 270-380°C, the lack of lowtemperature phase transitions and the presence of distinct stable SD properties (i.e., Roberts, 1995). With regards to these latter properties, in particular, greigite-bearing sediments show: (a) SD-like hysteresis ratios, with  $M_{\rm rs}/M_{\rm s}$  often exceeding 0.5 (where  $M_{\rm rs}$  is the saturation remanent magnetization and  $M_s$  is the saturation magnetization) and  $B_{cr}/B_c$  often lower than 1.5, (b) high values of the SIRM/k ratio (where SIRM is the saturation IRM and k the low-field magnetic susceptibility), (c) a sensitivity to field impressed anisotropy and (d) a marked tendency for acquisition of gyromagnetic remanent magnetization (GRM) and RRM. GRM and RRM acquisition in greigite-bearing samples has been investigated in the detail in several specific studies (Snowball, 1997a,b; Hu et al., 1998; Sagnotti and Winkler, 1999; Stephenson and Snowball, 2001: Hu et al., 2002) that have shown that greigite has the highest effective gyrofield  $(B_g)$  reported so far for all magnetic minerals (of the order of several hundred microteslas for a peak AF of 80 mT) and that gyromagnetic effects are powerful indicators for the presence of greigite in sediments.

GRM and RRM are effects due to the application of an AF on SD grains. They are produced whenever there is an asymmetry in the number of magnetic moments that flip in a particular sense during the AF treatment. In other words, such remanences appear in any system where a particular sense of flip predominates (Stephenson, 1980a,b). RRM was explained in terms of a gyromagnetic effect associated with the irreversible flip of SD particles during rotation of the sample in an AF (Stephenson, 1985).

The typical SD properties of natural greigite grains may be explained by its intrinsic magnetic and crystalline structure, with the magnetocrystalline anisotropy dominating the magnetization process. The theoretically estimated size range of stability for prismatic greigite SD grains extends well beyond that of magnetite, suggesting that elongated greigite crystals may be in a SD state even for very large sizes (up to several micrometers) (Diaz Ricci and Kirschvink, 1992). Moreover, direct magnetic optical observations indicated that the single- to two-domain transition in greigite may occur for grain sizes of  $0.7-0.8 \,\mu\text{m}$  (Hoffmann, 1992) and that greigite usually occurs in framboidal aggregates of grains individually smaller than 1  $\mu$ m (i.e., Jiang *et al.*, 2001).

The maximum value for the  $M_{\rm rs}/M_{\rm s}$  ratio in SD grains with shape anisotropy is 0.5. Conversely, if magnetocrystalline anisotropy controls the hysteresis behavior and the <100> axis is the easy axis of magnetization, it would be expected that  $M_{\rm rs}/M_{\rm s}$  would approach a value of 0.832 as  $B_{\rm cr}/B_{\rm c}$  approach unity. Under the same circumstances if <111> is the easy axis of magnetization  $M_{\rm rs}/M_{\rm s}$  is predicted to approach 0.866 (O'Reilly, 1984; Dunlop and Özdemir, 1997).

A magnetic method for discriminating between greigite and pyrrhotite in paleomagnetic samples has been proposed by Torii *et al.* (1996), based on the thermal demagnetization of a composite IRM and relying upon the instability and alteration of greigite during thermal heating at temperatures above 200 °C.

Notwithstanding its metastable properties and magnetic instability, the importance of greigite for paleomagnetism and magnetostratigraphy has been particularly stressed in recent years since it has been widely recognized as a carrier of stable chemical remanent magnetization (CRM) in lacustrine and marine sediments, with ages ranging from the Cretaceous to the Present (e.g., Snowball and Thomson, 1990; Snowball, 1991; Hoffmann, 1992; Krs *et al.*, 1990, 1992; Roberts and Turner, 1993; Hallam and Maher, 1994; Reynolds *et al.*, 1994; Roberts, 1995; Roberts *et al.*, 1996; Sagnotti and Winkler, 1999), as well as in soils (Fassbinder and Stanjek, 1994).

#### Fe-Ni sulfides

Smythite (Fe, Ni)<sub>9</sub>S<sub>11</sub>, pentlandite (Fe, Ni)<sub>9</sub>S<sub>8</sub>, and other complex Fe-Ni sulfides were occasionally reported in sediments (i.e., Krs *et al.*, 1992; Van Velzen *et al.*, 1993) in association with pure Fe sulfides, but their magnetic properties have not been studied in the detail so far.

# Occurrences: formation, preservation, problems, and potential for use in paleomagnetism

Troilite is common in meteorites and lunar rocks, but not on Earth.

Pyrrhotites are ordinary magnetic carriers in magmatic, hydrothermal, and metamorphic rocks. Pyrrhotite in metamorphic rocks has been shown to acquire postmetamorphic partial thermomagnetic remanent magnetization (pTRM) during the uplift of mountain belts and has been used as a thermometer for postmetamorphic cooling (thermopaleomagnetism) and for dating and evaluation of exhumation rates through various reversals of the Earth magnetic field (i.e., Crouzet *et al.*, 1999, 2001a,b).

Pyrrhotite has also been recognized as the main remanence carrier in Shergotty-Nakhla-Cassigny type (SNC) Martian meteorites, and inferred as a main magnetic phase in the crust of Mars with significant implication for a proper evaluation of magnetic anomalies on such planet (Rochette *et al.*, 2001). Pyrrhotite and greigite occur also as authigenic phases in geologically young or recent sediments deposited under anoxic, sulfatereducing conditions (Figure 132).

The presence of magnetic iron sulfides in sediments is of special interest, since they have important implication for magnetostratigraphy and environmental magnetism. Reduction diagenesis and authigenesis can significantly affect the magnetic mineralogy of sediments (Karlin and Levi, 1983; Karlin, 1990a,b; Leslie *et al.*, 1990a,b). In particular, magnetic iron sulfides can be produced through a number of different processes: (1) bacterially mediated synthesis of single-domain greigite, in the form of magnetosomes produced by magnetotactic bacteria (Mann *et al.*, 1990; Bazylinski *et al.*, 1993), and/or (2) precipitation from pore waters, and/or (3) dissolution of detrital iron oxides and subsequent precipitation of iron sulfides.

Authigenic growth of iron sulfides is a common and relatively wellunderstood process in anoxic sedimentary environments with relatively high organic carbon contents (e.g., Berner, 1984; Leslie *et al.*, 1990a,b; Roberts and Turner, 1993). Authigenic magnetic iron sulfides

**Figure 132** (a) Backscattered electron micrograph of an iron sulfide nodule from the Valle Ricca section, Italy (see Florindo and Sagnotti, 1995). The nodule shows evidence for multiphase sulfidization and contains framboidal pyrite (Py) and greigite (G), which always occurs with finer crystal sizes than the co-occurring pyrite, and intergrown plates of hexagonal pyrrhotite (Pyrr). (Courtesy of Andrew P. Roberts and Wei-Teh Jiang.) (b) Backscattered electron micrograph of a Trubi marl sample from Sicily (see Dinarès-Turell and Dekkers, 1999) showing framboidal pyrite (Py) filling foraminifera shells and pyrrhotite (Pyrr) intergrown plates dispersed in the rock matrix. (Courtesy of Jaume Dinarès-Turell.)

(pyrrhotite and greigite) are intermediate mineral phases within the chemical iron reduction series that eventually forms stable paramagnetic pyrite (FeS<sub>2</sub>; Berner, 1969, 1970, 1984; Canfield and Berner, 1987). The process can be mediated by bacterial activity that reduces pore-water sulfate  $(SO_4^{2+})$  to sulfide  $(S^-)$  associated with consumption of organic carbon during burial. Hydrogen sulfide (H2S) then progressively reacts with detrital iron minerals to ultimately produce pyrite. Intermediate magnetic iron sulfides are metastable with respect to pyrite in the presence of excess H<sub>2</sub>S. The major factors controlling pyrite formation and the preservation of the (magnetic) intermediate phases in marine sediments are the amounts of dissolved sulfate, reactive iron detrital minerals, and decomposable organic matter (Berner, 1970, 1984). Intermediate magnetic iron sulfides may be preserved in all cases when the limited availability of sulfide, reactive iron and/ or organic matter prevents completion of the processes that result in formation of pyrite. In normal marine environments, sulfate and reactive detrital iron minerals are practically unlimited and the major controlling factor on the pyritization process appears to be the availability of detrital organic matter (Kao et al., 2004). In this case, the small amounts of sulfide produced will rapidly react with dissolved iron; the rapid consumption of sulfide means that formation of intermediate greigite is favored over pyrite. However, in some settings, organic carbon may have different sources and greigite has also been reported to form during later burial as a consequence of the diffusion of hydrocarbons and gas hydrates through permeable strata (Reynolds et al., 1994; Thompson and Cameron, 1995; Housen and Mousgrave, 1996).

Greigite is the more common magnetic iron sulfide in fine-grained sediments; pyrrhotite, however, has also been reported in various fine-grained sediments, often alongside greigite (Linssen, 1988; Mary et al., 1993; Roberts and Turner, 1993; Dinarès-Turell and Dekkers, 1999; Horng et al., 1998; Sagnotti et al., 2001; Weaver et al., 2002) (Figure I32). The relative abundance of reactive iron versus organic matter appears to be the controlling factor for the transformation pathway of initial amorphous FeS into greigite or into pyrrhotite (Kao et al., 2004). Compared to greigite, pyrrhotite is favored by more reducing environments (i.e., lower Eh) and higher concentration of H2S, both implying a higher consumption of organic carbon (Kao et al., 2004). Even under appropriate diagenetic conditions, however, monoclinic pyrrhotite (Fe<sub>7</sub>S<sub>8</sub>) formation will be extremely slow below  $\sim$ 180°C, which makes it a highly unlikely carrier of early diagenetic remanences in sediments (Horng and Roberts, 2006). The abundance of monoclinic pyrrhotite in regional metamorphic belts makes it a likely detrital rather than authigenic magnetic mineral in marginal basins in such settings (Horng and Roberts, 2006).

During nucleation and crystal growth, authigenic greigite and pyrrhotite acquire a CRM, which contributes to the total NRM of the sediments. Authigenic formation of magnetic iron sulfides is generally believed to occur at the very first stages of diagenesis and NRM carried by magnetic iron sulfides were used for detailed paleomagnetic studies, assuming they reflect primary components of magnetization (e.g., Tric et al., 1991). However, many studies documented a significant delay between the deposition of the sediment and the formation of magnetic iron sulfides, implicating late diagenetic magnetizations. In particular, sediments bearing magnetic iron sulfides were often reported to carry CRM that are antiparallel either to those carried by coexisting detrital magnetic minerals and of opposite polarity with respect to the polarity expected for the age of the rock unit (e.g., Florindo and Sagnotti, 1995; Horng et al., 1998; Dinarès-Turell and Dekkers, 1999; Jiang et al., 2001; Weaver et al., 2002; Oms et al., 2003; Roberts and Weaver, 2005; Sagnotti et al., 2005). Such studies demonstrate that magnetic iron sulfides can carry stable magnetizations with a wide range of ages and that a syndepositional age should not be automatically assumed.

# JESUITS, ROLE IN GEOMAGNETISM

The Jesuits are members of a religious order of the Catholic Church, the Society of Jesus, founded in 1540 by Ignatius of Loyola. From 1548, when Jesuits established their first college, their educational work expanded rapidly and in the 18th century, in Europe alone, there were 645 colleges and universities and others in Asia and America. As an innovation in these colleges, special attention was given to teaching of mathematics, astronomy, and the natural sciences. This tradition has been continued in modern times in the many Jesuit colleges and universities and this tradition thus spread throughout the world. Jesuits' interest in geomagnetism derived from teaching in these colleges and universities. In many of these colleges and universities observatories were established, where astronomical and geophysical observations were made (Udías, 2003). Missionary work in Asia, Africa, and America, where scientific observations were also made and some observatories established, was another factor in the role of Jesuits in geomagnetism. In this work we must distinguish two periods. The first, from 1540 to 1773, ended with the suppression of the Jesuit order. The second began in 1814 with its restoration and lasts to our times.

#### Early work on magnetism

Terrestrial magnetism attracted Jesuits' attention from very early times (Vregille, 1905). José de Acosta, a missionary in America, in 1590 described the variation of the magnetic declination across the Atlantic and the places where its value was zero, one of them at the Azores islands. His work is quoted by William Gilbert (q.v.). In 1629, Nicolò Cabbeo (1586–1650) was the first Jesuit to write a book dedicated to magnetism, Philosophia Magnetica, where he collected all that was known in his time, together with his own experiments and observations. Some of his work is based on that of a previous Jesuit Leonardo Garzoni (1567-1592), professor at the college of Venice, who could well be the first Jesuit interested in such matters. Cabbeo was opposed to Gilbert on the origin of terrestrial magnetism. The best-known early work on magnetism by a Jesuit is that of Athanasius Kircher (1601-1680) (q.v.), Magnes sive de arte magnetica, published in 1641. Martin Martini (1614-1661), who sent many magnetic observations from China to Kircher, proposed to him in 1640 to draw a map with lines for the magnetic declination. Had his suggestion been followed this would have been the first magnetic chart (before that of Edmund Halley (q.v.)).

A curious work is that of Jacques Grandami (1588–1672), Nova demonstratio inmobilitatis terrae petita ex virtute magnetica (1645), in which, in order to defend the geocentric system, he tried to show that the Earth does not rotate because of its magnetic field. Among the best observations made in China are those of Antoine Gaubil (1689–1759), who mentioned that the line of zero declination has with time a movement from east to west. His observations and those of other Jesuits in China were published in France in three volumes between 1729 and 1732. In 1727, Nicolas Sarrabat (1698–1739) published *Nouvelle hypothèse sur les variations de l'aiguille aimantée*, which was given an award by the Académie des Sciences of Paris. In 1769, Maximilian Hell (1720–1792), director of the observatory in Vienna, made observations of the magnetic declination during his journey to the island of Vardö in Lapland, at a latitude of 70°N, where he observed the transit of Venus over the solar disk.

#### Magnetic observatories

The Jesuit order was suppressed in 1773 and restored in 1814. From this time work on geomagnetism was taken up again at the new Jesuit observatories (Udías, 2000, 2003). A total of 72 observatories were founded throughout the world. Magnetic stations were installed in 15 of them: five in Europe, one in North America, four in Central and South America, and five in Asia, Africa, and the Middle East. Some of those magnetic stations in Europe were among the first to be in operation. Observatories in Central and South America, Asia, and Africa provided for some time the only magnetic observations in those regions. Details of these observatories can be found in Udías (2003). At present, most of them have been either closed or transferred to other administration.

The first of these observatories was established in 1824 at the Collegio Romano (Rome). There, in 1858, Angelo Secchi (1818-1878) began magnetic observations, using a set of magnetometers, a declinometer, and an inclinometer. He studied the characteristics of the periodic variations of the different components of the magnetic field and tried to relate magnetic variations with solar activity, considering the Sun to be a giant magnet at a great distance. Relations between geomagnetism and solar activity were to become a favorite subject among Jesuits. In the same year, 1858, magnetic observations begun at Stonyhurst College Observatory (Great Britain). Stephen J. Perry (1833-1889, Figure J1) began his work on geomagnetism, carrying out three magnetic surveys: two in France in 1868 and 1869 and the third in Belgium in 1871 (Cortie, 1890). In each of these surveys, at each station, careful measurements were made of the horizontal component of the magnetic field, magnetic declination, and inclination or dip (Perry, 1870). In Belgium, Perry found large magnetic anomalies related to coal mines. In order to study the relation

Figure J1 Stephen J. Perry (1833–1889), Director of Stonyhurst Observatory.

between solar and terrestrial magnetic activity, which was still a controversial subject, Perry at Stonyhurst began a series of observations of sunspots, faculae, and prominences in 1881. For this purpose he installed direct-vision spectroscopes and photographic-grating spectrometers and made large drawings of the solar disk (27 cm diameter). Perry collaborated with Edward Sabine (q.v.) in this work. Perry participated in several scientific expeditions. The most important was to Kerguelen Island in 1874 to observe the transit of Venus; there he carried out a very comprehensive program of magnetic observations. His project of collecting and comparing all his magnetic and solar observations was never completed due to his untimely death during a scientific expedition to the Lesser Antilles to observe a solar eclipse. In 1874 he was elected a Fellow of the Royal Society for his work in terrestrial magnetism. Perry's successor Walter Sidgreaves (1837-1919) completed the work and showed the correlation between magnetic storms and the maxima of sunspots (Sidgreaves, 1899-1901). The continuous magnetic observations from 1858 to 1974 at Stonyhurst may be one of the longest series at the same site.

Solar-terrestrial relations were also the main subject of Haynald Observatory, founded in 1879 by Jesuits in Kalocsa (Hungary). Between 1885 and 1917, Gyula Fényi (1845–1927) carried out a long program of magnetic and solar observations. He concentrated his efforts on the study of sunspots and prominences, making detailed observations (about 40000 of them) and proposing some interesting, for that time, new ideas about their nature. Magnetic observations began in 1879.

The Manila Observatory (Philippines) was founded by Spanish Jesuits in 1865. Martín Juan (1850–1888) was trained in geomagnetism by Perry in Stonyhurst. Juan brought new magnetic instruments to Manila where he took charge of the magnetic section in 1887. In 1888, he carried out a magnetic field survey on various islands of the archipelago. His death did not allow him to finish the work; this was done in 1893 by Ricardo Cirera (1864–1932), who extended the survey to the coasts of China and Japan (Cirera, 1893).

In the observatory of Zikawei, founded in 1872 near Shanghai, magnetic instruments for absolute measurements and variations were installed in 1877; instruments were moved to two nearby sites, first Lukiapang in 1908 and then Zose in 1933. Results were published in

nine volumes between 1908 and 1932 (*Études sur le magnetisme terrestre*, pp. 1–39). Joseph de Moidrey (1858–1936) carried out some early work on the secular variation in the Far East region (de Moidrey and Lou, 1932). These observations continued until 1950 when Jesuits were expelled from China by the Communist government.

After returning to Spain, Cirera founded in 1904 the Observatorio del Ebro, Roquetas (Tarragona; Figure J2), dedicated specifically to the study of the relations of solar activity and terrestrial magnetism and electricity. The observatory was equipped from the beginning with the most up-to-date instrumentation for this purpose and has kept updating its instrumentation since then. Luis Rodés (1881–1939) studied the influence of various forms of solar activity, mainly sunspots and prominences on the terrestrial magnetic and electric fields (Rodés, 1927). After the Spanish civil war, work was resumed by Antonio Romañá (1900–1981) and José O. Cardús (1914–). Since 1958, Ebro has been the base of the International Association of Geomagnetism and Aeronomy (IAGA) (q.v.) Commission for rapid magnetic variations. Romañá and Cardús held office in IAGA for many years.

Maintaining magnetic observatories in Africa was a difficult task, which Jesuits undertook early. One of the earliest observatories was established in 1889 in Antananarive, Madagascar. Continuous magnetic observations were made until 1967 when the observatory was transferred to the University of Madagascar. A magnetic station was established in the observatory founded in 1903 in Bulawayo, Zimbabwe. Edmund Goetz (1865-1933), its director for 23 years, in 1909 and 1914 carried out two magnetic field surveys, the first with a profile from Broken Hill (Kabwe, Zambia) to the "Star of the Congo Mine" (Congo) and the second in Barotseland (Zambia) covering a distance of more than 200 miles from Kazungula to Lealui (Goetz, 1920). The third observatory was a state observatory entrusted to and directed by Jesuits in Ethiopia. This observatory arose from a recommendation of the Scientific Committee of the International Geophysical Year in 1955 for a magnetic station near the magnetic equator. The station was established in Addis Ababa in 1958 and directed by Pierre Gouin (1917-) for 20 years. Gouin with the collaboration of Pierre Noel Mayaud (1923-), a Jesuit working at the Institute de Physique du Globe in Paris, studied temporal magnetic variations and magnetic storms. Mayaud participated in French expeditions to the Antarctica, studied the magnetic activity in the polar regions and worked mainly on the nature and practical use of geomagnetic indices (Mayaud, 1980). Early magnetic observations were also made by Jesuits in Central and South America. These observations began in 1862 in Belen Observatory (Havana, Cuba) and continued to about 1920. In Puebla (Mexico), magnetic observations were made between 1877 and 1914.

#### Summary

As an important part of their scientific tradition Jesuits dedicated much of their efforts to the study of terrestrial magnetism. Jesuits' dedication to science can be explained by their peculiar spirituality, which unites prayer and work and finds no activity too secular be turned into prayer. Teaching mathematics and observing the magnetic field of the Earth or of the Sun are activities, as has been shown, that a Jesuit finds perfectly compatible with his religious vocation and through which he can find God in his life. Early work on magnetism was carried out in the 17th and 18th centuries. Jesuit missionaries during those centuries carried out magnetic observations, which were analyzed and published in Europe. Modern work was done through the establishment of observatories. In at least 15 of these observatories magnetic observations were made. Jesuits contributed to the earliest magnetic observvations in Africa, Asia, and Central and South America.

# KIRCHER, ATHANASIUS (1602–1680)

Athanasius Kircher was born in Geisa near Fulda (Germany) on May 2, 1601 (or 1602—there is a disagreement in his biographies). After his primary education at the Jesuit school in Fulda, he joined (October 1618) the Jesuit order in Paderborn, where he began to study Latin and Greek. As a consequence of the Thirty Years War he went to Münster and Cologne, where he studied philosophy. He taught for a short time at the secondary school in Coblenz and afterward in Heiligenstadt. Later he went to Mainz to study theology, where he was ordained priest in 1628 and at the end of his Jesuit training was appointed professor of ethics and mathematics at the Jesuit University in Würzburg. He again migrated as a result of the war and went to Avignon (France) and was finally appointed professor of mathematics and oriental languages at the Roman College, which is now the well-known Gregorian University in Rome, where he died on November 27, 1680.

One cannot use modern standards of scientific evaluation to understand his real value, as Kircher's thinking and his methods are typical for the 17th century. First of all, he was a polymath interested in almost every kind of knowledge. His books (over 30 printed volumes) range from oriental languages-Arabic grammar; translation of old Coptic books and an extensive research to decipher Egyptian hieroglyphics: Lingua Egyptiaca restituta (1643), Oedypus Egyptiacus (1652), Obeliscus Pamphilius (1650)-to physics-optics: Ars Magna Lucis et Umbra (1646); magnetism: Ars Magnesia (1631), Magnes, sive de Arte Magnetica (1641, 1643, 1654), Magneticum Naturae Rerum (1667); music: Musurgia Universalis sive Ars Magna consoni and disoni (1650), Phonurgia Nova (1673); geophysics: Mundus Subterraneus (1664); and also medicine: Scrutinium physico-medicum contagiosae luis quae pestis dicitur (1657). He also wrote on biblical subjects such as Arca Noe (1675) and Turris Baabel (1679), in which he combines science and archeological imagination. This imagination together with his knowledge of many different subjects inclined him to encyclopedism as in his works Itinerarium Extaticum (1656) and Iter Extaticum II (1657), in which he discusses theories of the solar system and beyond while telling the fictitious story of an imaginary journey through Earth and celestial bodies.

Kircher tries to find some sort of unity among the many different subjects with which he dealt, not only in written language—*Polygraphia nova universalis* (1663)—but also in the much more universal concept of knowledge itself as in *Ars Magna Sciendi* (1669). Although mathematical combinations in Kircher's book are far removed from the cabalistic usage, which was so frequent in his time, there is a misleading use of the word "magnetism" in his writings: for him magnetism with its two polarities is a metaphorical symbol of the dualism in things and forces acting in nature: attraction and repulsion; love and hatred; and light and darkness. This use allows him to talk about the magnetism of celestial bodies, music, medicine, love, and to print, perhaps for the first time in a scientific book, the word electromagnetism (Kircher, 1654, p. 451), although this word has nothing to do with the concept introduced many years afterward by Maxwell.

He was certainly dominated by Baroque culture, redundant in many aspects of his expression, overlengthy in his writings, and not easy to read in his Latin, which is far removed from the classical language. That Kircher was accepted during his lifetime as one of the best scholars in Europe is proven by the fact that the Imperial Court in Vienna invited Kircher to be professor of astronomy in the University of Vienna as successor of Kepler, who died in 1632. It was only by the influence of Cardinal Barberini and of Pope Urban VIII that he was prevented from accepting the post, and was called to Rome. They accepted the request of the French gentleman Nicolaus Claude de Peiresc, who wanted Kircher to continue his work on the interpretation of Egyptian hieroglyphics. Since his death importance of Kircher as a scientist has been much debated although now his value seems to be accepted again.

Of the three books that Kircher wrote on magnetism the first *Ars Magnesia* (his first printed book) is a short booklet of 48 pages and seems to be the printed edition of a talk he gave some years earlier when he was teaching at Heiligenstadt. That can be inferred from the explanation that follows the title where he says he will deal with the nature, force, and effects of the magnet together with several applications of it. In the third book, *Magneticum Naturae Rerum*, the word "magneticum" is taken in the metaphorical sense that includes all forces that act on all things in nature.

The second book *Magnes sive de Arte Magnetica Opus Tripartitum* (Kircher, 1654) (a copy of its 3rd edition is in the library of the Ebro Observatory) contains the scientific contribution of Kircher to geomagnetism. It is divided into three "books:"

- 1. On the Nature and Properties of the Magnet
- 2. The Use of the Magnet
- 3. The Magnetic World

In the first book Kircher tries to investigate what magnetism is, using as a starting point what was known in his time: the natural existence of loadstones, the fact that iron may become magnetic with two poles acting in opposite senses on other magnetic bodies. He also accepts the hypothesis of the Earth being a magnet after repeating Gilbert's experiments with the *terrella*, but it is easy to see that the data is too poor to explain what magnetism is.

In the second book, Kircher shows with the help of several experiments how magnetic force is distributed in magnetic bodies of different shapes and how to find what he calls the barycentre. He tries to show that in a spherical body magnetism propagates linearly to the poles in its interior and spherically to the poles in the exterior. He finds that both poles have equal force and explains how to make magnetic needles to measure inclination and declination accurately. For him it is a well-established fact that "in the Boreal Hemisphere there is a distribution of inclination in accordance with latitude, whether it exists also past the equator I do not know, as to my knowledge nobody has studied these concordances" (Kircher, 1654, p. 295). At this point he accepts the idea already given by Gilbert and prints a table of magnetic inclinations for each degree of northern latitudes. He includes his own calculations and some of Gilbert's values (Kircher 1654, p. 306).

Declination is treated quite differently in Kircher's works: he accepts that its value is related with geographical position but he does not believe that it depends only on longitude because it deviates from the local meridian either eastward or westward and also because it changes values at different latitudes on the same meridian. The solution of this point is of greatest importance in geography and navigation. He also realized the errors of many of these values: "there is no doubt about declination, the only doubt is in its quantity (=value)" and a little afterward he adds "the only way to get out of this problem is to make all around the world as many reliable observations as possible" (Kircher, 1654, p. 313) and for Kircher it was easy to see that his Jesuit order, with many colleges in Europe and missionaries traveling to America and Asia, could be a reliable instrument to perform this task.

After talks with his colleagues in Rome and with the approval of his superior general, he prepared a *Geographical Consilium* (an instruction manual) about declination and inclination, what kind of instruments were needed, how to use them, and how to report the results. On the occasion of one of the regular meetings of Jesuits from around the world in Rome in 1639, Kircher collected names of Jesuits who could do the work and wrote letters to all of them.

Three long tables are the result: the first one (Table K1) "Magnetic declination on the oceans observed by Jesuits" is a long list of nearly 200 geographical points with their declination and latitude. The latitudes extend as far as from  $81^{\circ}0'N$  to  $54^{\circ}27'S$ , and the declinations from  $25^{\circ}0'E$  to  $35^{\circ}30'W$ . Table K2 "Longitudes and latitudes of several places with their declination" seems to be arranged in increasing longitude from  $0^{\circ}17'$  to  $359^{\circ}40'$ , but longitudes from  $347^{\circ}25'$  to  $359^{\circ}40'$  are included between  $41^{\circ}10'$  and  $42^{\circ}7'$ . Declinations go from  $0^{\circ}0'$  to  $33^{\circ}$ . There is no indication whether they are to the east or to the west, but the fact that longitudes from  $42^{\circ}$  to  $346^{\circ}$  are listed at the end of the table may suggest some elaboration of the data, which are not explained by Kircher. Table K3 is the list of declinations observed in

Europe following Kircher's request. The names of some 57 authors and of 66 cities in Europe with their declination are mentioned in it. Values in the list extend from Lisbon to Constantinople and from Vilna to Malta. Kircher adds six other cities: Aleppo (Syria), Alexandria (Egypt), Goa and Narfinga (India), and Canton and Macau (China). Behind this third table Kircher adds the copy of a letter from Francis Brescianus, who observed in his travel westward to Canada the following declination changes: from Europe to a place near the Azores the declination was around  $2^{\circ}E$  or  $3^{\circ}E$ , at the Azores it was about 0°, from there for some 300 leagues it increased regularly up to around  $21^{\circ}$  or  $22^{\circ}$  and from there it decreased again but more quickly as one approached America. In Quebec it was 16° and further west, in the land of the Huron Indians, some 200 leagues from Quebec, it was only 13°. Kircher adds also a letter from his pupil in Rome, P. Martin s.I. with 13 declinations but their geographical positions are too vague as "in the meridian of river Laurentij Marques" (Kircher, 1654, p. 348). In this letter Martin suggested a method for drawing a world chart of declination. This suggestion was not followed by Kircher and the first isogonic chart of the Atlantic was not published until 1701 by Edmund Halley (Chapman and Bartels, 1940).

Unfortunately, the final result of all this observational work was never completed. As Kircher says: "When I was keeping the work, composed with no small effort, in my Museum and waiting for the right moment to publish it for the good of the Republic of Letters, it was secretly removed by one of those people who came to me almost every day from all around the world to see my Museum" (Kircher, 1654, p. 294).

This combined and centralized effort is probably the first one of that kind in magnetism and must be considered as the great contribution of Kircher to the advancement of geomagnetism. It is certainly not a milestone on the long way of progress in science but it is an important step in it.

# LANGEL, ROBERT A. (1937–2000)

A NASA (UnitedStates) scientist who served as the project scientist for the Magsat mission. Trained as an applied mathematician and physicist, Langel was born in Pittsburgh, Pennsylvania. He was a strong advocate of high-accuracy vector magnetic measurements from satellite. These measurements were used to demonstrate the break in the power spectra at about spherical harmonic degree 13 that represents the transition from core-dominated processes to lithosphericdominated processes (Figure L1; Langel and Estes, 1982). Tantalizing

**Figure L1** Comparison of the Lowes-Mauersberger spectra at the Earth's surface for a recent comprehensive model (line) of the core and lithospheric fields by Sabaka *et al.* (2004) and a lithospheric field model (symbols) by Fox Maule *et al.* (2005).  $R_n$  is the mean square amplitude of the magnetic field over a sphere produced by harmonics of degree *n*.

suggestions of such a break had previously been reported from total field-intensity measurements acquired on an around-the-world magnetic profile (Alldredge et al., 1963). Langel also made use of the high-accuracy vector measurements, and magnetic-observatory measurements, for the coestimation of internal (core and lithosphere), external (ionosphere and magnetosphere), and induced magnetic fields. These comprehensive models of the geomagnetic field were developed in collaboration with T. Sabaka (NASA) and N. Olsen (Denmark). Earlier workers had relied on a sequential approach, beginning with the largest (core) fields. Langel also pioneered mathematical techniques for the merging of a priori long-wavelength lithospheric magnetic field information with shorter wavelength observations (Figure L1; Purucker et al., 1998) using inverse techniques. This is necessary because the longest-wavelength lithospheric magnetic fields are inaccessible to direct observation as they overlap with the much-larger magnetic fields originating in the Earth's outer core. Significant earlier developments with forward models came from Cohen (1989) and Hahn et al. (1984). Langel authored or coauthored in excess of 94 peer-reviewed publications and helped train a generation of geomagnetists by virtue of his work on Magsat and his teaching at Purdue University (UnitedStates) and Copenhagen University (Denmark).

Bob was devoted to his family and church. His religiosity was well known among his colleagues, and he undertook missionary work, lead Bible study groups, and worked with teenagers.

# LAPLACE'S EQUATION, UNIQUENESS OF SOLUTIONS

Potential theory lies at the heart of geomagnetic field analysis. In regions where no currents flow the magnetic field is the gradient of a potential that satisfies Laplace's equation:

$$\mathbf{B} = -\nabla V \tag{Eq. 1}$$

$$\nabla^2 V = 0 \tag{Eq. 2}$$

We can find the geomagnetic potential *V* everywhere in the source-free region by solving Eq. (2) subject to appropriate boundary conditions. Equation (1) means that we are dealing with a single scalar, the geomagnetic potential, and Eq. (2) means that we only have to know that scalar on surfaces rather than throughout the entire region. This reduces the number of measurements enormously. I shall discuss here two idealized situations appropriate to geomagnetism and paleomagnetism: measurements on a plane in Cartesian coordinates (x, y, z) with z down, continued periodically in x and y, appropriate for a small survey, and measurements on a spherical surface r = a in spherical coordinates  $(r, \theta, \phi)$ , where a is Earth's radius. Simple generalizations are possible to more complex surfaces.

It is well known that solutions of Laplace's equation within a volume  $\Omega$  are unique when V is prescribed on the bounding surface  $\partial\Omega$ , the so-called *Dirichlet* conditions. This is of no use to us because we cannot measure the geomagnetic potential directly. We can, however, measure the component of magnetic field normal to the surface, which also guarantees uniqueness (the so-called *Neumann* conditions). Thus measurement of a single component of magnetic field on a surface can be used to reconstruct the magnetic field throughout the current-free region, provided the sources are entirely inside or outside the measurement surface. When both internal and external sources are present two components need to be measured on a single surface, when it is also possible to separate the parts (see *Internal external field separation*). Here I shall focus on the case of purely internal sources.

Components other than the vertical also provide uniqueness. As illustration consider the general solution of Laplace's equation in Cartesian coordinates:

$$V(x, y, z) = \sum_{k,l,m} C_m \exp(mz) \cos(kx + \ell y + \alpha_{k,\ell}), \quad (Eq. 3)$$

where  $m = \sqrt{k^2 + \ell^2}$  is positive to ensure a finite solution as  $z \to -\infty$ and the  $\{\alpha_{k,\ell}\}$  are phase factors. If  $B_z = \partial V/\partial z$  is known on z = 0 we can differentiate Eq. (3) with respect to z, set z = 0, and determine the arbitrary coefficients  $\{C_{k,\ell}, \alpha_{k,\ell}\}$  from the usual rules for Fourier series. This is the case of Neumann boundary conditions. Of course, solutions of Eq. (3) are periodic in x and y with periods  $2\pi/k$  and  $2\pi/l$ , respectively.  $B_x$  and  $B_y$ , however, do not give unique solutions. Differentiating Eq. (3) with respect to x and putting z = 0, for example, allows determination of all the Fourier coefficients except those with k = 0. The ambiguity in the solution takes the form  $V_0(y, z) =$  $\sum_l C_l \exp(-lz) \cos(ly + \alpha_l)$ . Similarly, measurement only of  $B_y$ leaves an ambiguity independent of y. Knowing  $B_x$  and  $B_y$  overdetermines the problem.

The spherical case is slightly different.  $B_r$  (-Z in conventional geomagnetic notation) provides Neumann boundary conditions and so will give a unique solution.  $B_{\phi}$  (east) allows an axisymmetric ambiguity similar to that for the cartesian  $B_x$  and  $B_y$  cases. Surprisingly,  $-B_{\theta}$ (north) gives a unique solution; the condition that *V* be finite at the poles provides the necessary constraint to remove the arbitrary parts of the solution. Proof involves the general solution of Laplace's equation as a spherical harmonic expansion (see *Main field modeling*) in similar fashion to the use of the Fourier series solution in the cartesian case (see *Magnetic anomalies, modeling*). More elegant formal proofs of these standard results making use of Green's theorem are to be found in texts on potential theory (e.g., Kellogg (1953)).

Formal mathematical results dictate the type of measurements we must make in order to obtain meaningful estimates of the geomagnetic field in the region around the observation surface. Clearly in the real situation other complications arise from finite resolution and errors, but with a uniqueness theorem we can at least be confident that the derived field will converge toward the correct field as the data are improved; for this to happen we must measure the right components of magnetic field, but this is not always possible. Instrumentation has changed over the years, dictating changes in the type of measurement available. Table L1 gives a summary of the bias in available datasets.

Backus (1970) addressed the problem of uniqueness when only *F* is known on the surface. He showed that, for certain magnetic field configurations, there exist pairs of magnetic fields  $\mathbf{B}_1$  and  $\mathbf{B}_2$ , which satisfy  $\nabla \cdot \mathbf{B} = 0$  and  $\nabla \times \mathbf{B} = 0$  outside  $\partial \Omega$  and such that  $|\mathbf{B}_1| = |\mathbf{B}_2|$  everywhere on  $\partial \Omega$ , but  $|\mathbf{B}_1| \neq |\mathbf{B}_2|$  elsewhere. This result led to the decision to make vector measurements on the MAGSAT satellite. In practice **B** obtained from intensity measurements alone can differ by 1000 nT from the correct vector measurements. The difference takes the form of a spherical harmonic series with terms dominated by l = m, now called the Backus ambiguity or series. Additional information does provide uniqueness (e.g., locating the dip equator (Khokhlov *et al.*, 1997)).

Backus (1968, 1970) gives details of the proof in both two and three dimensions. The 2D proof uses complex variable theory and is particularly simple and illuminating. We use the complex potential w(z), where z = x + iy. The field is given by the real and imaginary parts of dw/dz, and |dw/dz| is known on the bounding circle. Focus attention on

$$\zeta(z) = i \log dw/dz = \zeta + i\eta = -\arg |dw/dz| + i \log |dw/dz|. \quad (Eq. 4)$$

Both  $\xi$  and  $\eta$  satisfy Laplace's equation as the real and imaginary parts of an analytic function, except where dw/dz = 0. When such singularities exist, taking a circuit enclosing the source region gives an increase of  $2\pi$  in the argument of the logarithm. This defines the ambiguity. The number of singularities determines the number of different solutions; singularities exist if the field has more than two dip poles on the surface.

Paleomagnetic and older geomagnetic data sets are dominated by directional measurements. Early models made the reasonable but

unproven assumption that direction determined the magnetic field up to a single multiplicative factor. Proctor and Gubbins (1990) found a result in 2D using Backus' method above, focussing instead on the potential

$$\zeta(z) = \log dw/dz = \log |dw/dz| + i \arg |dw/dz|.$$
 (Eq. 5)

The above argument then leads to a general solution with one arbitrary multiplicative constant plus n - 1 additional arbitrary constants, where 2n is the number of dip poles.

As with the intensity problem, extension of the 2D proof into 3D is not straightforward. Proctor and Gubbins (1990) conjectured a similar result in 3D and provided an axisymmetric example. They also gave a practical recipe for determining the ambiguity using standard methods of inverse theory. The problem is homogeneous in the sense that, if  $\mathbf{B}_1$  and  $\mathbf{B}_2$  are fields derived from harmonic potentials and are parallel on  $\partial \Omega$ , then any linear combination of the form  $a_1\mathbf{B}_1 + a_2\mathbf{B}_2$  is also a solution. Thus, having found one solution,  $\mathbf{B}_1$ say, a linear error analysis around  $\mathbf{B}_1$  will yield a direction in solution space along  $\mathbf{B}_1 - \mathbf{B}_2$  that defines an annihilator for the problem. Homogeneity then guarantees that this linearized analysis will be valid globally. Application of this procedure to the axisymmetric example did yield both solutions, but only when a very large number of spherical harmonics were used in their representation, confirming Backus' view that uniqueness demonstrations on solutions restricted to finite spherical harmonic series could be misleading.

Hulot *et al.* (1997) finally found a formal proof in 3D using the homogeneity of the problem. The key is to show that the solution space is linear; the proof follows using relatively recent general results from potential theory. They show that, if *n* is the number of loci where the field is known to be either zero or normal to the surface then the dimension of the solution space (number of independent arbitrary constants) is n - 1. This result holds whether sources are outside or inside the surface. For the related problem of gravity, which allows monopoles, the dimension is *n*.

It is rather easy to prove that directional measurements throughout a volume provide uniqueness to within a single arbitrary constant (Blox-

ham, 1985). Given one solution **B** others must have the form  $\alpha$ **B** and must be solenoidal and curl-free:

$$\nabla \cdot (\alpha \mathbf{B}) = \mathbf{B} \cdot \nabla \alpha = 0 \tag{Eq. 6}$$

$$\nabla \times (\alpha \mathbf{B}) = -\mathbf{B} \times \nabla \alpha = 0. \tag{Eq. 7}$$

Thus  $\nabla \alpha = 0$  and  $\alpha$  must be a constant. Knowing the field everywhere inside the volume of measurement enables us to construct the field component normal to the boundary and solve Laplace's equation outside the volume of measurement, all within a single-multiplicative constant.

The earliest historical data sets are dominated by declination. In this case we know the direction of the horizontal field and location of the dip poles. Suppose the potential field  $B_r + \alpha \mathbf{B}_h$  fits the data;  $\mathbf{B}_h$  is known but  $B_r$  and  $\alpha$  are unknown. The radial component of  $\nabla \times \mathbf{B}$  does not involve  $B_r$  or  $\partial/\partial r$ , so  $\nabla_h \times (\alpha \mathbf{B}_h) = 0$  and

$$\nabla \boldsymbol{\alpha} \times \mathbf{B}_{\rm h} = 0. \tag{Eq. 8}$$

The unknown  $\alpha$  is therefore invariant along contours of  $\mathbf{B}_h$ ; measurement of horizontal intensity along any line joining the dip poles is therefore sufficient to guarantee uniqueness of  $\mathbf{B}_h$ , which in turn would allow us to determine the potential and  $\mathbf{B}$ . The coverage of additional data required is therefore reduced enormously from the whole surface to a line. Unfortunately horizontal intensity is not available for the early historical epoch, and paleoinclinations are too inaccurate to be of any use (Hutcheson and Gubbins, 1990), but inclination did become available from the early 18th century on voyages from Europe round Cape Horn and through the Magellan Straits into the Pacific, which represents a fair approximation to the ideal case of horizontal intensity between the north and south dip poles.

Uniqueness results are summarized in Table L2. Practical aspects of the problem are discussed further by Lowes *et al.* (1995).

# LARMOR, JOSEPH (1857–1942)

Joseph Larmor is known in geomagnetism for the precession frequency of the proton that now bears his name and his seminal paper of 1919 proposing the dynamo theory for the first time. His main purpose was to explain the solar magnetic field, but he also had the geomagnetic field in mind.

Born in 1857 in Magherhall, County Antrim, and educated at the Royal Belfast Academical Institution and Queen's College, Belfast, Larmor showed an early ability in mathematics and classics. He was senior wrangler in the Mathematics Tripos at Cambridge, beating J.J. Thomson to second place. He succeeded George Stokes as Lucasian Professor of Mathematics in 1903, and was knighted in 1909.

Larmor worked at the dawn of modern physics and was concerned with the aether and with unifying electricity and matter. His greatest work, *Aether and Matter*, was revolutionary and inspiring. His contributions are often compared with those of Lorentz. His discovery of what we now call *Larmor precession* was incidental: he showed that in a magnetic field, an electron orbit precesses with angular velocity proportional to the magnetic field strength while remaining unchanged in form and inclination to the magnetic field. The same principle applies to a particle, such as a proton, that possesses a magnetic moment, and the frequency of precession of a proton in an applied magnetic field is called the *Larmor frequency*. The proton magnetometer, developed 30 years after his death, determines the absolute intensity of a magnetic field by measuring the precession frequency.

Later in his career he contributed to many of the geophysical problems of the day, publishing on the Earth's precession and irregular axial motion, and on the effects of viscosity on free precession, which Harold Jeffreys later used in his argument against mantle convection. Larmor published on the origin of sunspots, which G.E. Hale had shown were associated with strong magnetic fields, and became a leading authority on geomagnetism. This was a time when theories of the origin of the magnetic fields of the Earth and of the Sun abounded. His 1919 paper, presented at the British Association for the Advancement of Science meeting in Bournemouth (Larmor, 1919) is only two pages long; he dismisses permanent magnetization and convection of electric charge as candidates for both bodies. For the Sun he considers three theories: the dynamo theory, electric polarization by gravity or centrifugal force, and intrinsic polarization of crystals. He dismisses the last two in the case of the Earth because of the secular variation, arguing that they predict proportionality between the magnetic field and spin rate in contrast to the observation of a changing dipole moment and constant spin rate. His version of the dynamo theory is quite explicit and requires fluid motion in meridian planes. It was this very specific theory that was tested by Cowling (1934) in establishing his famous antidynamo theorem (see Cowling's theorem).

According to Eddington (1942-1944) he was a retiring and complicated man, refusing a celebration in his honor organized by Cambridge University. His lectures were "ill-ordered and obscure but... even the examination-obsessed student could perceive that here he was coming to an advanced post of thought, which made all his previous teaching seem behind the times." He was one of only three lecturers E. C. Bullard (q.v.) bothered with during his undergraduate days. Darrigol (2000) says "Larmor's physics was freer and broader than conceptual rigor and practical efficiency commanded." In similar vein, Bullard once described him to me as a lazy man, which I took to refer to his rather casual outline of the dynamo theory and failure to follow it up with any mathematical analysis, of which he was eminently capable, leaving Cowling to pick it up a decade later. But how right he was! How much better to take the credit for a correct theory and avoid the disappointments of the next half-century, from the antidynamo theorems to the numerical failure of Bullard and Gellman's attempt at solution, and the graft of the subsequent 30 years of mathematical and computational effort it has taken to put the dynamo theory onto a secure footing!

# LEHMANN, INGE (1888–1993)

In 1936, Miss Inge Lehmann (Figure L2) proposed a new seismic shell of radius 1400 km at the center of the Earth, which she called the "inner core." It was already known that low seismic velocities in the outer core created a shadow at angular distances between  $105^{\circ}$  and  $142^{\circ}$  and that seismic waves diffracted some considerable distance into the shadow. Wiechert also attributed seismic arrivals before  $142^{\circ}$  to diffraction, but Gutenberg and Richter (1934) had already found their

amplitude too large and frequency too high to fit with the diffraction theory. Measurements of the vertical component of motion clinched the interpretation as waves reflected or refracted through a large angle. Lehmann's paper remains a classic example of lateral thinking, careful interpretation, and cautious conclusions. The proposed radius was close to the currently accepted one of 1215 km.

The inner core was rapidly accepted into the new Earth models being constructed by Gutenberg and Richter (1938) in the United States and Jeffreys (1939) in the U.K., although the scattered nature of the arrivals in the shadow zone demanded a thick transition zone at the bottom of the outer core, where the seismic velocity increased gradually. In the first edition of his book on seismology, Bullen (1947) labeled the Earth's layers A-G, with A as the crust and G the inner core, with F denoting the inner core transition. The need for this layer was largely removed when seismic arrays showed that much of the scattered energy came not from the inner-core boundary but from the core-mantle boundary (Haddon and Cleary, 1974). The inner core is vital in the theory of geomagnetism because its slow accretion, a consequence of the Earth's secular cooling, powers the geodynamo and influences core convection (see Inner core tangent cylinder). The F-layer lives on in name at least, despite the removal of seismological evidence, in the form of the required boundary layer between the inner and outer cores.

Although the inner core was probably the most spectacular of Lehmann's discoveries, she enjoyed a long and distinguished career in seismology, remaining active throughout her long retirement. Born in Copenhagen into a distinguished family, she benefited from an exceptionally enlightened early education and read mathematics at the University of Copenhagen from 1908. A spell in Cambridge in 1910 came as a shock because of the restrictions placed on women there (Cambridge did not grant women degrees until much later).

Lehmann's career as a seismologist began in 1925 when she was appointed assistant to Professor N.E. Norland, who was engaged in establishing a network of seismographs in Denmark. She met Beno Gutenberg at this time. In 1928 she was appointed chief of the seismological department of the Royal Danish Geodetic Institute, a post she held until retirement in 1953. In retirement she enjoyed frequent visits to Lamont and other institutions in the United States and Canada. It seems her international reputation was strong before her work was recognized at home in Denmark. She was elected Foreign Member of the Royal Society in 1969, was awarded the Bowie Medal (the American Geophysical Union highest honor) in 1971, and now has an AGU medal named in her honor.

Further details of her life may be found in Bolt (1997).

Inner Core Tangent Cylinder

# LENGTH OF DAY VARIATIONS, DECADAL

It is a truism to say that the Earth rotates once per day. However, the length of each day is not constant, but varies over timescales from everyday to millions of years. Perhaps the best-known variation is the gradual slowing of the rotation rate due to the tidal interaction between the Earth and the moon (see Length of day variations, longterm). Historical observations are well fit by an increase in length of day (LOD) of about 1.4 ms per century, most clearly seen in the timing of eclipses recorded by ancient civilizations. (Note that there are 86400 seconds in a day, so these millisecond changes are of order 1 part in  $10^8$  of the basic signal.) Geological evidence also supports increase in LOD over Earth history (Williams, 2000). At the other end of the scale, modern measurements from the global positioning system (GPS) or very-long baseline interferometry (VLBI) demonstrate a signal on yearly and sub-yearly timescales, again of a few milliseconds in magnitude. These variations are dominated by angular momentum exchange between the atmosphere and the solid Earth; put crudely, winds blowing against mountain topography (particularly north-south ranges such as the Rockies in America) push the solid Earth, speeding up or slowing down the rate of rotation. Atmospheric angular momentum calculated from models of the global circulation can explain almost all the short-period signals. The small remaining residual (of amplitude  $\sim 0.1$  ms) shows strong coherence with estimates of oceanic angular momentum (Marcus et al., 1998), and the hydrological cycle is also probably important, by causing small variations in the Earth's moment of inertia. However, surface observations are unable to explain a decadal fluctuation, again of a few milliseconds in LOD. This signal was first recognized in the early 1950s, and because the core is the only fluid reservoir in the Earth capable of taking up the requisite amount of angular momentum and due to its correlation with various geomagnetic data (in particular records of magnetic intensity and declination at certain magnetic observatories), it was assumed to result from exchange

470

of angular momentum between the fluid core and solid mantle. More robust evidence was provided by Vestine (1953), who demonstrated a good correlation between the change in length of day ( $\Delta$ LOD) signal and core angular momentum (CAM) estimated from observations of *westward drift* (*q.v.*).

The connection between core processes and  $\Delta LOD$  was put on a rigorous footing by Jault et al. (1988). They realized that models of surface core flow reflect motions throughout the core and can be used to estimate changes in angular momentum of the core, matching changes in angular momentum of the solid Earth required to explain the observed decadal ALOD. Most processes in the core have characteristic timescales which are either of centuries or longer (for example the planetary waves that have been proposed as an explanation for westward drift (q.v.), or which are short, of order days (Alfvén waves (q.v.) or inertial waves). Torsional oscillations (q.v.), however, are thought to have characteristic periods of decades. These are solid-body rotations of fluid cylinders concentric with the Earth's spin axis, about that axis. Such motions carry angular momentum about the spin axis, and extend to the core surface. Therefore, changes in CAM can be calculated using surface flow models. Such a calculation ignores the inner core, and assumes uniform density for the liquid core; however, the value calculated is not sensitive to these assumptions. Most commonly, a surface flow is used that is assumed to be tangentially geostrophic (the force balance in the horizontal direction is assumed to be between pressure gradients and Coriolis force). The core surface flow is expanded in a poloidal-toroidal decomposition in spherical coordinates (r,  $\theta$ ,  $\varphi$ ) (r is radius,  $\theta$  is colatitude, and  $\varphi$  is longitude), such that

$$\mathbf{v} = \sum_{l=1}^{\infty} \sum_{m=0}^{l} \nabla_{\mathrm{H}} \left( r s_{l}^{m} Y_{l}^{m} \right) + \nabla_{\mathrm{H}} \times \left( \mathbf{r} t_{l}^{m} Y_{l}^{m} \right)$$
(Eq. 1)

where  $\nabla_{\rm H}$  is the horizontal part of the gradient operator, and  $s_l^m$  and  $t_l^m$  are poloidal and toroidal scalars, respectively, corresponding to surface *spherical harmonics* (*q.v.*)  $Y_l^m(\theta, \varphi)$  of degree *l* and order *m*. Then, core angular momentum depends only on two large-scale toroidal, zonally symmetric, surface flow harmonics. Using standard parameters for the Earth, the relation

$$\delta T = 1.138 \left( \delta t_1^0 + \frac{12}{7} \delta t_3^0 \right)$$
 (Eq. 2)

is obtained, where  $\delta T$  is the change in LOD in milliseconds and the changes in the toroidal flow coefficients are measured in km y<sup>-1</sup>. The  $t_1^0$  harmonic corresponds to a uniform rotation of the core surface about the Earth's rotation axis. Figure L3 shows a calculation of Jackson *et al.* (1993) using the ufm *time-dependent model of the main field* (*q.v.*) to calculate the predicted LOD variations, compared with observations of McCarthy and Babcock (1986). Despite the highly idealized theory, the agreement is striking, especially over the last century.

The correlation post-1900 between LOD and calculated coreangular momentum is remarkably robust, being evident for many different strengths of flow (explaining more or less of the secular variation) and for different physical assumptions about the flow (for example, assuming that the flow is toroidal, or steady but within a drifting reference frame). By 1900 the network of magnetic observatories (q.v.) was globally distributed; these stations provide by far the most sensitive and accurate measurements of the global magnetic secular variation from which the flows are calculated. Before 1900, as more observatory data become available, the time variation of the field models reflects changes in data quality as well as any physical processes; these changes map into the flow models, giving unphysical results and poorer correlation with observed  $\Delta$ LOD. There is some evidence that this problem can be overcome by calculating simpler flow models; a notably better correlation is provided by the original analysis (Vestine, 1953) of westward drift!

**Figure L3** Comparison of observed decadal variations in length of day LOD (with a long-term trend of 1.4 ms/century removed) with the prediction from a model of surface core flow (following Jackson *et al.*, 1993).

More recent work has considered whether the core could have a role to play in angular momentum exchange at shorter periods. It has been argued that the core may well change the phase of the observed LOD signal compared with forcing from the atmosphere and oceans, but there is no strong evidence in subdecadal  $\Delta$ LOD of a signal from the core.

The study of LOD variations as described here is essentially phenomenological—there is no need to assume any particular mechanism for the exchange of angular momentum between the core and the mantle. How the exchange of angular momentum may be effected, and the influence of the dynamics of the *torsional oscillations* (q.v.), are discussed elsewhere.

# LENGTH OF DAY VARIATIONS, LONG-TERM

# **Tidal friction**

The Moon raises tides in the oceans and solid body of the Earth. The Sun does likewise, but to a lesser extent. Let us first consider the action of the Moon. Due to the anelastic response of the Earth's tides, the tidal bulges can be thought of as being carried ahead of the sublunar point by the Earth's rotation. This misalignment of the tidal bulges produces a torque on the Moon, which increases its orbital angular momentum and drives it away from the Earth, while reducing the Earth's rotational angular momentum by the opposite amount. The rate of rotation of the Earth is reduced through the action of tidal friction, which occurs very largely in the oceans. By analogy, the solar tides make a smaller contribution to slowing down the Earth, but the reciprocal effect on the Sun is negligible. As the Earth slows down the length of the day (LOD) increases. The change in the rate of rotation of the Earth under this mechanism is usually termed its tidal acceleration. Beside this long-term change, there are relative changes between the rotation of the mantle and the core on shorter timescales. The transfer of angular momentum, which produces these changes, is caused by core-mantle coupling and the astronomical results discussed here shed light on the timescale of the geomagnetic processes involved.

The tidal acceleration of the Earth has been measured reliably in the following way. Analysis of the perturbations of near-Earth satellites produced by lunar and solar tides, together with the requirement that angular momentum be conserved in the Earth-Moon system, leads to an empirical relation between the retardation of the Earth's spin and the observed tidal acceleration of the Moon (see, for example, Christodoulidis et al. (1988)). Lunar laser ranging gives an accurate value for the Moon's tidal acceleration and inserting this in the relation gives the result  $-6.1 \pm 0.4 \times 10^{-22}$  rad s<sup>-2</sup> for the total tidal acceleration of the Earth (Stephenson and Morrison, 1995). This result is equivalent to a rate of increase in the LOD of  $+2.3 \pm 0.1$  ms per century (ms/100 y). For the interconversion of units see Table 2 of Stephenson and Morrison (1984). These satellite and lunar laser ranging measurements were obtained from data collected over the past 30 years or so. However, they can be applied to the past few millennia because the mechanism of tidal friction has not changed significantly during this period (see, for example, Lambeck, 1980, Section 10.5).

While the tidal component of the Earth's acceleration can be derived from recent high-precision observations, the actual long-term acceleration, which is the sum of the tidal and nontidal components, cannot be measured directly because it is masked by the relatively large decade fluctuations. Instead, observations from the historical past, albeit crude by modern standards, have to be used. By far the most accurate data for measuring the Earth's rotation before the advent of telescopic observations (ca. A.D. 1620) are records of eclipses. Useful records of eclipses extend back to about 700 B.C.

# Eclipses and the Earth's rotation

Early eclipse observations fall into two main independent categories: untimed reports of total solar eclipses; and timed measurements of solar and lunar eclipse contacts. The tracks of total solar eclipses on the Earth's surface are narrow and distinct. The retrospective calculation of their occurrence is made by running back the Sun and Moon in time along their apparent orbits around the Earth, the Moon's motion having been corrected for the lunar tidal interaction with the Earth. Unless special provision is made, this computation presupposes the uniform progression of time and hence the uniform rotation of the Earth on its axis. For each observation, the displacement in longitude between the computed position of the track of totality and the actual observed track measures the cumulative correction to the Earth's rotational phase due to variations in its rate of rotation over the intervening period. This displacement in degrees, divided by 15, gives the correction in hours to the Earth's "clock," usually designated by  $\Delta T$ . Stephenson and Morrison (1995) analyzed all the available reliable records of solar and lunar eclipses during the period 700 B.C. to A.D. 1600 from ancient Babylon, China, Arab, and European sources in order to measure  $\Delta T$  at epochs in the past. For full translations of the various historical records see Stephenson (1997). The untimed data consist of unambiguous descriptions of total solar eclipses from known places on particular dates, but without timing. The measurement of time is not necessary because of the narrowness of the belt of totality (a few minutes of time) relative to the quantity being measured ( $\Delta T$ ), which amounts to several hours in the era B.c. The timed data, on the other hand, include a timing of the occurrence of one or more of the contacts during solar and lunar eclipses.

Their results for  $\Delta T$  from the untimed data are shown in Figure L4. Some less-critical data have been omitted here from the figure for the sake of clarity. A single parabola does not adequately represent all the data, so Stephenson and Morrison fitted a smooth curve to the data using cubic splines, with economical use of knots in order to follow the degree of smoothness in the observed record after A.D. 1600. The details of the fitting procedure can be found in their 1995 paper. Their results from the independent timed data are very close to the untimed data, and are not reproduced here.

# Long-term accelerations in rotation

The parabola in Figure L4 corresponds physically to an acceleration of  $-4.8 \pm 0.2 \times 10^{-22}$  rad s<sup>-2</sup> in the rotation of the Earth. This is significantly less algebraic than the acceleration expected on the basis of tidal friction alone,  $-6.1 \pm 0.4 \times 10^{-22}$  rad s<sup>-2</sup>. Some other mechanism, or mechanisms, must account for the accelerative component of  $+1.3 \pm 0.4 \times 10^{-22}$  rad s<sup>-2</sup>. This nontidal acceleration may be associated with the rate of change in the Earth's oblateness attributed to viscous rebound of the solid Earth from the decrease in load on the polar caps following the last deglaciation about 10000 years ago (Peltier and Wu, 1983; Pirazzoli, 1991). From an analysis of the acceleration of the motion of the node of near-Earth satellites, a present-day fractional

**Figure L4** Corrections to the Earth's clock derived from the differences between the observed and computed paths of (untimed) solar eclipses. The vertical lines are not error bars, but solution space, anywhere in which the actual value is equally likely to lie. Arrowheads denote that the solution space extends several hours in that direction. The solid line has been fitted by cubic splines. The dashed line is the best-fitting parabola.

**Figure L5** Changes in LOD -500 to +2000 obtained by taking the first time-derivative along the curves in Figure L4. The change due to tidal friction is +2.3 ms/100 y. The high-frequency changes after +1700 are taken from Stephenson and Morrison (1984).

rate of change of the Earth's second zonal harmonic  $J_2$  of  $-2.5 \pm 0.3 \times 10^{-11}$  per year has been derived, which implies an acceleration in the Earth's rotation of  $+1.2 \pm 0.1 \times 10^{-22}$  rad s<sup>-2</sup>. This is consistent to within the errors of measurement with the result from eclipses, assuming an exponential rate of decay of  $J_2$  with a relaxation time of not less than 4000 years. Other causes may include long-term core-mantle coupling and small variations in sea level associated with climate changes.

#### Long-term changes in the length of the day

The first time-derivative along the curves in Figure L4 gives the change in the rate of rotation of the Earth from the adopted standard. This standard is equivalent to a LOD of 86400 SI s. The change in the LOD is plotted in Figure L5. The wavy line is the derivative along the cubic splines in the period 500 B.C. to A.D. 1600. After A.D. 1600, the higher resolution afforded by telescopic observations reveals the decade fluctuations (see Length of day variations, decadal), which are usually attributed to core-mantle coupling (see Core-mantle coupling) (see Ponsar et al., 2003). Similar fluctuations are undoubtedly present throughout the whole historical record, but the accuracy of the data is not capable of resolving them. All that can be resolved is a long-term oscillation with a period of about 1500 years and amplitude comparable to the decade fluctuations. The observed acceleration of  $-4.8 \pm 0.2 \times 10^{-22}$  rad s<sup>-2</sup> in Figure L4 is equivalent to a trend of  $+1.8 \pm 0.1$  ms/100 y in the LOD. In our considered opinion, no reliable eclipse data suitable for LOD determinations are available before са. 700 в.с.

# Paleorotation

The rotation of the Earth about 400 Ma ago can, in principle, be measured from the seasonal variations in growth patterns of fossilized corals and bivalves. This leads to estimates of the number of days in the year at that time, and hence the LOD (the year changes very little). Lambeck (1980) reviews the data and arrives at the value  $-5.2 \pm 0.2 \times 10^{-22}$  rad s<sup>-2</sup> (=  $+1.9 \pm 0.1 \text{ ms/100 y}$  in LOD) for the tidal acceleration over the past 4  $\times 10^8$  years, which implies that tidal friction was less in the past.

# LLOYD, HUMPHREY (1808–1881)

Humphrey Lloyd (Figure L6) was a distinguished and influential experimental physicist whose entire career was pursued at Trinity College, Dublin (O'Hara, 2003).

Figure L6 Humphrey Lloyd.

Figure L7 Lloyd's magnetic survey of Ireland, undertaken with Ross and Sabine.

In optics, he is remembered for his experimental confirmation of Hamilton's prediction of conical refraction, his demonstration of interference fringes with a pair of mirrors, and his authoritative report on the wave theory of light for the British Association. He had a lifelong interest in terrestrial magnetism and played an important role in the establishment of magnetic observatories, beginning in the 1830s.

His first venture into geomagnetism was a survey of Ireland (Figure L7) (Lloyd *et al.*, 1836) undertaken, at the instigation of the British Association, with Ross and *Sabine* (q.v.) in 1834 and 1835. In addition to dip and the horizontal component of the Earth's field, measured following the oscillation method of *Hansteen* (q.v.), simultaneous measurements of dip and intensity were made by a static balance method of his own devising.

Following the lead of *von Humboldt* (q.v.) and *Gauss* (q.v.) and with the detailed advice of the latter, Lloyd proceeded to have his Magnetical Observatory built in the grounds of the college. This charming edifice can still be viewed, but in the grounds of University College Dublin, some miles distant from its original home.

He conceived and designed many of the instruments that were to be used in the observatory: most were made by Thomas Grubb of Dublin. These included his balance magnetometer and a bifilar magnetometer, which he had developed to measure the horizontal component. Lloyd participated enthusiastically in Gauss's Europe-wide Magnetic Union, and when such observatories came to be established throughout the British colonies, at the urging of *Sabine* (q.v.)Lloyd was heavily involved. The Dublin facility served as a model for those far-flung stations and new observers were trained in the college. The association of European, Russian, and British observatories represented what Lloyd called "a spirit unparalleled in the history of science." They constituted the first global network devoted to a scientific project. (see *Observatories, overview*). The specific idea of a network for magnetic observations lives on today in Intermagnet.

Even his honeymoon in 1840 was subsumed in the busy program of overseas observatory visits that followed. Meanwhile his inventiveness continued to show itself in new and refined designs for instrumentation: for example an induction magnetometer for the vertical component (1841).

The current notion that terrestrial magnetism was linked to meteorological phenomena led him to study the latter, with a characteristically systematic approach. He also explored the conjecture that internal electric currents were responsible for the Earth's field, tried to relate this to the diurnal variation, and proposed new experiments to test this theory. Lloyd's father Bartholomew had been an inspiring leader of the college as a reforming mathematician and provost. Humphrey followed his example in becoming provost, and served as president of the Royal Irish Academy and the British Association. He was recognized with such awards as the German "Pour le Mérite" and Fellowship of the Royal Society. At home, he was awarded the Royal Irish Academy's Cunningham Medal.

He wrote 8 books and 64 papers and reports that record the achievements and insights of a remarkable experimentalist, organizer, and educator. A bust and a number of portraits survive in his college. There his father had created a new impetus in mathematics; the son accomplished the same for experimental science.

On his death, the Erasmus Smith Chair of Experimental and Natural Philosophy passed to George Francis Fitzgerald, together with much of Lloyd's energy and ideals. He had "struck an almost twentieth century note in his emphasis on the importance to a university of the cultivation of scientific research" (McDowell and Webb, 1982).

# MAGNETIC ANISOTROPY, SEDIMENTARY ROCKS AND STRAIN ALTERATION

The relationship between anisotropy of magnetic susceptibility (AMS) fabrics (the shape and orientation of the AMS ellipsoid) and rock fabrics has been studied for over 40 years. Many studies have employed magnetic fabrics as an independent data set to compare with remanent magnetization directional data. Magnetic fabrics can also be very sensitive indicators of low-intensity strain, though deformation exceeding 10% to 20% often modifies or destroys the fabric to the point of making a functional interpretation impossible. This is in part due to diagenetic processes; for example, reduction, pressure solution, recrystallization, fluid migrations, and growth of new mineral constituents occurring with greater degrees of strain. Thus, AMS techniques are most often successful in investigating tectonic strains on weakly deformed sedimentary rocks.

While AMS fabrics are most often easily interpreted in sedimentary rocks, the method is nonetheless complicated by the great range of primary sedimentary fabrics requiring correct interpretation before any modification to that fabric can be understood. It is important to note that AMS ellipsoids and grain-shape often do not correspond. Recent studies have pointed out the strong dependence of the AMS ellipsoid shape on mineral composition, for example, which can have a much larger effect than strain modification. Slight variations in ferromagnetic (or ferrimagnetic) trace minerals, for example, can strongly influence the shape and magnitude of the AMS ellipsoid, to the extent that composition-dependent variation may completely obscure the effects of strain. Finally, modeling and experimental studies have demonstrated that the relationship between incremental strain and the change in degree of anisotropy is highly complex. Some studies have determined power-law relationships, but with a great deal of variability reflecting differences in deformational style, intensity, and minerals that carry the anisotropy. Despite such complications, AMS methods as fabric indicators in sedimentary rocks have the advantages of being rapid, nondestructive, and result from the averaging of a susceptibility tensor from a very large population of magnetic grains. Weak deformation distinguished by AMS techniques may often be undetectable by nonmagnetic methods.

# Depositional (primary) sedimentary fabrics and processes

AMS studies have been directed at analyzing deep-sea current flow, bioturbation, fluvial and lacustrine fabrics, wind-deposited sand and loess fabrics, to name a few, as interpreted from AMS ellipsoids. Since sedimentary rocks should nearly always have a primary magnetic fabric, any fabric acquired as a result of later deformation will be superimposed upon a preexisting depositional fabric. Therefore, interpretation of altered AMS fabrics must begin with interpretation of the earlier (primary) fabric, which controls any subsequent alteration.

Studies of depositional AMS fabrics in sediments show that the shape and orientation of the susceptibility ellipsoid can be affected by a great variety of sedimentological processes predominantly formed during the deposition of particles from suspension in water or air (for a review, see Ellwood, 1980). Initial sedimentary fabrics are generally determined by gravity and hydrodynamics. Thus, to a first approximation, the shape and orientation of the AMS ellipsoid (which is the sum of the susceptibilities of a large number of grains present in the measured sample) is determined by both the characteristics of the grains themselves, and by the velocity and direction of transport of the medium through which they are carried. In general, sedimentary depositional fabrics are comparatively low in both susceptibility ( $<10^{-4}$  SI units) and in anisotropy (<5%). Typical primary depositional fabrics tend to be characterized by vertical or subvertical minimum susceptibility axes  $(K_3)$  (that is, the magnetic foliation is near the bedding plane) consistent with a conceptual model of grains settling flat on a surface. The maximum susceptibility axis  $(K_1)$  is often related to the transport or postdepositional current direction. However, this simple conceptual model can be complicated by factors such as the velocity of grains during deposition, the angle of slope on which grains settle, bulk mineralogy, compaction, fluid migration, and chemical changes such as growth of authigenic minerals or oxidation of iron-containing minerals, which may modify or completely destroy the original depositional fabric.

Many studies of deep-sea sediments have been aimed at describing variables such as current velocity or transport mechanisms through interpretation of the orientation of AMS ellipsoids, particularly the orientation of the maximum susceptibility axis ( $K_1$ ) or the lineation ( $K_1/K_2$ ). A number of studies have successfully used AMS to orient sediment cores used for studies of paleomagnetic remanence, and many investigations have described and identified the degree to which sampling techniques used for deep-sea sediments can distort the samples, thus affecting the measured AMS fabric.

In deep-sea sediments, both current-parallel and current-perpendicular alignments of the maximum susceptibility  $(K_1)$  axes are reported in a variety of depositional environments. One might imagine that the long axis of an elongate grain would align with current direction like a weather vane. In rock fabric studies, however, there are many reported instances of "rolling fabrics," in which elongated axes of grains are oriented perpendicular to the current direction as a result

of rolling along the surface of the depositional plane in the direction of current flow.

In general, AMS studies in deep-sea sediments call attention to the need for a better understanding of the relationship between the shape and orientation of AMS ellipsoids and current flow, such that transport mechanisms and sedimentation processes in deep-sea sediments (for example, turbidites, contourites, and channel deposits), can be identified using AMS data. Recent studies indicate bioturbation is a widespread and continuous process, which disturbs deep-sea sediments. Flood *et al.* (1985) evaluated the effect of bioturbation on AMS fabrics in deep-sea sediments and found characteristic alteration from weakly oblate, to secondary prolate fabrics in the uppermost centimeters of sediment. More study is needed to assess the degree to which deep-sea sediment fabrics are generally affected by bioturbation.

Grain orientations determined by microscopic measurement and AMS measurements in experimentally produced fluvial and winddeposited (eolian) sands were compared by Taira (1989). The study demonstrates the usefulness of AMS fabric in identification of sediment depositional processes. From analysis of experimentally produced fabrics, five distinct modes of deposition (gravity, flat bed and sloping bed, current, grain collision, and viscous flow) were distinguished, each with characteristic fabric parameters. In general, the maximum susceptibility was found to be oriented parallel to the current (shear stress) direction, whereas the minimum susceptibility was found to be oriented near normal, but with a distinct angle to the plane of shear stress (the imbrication angle). The five depositional types recreated in experimentally deposited sediments were found to fall into distinct groupings when two AMS measurement parameters are plotted against one another. The magnetic foliation/lineation (q) was plotted against the angle of imbrication of the minimum susceptibility axis  $(K_3)$  relative to the bedding plane  $(\beta)$ .

Many useful measurement parameters, such as q and  $\beta$ , which describe the magnitude, shape, or orientation of the AMS ellipsoid, have been defined. See *Magnetic susceptibility, anisotropy* (q.v.) for a complete treatment.

#### Strain alteration of sedimentary fabrics

Many studies have successfully correlated the orientation of the principal axes of the AMS ellipsoid with mesoscopic rock fabrics. More recent efforts have concentrated on correlating the AMS ellipsoid and the finite strain ellipsoid (for a review, see Tarling and Hrouda, 1993). While these studies have, in the main, found that the finite strain and susceptibility ellipsoids are coaxial in orientation, the compelling goal of such research is to quantitatively relate the AMS fabric of a strained rock with its measured strain (using passive markers for example). Such studies have been complicated by variations in magnetic mineralogy, for example, and attempts to correlate the magnitudes of the finite strain ellipsoid and the AMS ellipsoid continue to be a challenge (for a review, see Borradaile, 1988).

Some features of strain-induced modification to sedimentary AMS fabrics are well documented. A basic idea, common to interpretation of AMS in strain studies, is the concept that as primary principal axes are deformed, they will be deflected away from their original direction. As the intensity of strain increases, magnetic foliations tend to tilt away from the bedding plane, forming a "girdle" of poles parallel to the direction of shortening. Thus, fabrics can often show girdling of principal directions. This has allowed some workers to use AMS to reverse the strain from a rock in order to correct the remanent magnetization directions, resulting in improved clustering of the remanence directions (for a review, see Cogne and Perroud, 1987).

# Tectonic lineations

Secondary magnetic lineations acquired through transitional tectonic strains are reported (often termed a "pencil structure," Graham, 1978;

Kligfield et al., 1981). A pencil structure can be thought of as analogous to the intersection fabric between cleavage and bedding commonly used in structural analysis. In a true pencil structure, individual grains are mechanically and progressively rotated toward a direction perpendicular to the direction of principal stress, producing a lineation normal to the shortening direction. While fabrics of this type are often reported, clearly, magnetic susceptibility axes and grainshape do not correspond in all of these fabrics. For instance, many AMS fabrics found in weakly strained sediments in young compressional mountain belts show  $K_1$  in the bedding plane and perpendicular to the direction of tectonic transport, much like a pencil structure. These AMS maximum axes are often well-grouped perpendicular to the direction of principal stress, and are usually interpreted as having a tectonic origin. Such well-grouped magnetic lineations, however, are often reported in visually undeformed sediments, in which an analogous rigid deformation of the rock fabric seems very unlikely with such weak deformation.

Such fabrics can be explained by observing that, when principal axes have nearly equal magnetic susceptibilities, exchanging of axes can be instantaneous with very small increments of strain. A reorientation of 90° in the maximum susceptibility axis in very weakly strained rocks, with no girdling of principal axes, is the result. Consider an assemblage of magnetic grains with an initial sedimentary fabric, having a foliation in the bedding plane and  $K_1$  oriented in a downstream direction (for example, perpendicular to a compressional mountain range). Any shortening parallel to the bedding plane will have the effect of tilting the grains away from the bedding plane, thereby weakening the  $K_1$  of the bulk fabric, but leaving  $K_2$  unchanged. At some point, the susceptibility of  $K_1$  and  $K_2$  will become equal, and with the next increment of strain their orientations will abruptly exchange. In this way, a "pencil structure" might seem to develop with very weak strains as the susceptibility of initially well-clustered  $K_1$  axes are diluted by small changes in the grain orientations. This is most likely to occur with  $K_1$  and  $K_2$  very nearly equal in magnitude. Exchanging susceptibility axes, as in this example, can result in the "inverted fabrics" reported by some studies; grains will not physically reorient with very low strain, but the bulk AMS ellipsoid may.

An evolution of syndeformational magnetic fabrics was suggested in a study of sediments from a Neogene accretionary complex by Kanamatsu *et al.* (1996). In that study, sedimentary AMS fabrics were found to follow a path of decreasing shape parameter (T) and decreasing degree of corrected anisotropy (P') with the evolution from sedimentary through transitional to "tectonic" fabrics. That is, AMS ellipsoids were found to vary during weak progressive strain from oblate to prolate in shape, while anisotropy decreased (the shape parameter (T) and corrected anisotropy (P') have been adopted as standard parameters to evaluate AMS ellipsoids, and are discussed in Jelinek, 1981).

#### Strain-induced changes in mineral composition

Since AMS is determined from the combined susceptibility of all paramagnetic, diamagnetic, and ferromagnetic minerals in a sample, increased intensities of strain produces an important caveat for AMS studies. The growth of minerals through dissolution and recrystallization processes accompanying increased strain hampers interpretation of AMS ellipsoids. Housen and van der Pluijm (1990) demonstrated control of paramagnetic chlorite on AMS fabrics during development of slaty cleavage. Since magnetic anisotropy increases with increasing degree of crystallographic preferred orientation, the AMS ellipsoid can be determined by the crystallographic principal axes. Such studies point to the need for a thorough understanding of the paramagnetic and diamagnetic matrix as well as ferromagnetic constituents, especially under conditions of progressive strain. Fortunately, rock magnetic methods are providing increasingly sophisticated means to separate ferromagnetic and paramagnetic contributions to the susceptibility tensor. For example, the anisotropy of anhysteretic remanent magnetization (AARM) (see *Magnetization, anhysteretic remanent (ARM), q.v.*) is a method unaffected by paramagnetic constituents. In many cases, a reasonable approximation of single mineral anisotropies can increasingly be obtained. These methods will continue to provide exciting opportunities to advance the state of research relating magnetic fabrics and rock fabrics.

# MAGNETIC ANOMALIES FOR GEOLOGY AND RESOURCES

# Magnetic anomalies and geological mapping

Knowledge of the geology of a region is the scientific basis for resource exploration (petroleum, solid minerals, groundwater) the world over. Among the variety of rock types to be found in the Earth's crust, many exhibit magnetic properties, whether a magnetization induced by the present-day geomagnetic field, or a remanent magnetization acquired at some time in the geological past, or a combination of both. Mapping the patterns of magnetic anomalies attributable to rock magnetism has proved to be a very effective way of reconnoitering large areas of geology at low cost per unit area. The fact that most sedimentary rocks and surface-cover formations (including water) are effectively nonmagnetic means that the observed anomalies are attributable to the underlying igneous and metamorphic rocks (the so-called "magnetic basement"), even where they are concealed from direct observation at the surface. Anomalies arising from the magnetic basement are only diminished in amplitude and extended in wavelength through the extra vertical distance between source and magnetometer imposed by the nonmagnetic sediment layers. Thus aeromagnetic surveys (q.v.) are able to indicate the distribution of bedrock lithologies and structures virtually everywhere. Interpretation of magnetic anomaly patterns can then lead to maps of (hidden) geology that give direction to the exploration process (Figure M1/Plate 7b). In igneous and metamorphic ("hard rock") terranes, outlines of local areas promising for the occurrence of ore bodies can be delineated for closer follow-up studies. In the case of petroleum exploration, interpretation of the structure of the underlying basement can help understanding of basin development and help locate areas for (costly) seismic studies and drilling. Similar economies in the exploration process can be made through exploitation of aeromagnetic surveys in the systematic mapping of potential groundwater resources, of particular importance in the arid and semiarid areas of the world.

# Mineral exploration

The amplitude, shape, and internal texture of magnetic anomalies may be used to indicate the likelihood of finding of certain ore types. Initially, aeromagnetic measurements were used in direct prospecting for magnetic iron ores and in the indirect detection of certain classes of magmatic-hosted Ni-deposits, kimberlite pipes for diamonds, and so forth. Hydrothermally altered areas in magnetic environments are often detectable as low magnetic zones and may be prospective for Au and Pb. The largest concentrated source of magnetic anomaly in terms of magnetic moment is the Kursk low-grade magnetic iron-quartzite ore formation in Ukraine that can be measured even at satellite altitudes. Most of the major satellite anomalies are, however, attributable to entire provinces of relatively magnetic rocks, such as Northern Fennoscandia, of which the Kiruna magmatic iron ore is but a tiny part.

Most ore deposits within the crystalline basement are, either in themselves or through their host rocks, accompanied by magnetic

478

anomalies. These anomalies are often used further in the closer evaluation of the extent and geometry of a deposit and in assessing the mineral potential of other comparable geological formations. At the reconnaissance stage of mineral assessment, area selection and prospecting—particularly of soil-covered areas of crystalline basement geological mapping can be driven in large part by interpretation of detailed aeromagnetic anomaly maps. These provide, in a cost-effective and environmentally friendly way, a reliable picture of the underlying subsurface, including the location and extent of geological units and their lithology, structure, and deformation.

#### Continental and oceanic anomaly mapping

Given that most countries have a national program of mineral resource management, the foundation of which is the geological mapping program at an appropriate scale (say 1:1000000), ambitious national programs of aeromagnetic anomaly mapping have been instigated generally to supplement and accelerate geological mapping (for example Canada, Australia, former Soviet Union, the Nordic countries). National aeromagnetic anomaly maps, together with gravity anomaly maps, have therefore become preeminent in the geophysical support of geological reconnaissance. Given that gamma-ray spectrometer surveys are now usually flown simultaneously with aeromagnetic surveys at little additional cost, they form a third common type of geophysical support for geological mapping.

Over 70% of the Earth is covered by oceans. The geology here is totally obscured, even over the continental shelves. Until the advent of systematic ocean exploration in the second half of the 20th century,

**Figure M2/Plate 9e** Magnetic anomaly patterns in the North Atlantic Ocean showing the symmetry of the anomalies either side of the mid-Atlantic Ridge in the vicinity of Iceland. (Detail from Verhoef *et al.*, 1996, courtesy of the Geological Survey of Canada).

little was known of the geological evolution of the deep oceans. The patterns of magnetic anomaly stripes discovered, paralleling the mid-ocean ridges (Figure M2/Plate 9e from Verhoef *et al.*, 1996), became one of the leading lines of evidence in support of continental drift and, eventually, global tectonics (see *Vine-Matthews-Morley hypothesis*). This revelation must count as one of the most profound advances in our understanding of the Earth's history and its mode of development.

Being of igneous origin, the rocks of the oceanic crust solidify and cool at the mid-ocean ridge while inheriting a magnetic field direction from the erstwhile geomagnetic field. Repeated reversals of that field are recorded symmetrically either side of the ocean-spreading axis as new crust is relentlessly added, a few centimeters per year, at the axis itself. While people's interest in mineral resources of the deep ocean is still limited, understanding the previous locations of the continents, particularly during the past 200 Ma for which ocean floor can still be found, is central to our understanding of geological processes in this period. The sedimentary rocks laid down on the passive continental margins now separated by "new" oceans host a great deal of the world's hydrocarbon reserves.

Ocean crust is eventually recycled into the Earth's mantle via subduction zones with the result that ocean crust *in situ* older than about 200 Ma is no longer to be found. Evidence of the earlier 95% of geological history is therefore confined to the continents. Here a great deal of geological complexity is revealed (Figure M3/Plate 7d; Zonenshain *et al.*, 1991), reflecting repeated orogenesis (mountain building) and metamorphism since the time of the oldest known rocks, dating from the Archean. The patterns of repeated continental collisions and separations evident from more recent geology can be extrapolated into this past. However, poor rock exposure in most of the oldest, worndown areas of the world (Precambrian shields) hampers their geological exploration. Aeromagnetic surveys assist markedly here, though understanding at the scale of whole continents often necessitates maps extending across many national frontiers, as well as across oceans where present continents were formally juxtaposed.

What holds for investigations into geology and resources over regions or areas quite locally (say, scale 1:250000, a scale typical for geological reconnaissance) also holds for national compilations of larger countries (say scale 1:1000000) and at continental scale (1:5 million or 1:10 million). Magnetic anomaly mapping is arguably even more useful at such scales since it represents unequivocal physical data coverage, part of a nation's (or a continent's) geoscience data-infrastructure. The view it offers to the geological foundations of continents is therefore of prime importance to improved understanding of global geology. Repeated cycles of continental collision, coalescence, and rifting-apart have led to the present-day arrangement of the igneous and metamorphic rocks of the continental crust, as revealed in continental scale images of magnetic anomalies, such as Australia (Figure M4/Plate 7a; Milligan and Tarlowski, 1999).

# Continental and global compilations of magnetic anomalies

(Aero-)magnetic surveys usually record only the total strength of the magnetic field at any given point, thus avoiding the need for any precision orientation of the magnetometer. After suitable corrections have been applied for temporal field variations during the weeks or months of a survey, subtraction of the long wavelength (more than several hundred kilometers) components of the field leaves local anomalous values that should be comparable from one survey to another. Thus it is possible—though, in practice, challenging—to link many hundreds of surveys together to make national or continental scale coverages (Tarlowski *et al.*, 1996; Fairhead *et al.*, 1997).

The long wavelength components of magnetic anomalies must be defined in an internationally coherent way, for which purpose the IGRF (q.v.) was designed and is periodically updated by IAGA. Anomaly definitions still vary greatly between surveys for various

reasons and, in addition to consistent use of the IGRF, national and international cooperation is required to link and level together the variety of magnetic surveys to a common level. Magnetic anomaly data exist over most of the Earth's surface, mostly a patchwork of airborne surveys on land and marine traverses at sea (Reeves *et al.*, 1998). In 2003, IAGA appointed a Task Group to oversee the compilation of such a global magnetic anomaly map (www.ngdc.noaa.gov/IAGA/vmod/ TaskGroupWDMAM-04July12s.pdf) that endeavors to complete its work in time for the 2007 IUGG General Assembly.

# Magnetic mineralogy

The physical link between geological formations and their magnetic anomalies is the magnetic properties of rocks (Clark and Emerson, 1999). These are often measured, for example, in connection with Ocean Drilling Program (ODP) analyses, paleomagnetic studies, geological mapping, and mineral prospecting. ODP data provide local information at widespread oceanic locations giving a global coverage. International paleomagnetic databases represent the remanent magnetic properties acquired in the geological past (see Paleomagnetism). Magnetomineralogical studies reveal that by far the most common magnetic source mineral of Precambrian shield areas is magnetite. So far, the largest national campaign of magnetic property mapping was that carried out in the former Soviet Union. The results were presented as analog maps. Most of the world's resource of digital petrophysical data for the continents was collected in the Fennoscandian Shield by the Nordic countries (Korhonen et al., 2002a,b). Even so, these data represent only a small part of the crystalline basement of NW Europe. More, similar data sets are required if we are to understand how well this information represents crustal rocks more globally.

The results from Fennoscandia show that, when plotted on a diagram of induced magnetization against density (Figure M5a) the samples form two populations, A and B. Population A represents the paramagnetic range of susceptibilities defined by Curie's law. Compositional variation of Fe- and Mn-oxides correlates with density, the denser, more basic (mafic) rock lithologies being more magnetic than acid (silicic) ones by up to an order of magnitude. This population is only capable of causing anomalies less than about 25 nT, however. A second population of rocks (B), mostly acid in chemistry, represents the ferrimagnetic range of susceptibilities, mainly due to variations in the abundance and grain size of magnetite. This population is two

Figure M5 (a) Bulk density and induced magnetization in the Fennoscandian Shield (redrawn from Korhonen et al. 2002a). The lower population (A) contains the majority of rock samples, and represents the paramagnetic range of susceptibilities defined by Curie's law. A second population of rocks (B), mostly acid in chemistry, represents the ferrimagnetic range of susceptibilities, due mainly to variations in the abundance and grain size of magnetite. This population is two orders of magnitude more magnetic than the average of the first population (A). (b) Induced and remanent magnetization in the Fennoscandian Shield (redrawn from Korhonen et al., 2002b). For the relatively few rock samples (D) that depart from a low level of magnetization (C), the Q-ratio is mostly less than 1.0, indicating the predominance of induced magnetization over remanent. A few exceptions are, however, highly magnetic. (Courtesy of Geological Surveys of Finland, Norway, and Sweden and the Ministry of Natural Resources of the Russian Federation).

orders of magnitude more magnetic than the average of the first population (A). Population B rocks represent most sources of local, induced magnetic anomalies. Average susceptibilities vary typically from 0.04 to 0.02 SI units for these ferrimagnetic geological formations, but much variation is found from one formation to another.

Another important parameter is the relative proportion of ferrimagnetic (population B) rocks to the effectively "nonmagnetic" paramagnetic (population A) rocks in any given area. For example, it is only a few percent in the magnetic "low" of central Fennoscandia but almost 100% in the northern Fennoscandian "high." Overall in Fennoscandia the average value is about 25%. In oceanic areas, by contrast, it approaches 100%.

Spatial contrasts in magnetic rock properties that give rise to the local magnetic anomalies encountered in mineral exploration are attributable to such factors as (a) the aforementioned bimodal nature of magnetic mineralogy (populations A and B), (b) the effects of magnetic mineralogy and grain size, (c) the history of magnetization and demagnetization, and (d) the variation between induced and remanent magnetization. These are related in turn to geological causes such as initial rock lithology, chemical composition, oxygen fugacity, and metamorphic history.

The ratio of remanent to induced magnetization varies typically from 0.1 to 20, corresponding to rocks containing coarse-grained fresh magnetite (most susceptible to induced magnetization) via altered and fine-grained magnetites to pyrrhotite (with a very stable remanent magnetization). Figure M5b shows the results for induced and remanent magnetization from the Fennoscandian Shield. For the relatively few rock samples (population D) that depart from a low level of magnetization (population C), the Q-ratio is mostly less than 1.0, indicating the predominance of induced magnetization over remanent as a source of magnetic anomalies. A few exceptions are, however, highly magnetic (above 1.0 A m<sup>-1</sup>). For increasingly large source bodies, variations in the direction of all local remanent magnetizations cause the net remanent magnetization to sum up more slowly than the consistently oriented induced magnetization. Hence the effects of remanent magnetization are relatively more important in magnetic anomalies measured close to source bodies (such as on the ground) than farther away (from an aircraft or satellite). This effect is even more noticeable at magnetizations above 1 A  $m^{-1}$ , where Q-values tend to approach or even exceed 1.0 (Figure M5b).

# MAGNETIC ANOMALIES, LONG WAVELENGTH

Long-wavelength anomalies are static or slowly varying features of the geomagnetic field, and originate largely within the lithosphere. These anomalies stand in contrast to the rapidly time varying features characteristic of even longer wavelengths, which originate within the outer core. An inflection point, or change of slope, in the geomagnetic power spectrum (Figure M6) can be seen at degree 13 and is a manifestation of the relatively sharp transition from core-dominated processes to lithospheric-dominated processes. Long-wavelength anomalies (Figure M7a/Plate 5c) are most easily recognized from near-Earth satellites at altitudes of 350-750 km, and these altitudes define the shortest wavelengths traditionally associated with such geomagnetic features. The lithospheric origin of these features was firmly established by comparison with the marine magnetic record of seafloor spreading in the North Atlantic (LaBrecque and Raymond, 1985). Virtually identical features have now been recognized in satellite magnetic field records from POGO (1967-1971), Magsat (1979-1980), Ørsted (1999-), and CHAMP (2000-). Long-wavelength anomalies were first recognized by Cain and coworkers in about 1970 on the basis of total field residuals of POGO data.

Although electrical conductivity contrasts (Grammatica and Tarits, 2002) and motional induction of oceanic currents (Vivier et al., 2004) can produce quasistatic long-wavelength anomalies, the largest contributors to long-wavelength anomalies are induced  $(M_i)$  and remanent  $(M_r)$  magnetization in the Earth's crust. Contributions from the uppermost mantle may also be of importance, at depths where temperatures do not exceed the Curie temperature  $(T_c)$  of the relevant magnetic mineral. The earth's main field (H) is the inducing magnetic field responsible for induced magnetization of lithospheric materials.  $M_{\rm i} = kH$  expresses the linear relationship between the inducing field and induced magnetization, true for small changes in the inducing field. k is the volume magnetic susceptibility, treated here as a dimensionless scalar quantity, and reflects the ease with which a material is magnetized. If M does not return to zero in the absence of H, the resulting magnetic field is said to be remanent or permanent. Thus  $M = M_{\rm r} + M_{\rm i}$ , and the relative strength of the two contributions is referred to as the Koenigsberger ratio or  $Q = M_r/M_i$ .

Inversions of long-wavelength anomaly observations into lithospheric source functions, for example magnetic crustal thickness

**Figure M6** Comparison of the Lowes-Mauersberger ( $R_n$ ) spectra at the surface of the Earth and Mars for a variety of internal fields. The inflection point in the terrestrial power spectra represents the sharp transition from core processes at low *n* to lithospheric processes at higher *n*.  $R_n$  is the mean square amplitude of the magnetic field over a sphere produced by harmonics of degree *n*. The terrestrial spectrum of all internal sources comes from Sabaka *et al.* (2004), the Martian remanent spectrum is derived from Langlais *et al.* (2004), the terrestrial induced spectrum is derived from Fox Maule *et al.* (2005), and the terrestrial remanent magnetization spectrum (of the oceans, and hence a minimum value) was derived from Dyment and Arkani-Hamed (1998).

(Figure M7b/Plate 5d) are subject to many caveats. Simple solutions are preferred, which also agree with other independently determined lithospheric properties. Specific caveats with respect to inversions of these magnetic field observations are that (1) direct inversion, in the absence of priors, can uniquely determine only an integrated magnetization contrast, (2) a remarkably diverse assemblage of magnetic annihilators (Maus and Haak, 2003) exist, which produce vanishingly small magnetic fields above the surface, and (3) the longest wavelength lithospheric magnetic signals are obscured by overlap with the core and it is formally impossible to separate them.

Unresolved research questions include (1) the continuing difficulty of signal separation, especially with respect to external fields (Sabaka *et al.*, 2004), and the particular problem of resolving north-south features from polar-orbiting satellites, (2) the relative importance of magnetic crustal thickness variations and magnetic susceptibility variations in producing long-wavelength anomalies, (3) the relative proportions of induced and remanent magnetization in the continents and oceans, (4) the mismatch between the observed long-wavelength fields at satellite altitude, and surface fields upward continued to satellite altitude, (5) the separation of long-wavelength anomalies caused by motional induction of large-scale ocean currents, (6) the isolation and relative importance of shorter wavelength anomalies (between 660 and 100 km wavelength), and finally (7) the origin of the order of magnitude difference between the observed lithospheric magnetic fields of the Earth and Mars.

**Figure M7/Plate 5c,d** Long-wavelength anomalies (a) in the total field as seen by the CHAMP magnetic field satellite at an altitude of 400 km (MF-4 model of GFZ-Potsdam available at www.gfz-potsdam.de/pb2/pb23/SatMag/model.html). Spherical harmonic degrees between 16 and 90 are included within this map. The magnetic crustal thickness (b), derived as described in Fox Maule *et al.* (2005), explains the observations in (a). The map uses as a starting model the 3SMAC (Nataf and Ricard, 1996) compositional and thermal model of the crust and mantle. 3SMAC is modified in an iterative fashion with the satellite data, after first removing a model of the oceanic remanent magnetization (Dyment and Arkani-Hamed, 1998), until the magnetic field predicted by the model matches the observed magnetic field. A unique solution is obtained by assuming that induced magnetizations dominate in continental crust, and that vertical thickness variations dominate over lateral susceptibility variations (Purucker *et al.*, 2002). A starting model such as provided by 3SMAC is necessary to constrain wavelengths longer than about 2600 km. Longer wavelengths are obscured by overlap with the core field. The white lines delineate plate boundaries, transform faults, and mid-ocean ridges. Illumination on these shaded relief maps is from the east.

# MAGNETIC ANOMALIES, MARINE

Magnetic anomalies are perturbations of the geomagnetic field due to Earth structure. They are seen when one subtracts a regional magnetic field from a series of observed readings. They have a different character over surface of the deep oceans than on they do on land. The unique nature of marine magnetic anomalies became apparent in the early 1950s when submarine detecting magnetometers were used for geophysical exploration by research ships. Over the oceans important marine anomalies may have an amplitude of a few tens to a few hundreds nanotesla and a wavelength of about 100 km, depending upon the depth of water. Previously some geomagnetic field measurements had been made on nonmagnetic ships but these readings were taken so far apart that the short anomalies were not defined. A few aircraft measurements had been made but they were high above the ocean surface reducing the size of the anomaly or were made over the continental shelf where anomalies have a different character from those in the deep ocean.

### Early observations of marine anomalies

When research ships started taking measurements the magnetometer was towed behind the ship so the magnetic materials of which the ship was constructed did not influence the readings. Furthermore the intensity of the field, rather than its directional components, was measured thereby eliminating the need to know the orientation of the magnetometer. The first generation of marine magnetometers was of the fluxgate type, which had a small oriented special metal core. This core was mechanically oriented in the direction of the Earth's field by nulling the field measured by secondary cores, which were at right angles to the main core. This arrangement, while awkward, was used at sea for several years. The first systematic survey at sea was made by Scripps Institute of Oceanography using a fluxgate magnetometer towed by a Coast and Geodetic Survey ship in the Pacific Ocean off the western United States. When a regional magnetic field was subtracted from the observed field to get the anomalies, these anomalies were seen to be linear patterns, oriented nearly north-south, but with occasional sharp east-west offsets in the linear pattern (Vacquier, 1959). The source of these linear anomalies was unknown because there was no obvious seafloor feature, which could cause them.

At about the same time as the Pacific measurements were made miscellaneous cruise measurements off the US east coast, near the continental shelf showed major marine magnetic anomalies which were subparallel to the coast. They turned onto land and split into several parts over the states of Georgia and Florida.

Early shipboard measurements had shown a large magnetic anomaly over the center of the mid-Atlantic Ridge in several places. To investigate this in a systematic way, a low-level aeromagnetic survey was made over the part of the Reykjanes Ridge south of Iceland (Figure M8) (the Reykjanes, using a US Naval Oceanographic Office aircraft flying out of southern Iceland; Heirtzler *et al.*, 1966). This survey also showed linear anomalies, paralleling the ridge axis and symmetrically located about the axis of the Reykjanes Ridge. This suggested that the origin of these linear anomalies was related to the structure of the ridge.

## The origin of the anomalies

In 1963, while the Reykjanes Ridge was being flown, an important paper was published by Fred Vine and Drummond Matthews (Vine and Matthews, 1963) pointing out that the linear anomalies in the ocean might be caused by normally and reversely magnetized rocks of the ocean floor. These authors suggested, furthermore, that these rocks can be represented by magnetized blocks and they may have acquired their magnetization when they were extruded at the axis of the mid-ocean ridge in times past. Presumably the blocks moved out from both sides of the ridge. This is the basis of the seafloor spreading theory. The magnetism was acquired at the axis, while the upwelling magma cooled. It is called remanent magnetization. As the material moves away from the axis it is in the ambient geomagnetic field and so secondary magnetism is induced in the rocks. That is called induced magnetization. Thus, the magnetization has two components, although the remanent component is usually stronger.

Applying Vine-Matthews theory to the Reykjanes Ridge data and knowing the times of the most recent few reversals of the field it was possible to learn that the seafloor of the Reykjanes Ridge is spreading at about 1.5 cm  $y^{-1}$  away from the ridge axis. Reykjanes Ridge anomalies which were further from the axis allowed one, for the first time, to know the ages of the various reversals as far back as 10 Ma, assuming that the seafloor spreading rate has been constant.

**Figure M8** Marine magnetic anomalies over the Reykjanes Ridge (RR) south of Iceland. Positive anomalies are shaded black (after Heirtzler *et al.*, 1966).

This knowledge of the relationship between marine magnetic anomalies, reversals of the geomagnetic field, and seafloor spreading rates created a flurry of activity in marine geophysics in the 1960s. A new simplified (proton precession) magnetometer was developed, analytical methods were undertaken to relate the oceanic rocks to the anomaly observed. Cruises were undertaken in many parts of the world to extend the geomagnetic reversal timescale and to study seafloor spreading and the tectonics of the ocean floor. (See Figure M9/ Plate 8: World map of isochrons of the ocean floor).

The rocks of the ocean floor are usually covered with a thick layer of sediments. The sediments are weakly magnetized so they do not interfere with the magnetic anomalies caused by the rocks beneath. However, if a sediment core is taken and measured in the laboratory it will also show reversals of past geomagnetic field directions just like anomalies measured across the ocean surface. Thus one can date sediments using the timescale of geomagnetic field reversals.

Some geomagnetic field anomalies can be observed by magnetic field satellites in near-Earth orbit, although anomalies over the oceans are small and difficult to analyze. Magnetic measurements have also been made by magnetometers towed near the deep seafloor. These have proved especially useful in studying the transition between normally and reversely magnetized rocks.

## Using magnetic anomalies to date the ocean floor

The age of the seafloor is related to the distance of the magnetized blocks from the ridge axis, not the distance of the magnetic anomaly, from the ridge axis. Thus it is necessary to see how the position of the anomalies is related to the position of the source rocks. A computer

Figure M9/Plate 8 World map of isochrons of the ocean floor (after Muller et al., 2005).

program is commonly used to calculate the anomaly over a block. These programs assume the block is infinitely long in some direction (2D) rather than having a finite three-dimensional shape (3D), making the calculation simpler. The shape of the source block is changed until the calculated anomaly matches the observed anomaly. This technique is called a forward anomaly calculation. It is inherently nonunique in that several different shapes may cause the same anomaly. Other types of programs assign one dimension, for example the thickness, and then use the observed anomalies to locate the source body. Other programs convert the observed spatial series to a frequency spectrum and filter the spectrum to locate the bodies. It is also possible to mathematically convert the observed anomaly series to show how it would look at the magnetic pole. This transformed anomaly will be directly over its causative body.

Normal and reverse intervals of the geomagnetic field occur at irregular time intervals creating a pattern of magnetic anomalies with irregular spacing. Since this same irregular pattern is found in the different oceans of the world it aids in dating the anomalies in one ocean if they were already dated in another ocean. To refer to anomalies along an anomaly profile, the anomalies have been given numbers 1 (at the axis) to 34 (about 83 Ma). Intermediate intervals are assigned a "chron" notation (see *Geomagnetic polarity timescale, q.v.*).

### Older marine magnetic anomalies

Long shipboard magnetic profiles extending across the oceans showed a similar sequence of magnetic anomalies, although the shape varies a bit with latitude and the azimuth of the magnetic lineation. This suggested that seafloor spreading had been constant in each major ocean, although the spreading rate may be different from one ocean to another. In the South Atlantic anomaly 34 is close to the continental margins of South America and South Africa, indicating that the South Atlantic Ocean opened about 83 Ma ago. In the North Atlantic anomaly 34 does not reach the continental margins, because the North Atlantic Ocean is older than the South Atlantic Ocean.

In the Northwest Pacific the anomalies are linear but not subparallel to existing spreading centers. The spreading center, which created them, has since disappeared and the seafloor spreading has changed direction. Many are older than anomaly 34 and are assigned a number prefixed by the letter M to show that they be part of another (Mesozoic) series. Near the edges of the Pacific Ocean there are subduction zones where the seafloor turns under the continents. The magnetic anomaly pattern is extinguished at these subduction zones, such as off Alaska, off the Aleutians, off Japan, and at the Kermadac Trench north of New Zealand. It was found that, in the South Pacific Ocean, anomalies are symmetric about the ridge axis, even when the anomalies are separated by more than 1000 km. The Indian Ocean and the Arctic Ocean south of Australia abound with dated magnetic anomalies, although the oldest are not as old as the oldest in the Northwest Pacific.

By using a long profile in the South Atlantic Ocean the sequence of magnetic reversals (geomagnetic timescale) were originally determined for the last 80 Ma, where there were 171 reversals. By comparisons with dated rocks from the seafloor the original geomagnetic timescale has been slightly revised (Cande and Kent, 1995).

## MAGNETIC ANOMALIES, MODELING

#### Introduction

The magnetic anomalies of planetary lithosphere reflect the lateral variations of magnetization in the upper most part of the lithosphere that is colder than the Curie temperature of its magnetic minerals. The variations may arise from several processes, such as intrusive bodies with different magnetization than the country rocks, the juxtaposition of crustal blocks of different magnetization through plate tectonics, and the creation of the oceanic crust during different core field polarity periods.

A magnetic anomaly is the projection of the magnetic field of a body in the direction of the local geomagnetic field. The measured magnetic data have contributions from the core field, the lithospheric field, the external field, the field arising from the induced currents in the mantle because of the time variations of the external field, and the measurement errors. The core and the lithospheric fields are time-invariant within a few years, while the external field is strongly time-dependent. A time-varying external field with a period of  $\tau$  is translated to a special variation of wavelength  $\lambda = \tau v$  when the magnetic data is acquired by a vehicle (airplane, ship, or satellite) moving at speed v, and contaminates the lithospheric field of the same wavelength. To avoid the contamination, the magnetic data acquired during the quiet times of the external field are generally used. The core field, with amplitudes ranging from 30000 to 70000 nT, dominates the lithospheric field, which has usually an amplitude of a few hundred nanotesla near the surface and less than 20 nT at satellite altitudes of  $\sim$ 400 km. The instrument errors are nowadays negligible, but the measurement error can be appreciable especially for the satellite magnetic data. An attitude error of only 10" in the orientation of the coordinate axes fixed to a satellite can produce an error on the order of 2-4 nT, depending on the satellite's latitude, which is comparable to a vector component of the lithospheric magnetic field at the satellite elevations. One possible way of removing the error arising from the attitude is to use the magnetic intensity data, which is independent of the orientation of the coordinate system. Let  $\vec{F}$  denote the measured magnetic field and assume that it consists of the core field  $\vec{B}$  and the lithospheric field f, ignoring the external field. Then

$$|\vec{F}| = |\vec{B} + \vec{f}| \tag{Eq. 1}$$

The magnetic anomaly T is the difference between the intensity of the observed field and that of the local core field,

$$T = |\vec{F}| - |\vec{B}| \tag{Eq. 2}$$

which to the first approximations is reduced to

$$T = \vec{f} \cdot \hat{B} \tag{Eq. 3}$$

where  $\hat{B}$  is the unit vector in the core field direction. Almost all aeromagnetic measurements on Earth result in magnetic anomalies as defined in Eq. (3). In case of a planet with no core field, such as Mars, a magnetic anomaly simply refers to the magnetic field of the lithosphere.

This article addresses modeling of the magnetic anomalies of the planetary lithosphere. The first section describes the forward modeling, where the shape and magnetization of a magnetic body is given and the magnetic anomaly of the body is to be determined. The second section considers the inverse problem, where the magnetic anomalies are measured and the shapes and magnetization of the magnetic source bodies are to be determined.

### Forward modeling

The magnetic potential V of a magnetic body is

$$V(\vec{r}) = -\frac{\mu_0}{4\pi} \int \int \int \vec{M}(\vec{r}_0) \cdot \nabla \frac{1}{|\vec{r} - \vec{r}_0|} d\nu_0$$
 (Eq. 4)

where  $\mu_0$  is the magnetic permeability of free space  $(4\pi \times 10^{-7} \text{ H m}^{-1})$ ,  $\vec{M}(\vec{r}_0)$  is the magnetic dipole moment per unit volume, called magnetization, and the integration is over the entire volume of the body. Equation (4) is quite complicated especially when the body is irregular in shape and has heterogeneous magnetization. In forward modeling it is usually assumed that the magnetic body is uniformly magnetized in a given direction. The size and magnetization of the source body is determined by fitting the model anomaly to the observed one. To better fit the model field to the observation, it is often required to divide the body into several parts with different magnetization, but each part has still a uniform magnetization. The constant magnetization assumption reduces Eq. (4) to

$$V(\vec{r}) = -\frac{\mu_0}{4\pi} \iint \frac{\vec{M}}{|\vec{r} - \vec{r}_0|} \cdot \vec{ds}_0$$
 (Eq. 5)

upon the application of the divergence theorem.  $ds_0$  is a surface element and the integration is over the entire surface of the body. This equation shows that the magnetic field outside a uniformly magnetized body is equivalent to the magnetic field of magnetic poles (north or south) distributed on the surface of the body. A uniformly magnetized body acts by its surface rather than its entire volume. For example, to determine the magnetic field of a vertically upward magnetized vertical prism it is sufficient to assume a north pole distribution on the upper surface and a south pole distribution on the bottom surface. An interesting case is a uniformly magnetized infinite horizontal layer of constant thickness, which produces no magnetic field outside regardless of its magnetization intensity and direction. Such a layer is used as an annihilator in the inverse problems (e.g., Parker and Huestis, 1974).

Equation (4) can also be written as

$$V(r) = -\left(\frac{\mu_0}{4\pi\rho G}\right)\vec{M}\cdot\nabla\int\int\int\frac{G\rho}{\left|\vec{r}-\vec{r}_0\right|}dv_0$$
 (Eq. 6)

for a uniformly magnetized body, where  $\rho$  denotes an arbitrary constant density of the body and G is the gravitational constant. This equation is further reduced to

$$V(r) = \left(\frac{\mu_0 M}{4\pi\rho G}\right) \hat{M} \cdot \nabla U(\vec{r})$$
 (Eq. 7)

where  $\hat{M}$  is the unit vector of the magnetization and  $U(\vec{r})$  denotes the gravitational potential of the body with the density  $\rho$ . Equation (7) emphasis that the magnetic field outside a uniformly magnetized body is just the gradient of the gravitational potential of the body in the direction of its magnetization vector, with a multiplying factor  $(\mu_0 M/4\pi\rho G)$  called the Poisson factor. This tremendously simplifies the calculations of the magnetic field of a body, from integration of an integrand involving vector functions to that includes only a scalar function. A simple example is the magnetization  $\vec{m}_0$  centered at  $\vec{r}_0$ , which according to Eq. (7) is

$$V(\vec{r}) = -\left(\frac{\mu_0}{4\pi}\right) \frac{4\pi}{3} R^3 \vec{m}_0 \cdot \nabla \frac{1}{|\vec{r} - \vec{r}_0|}$$
(Eq. 8)

which is equivalent to the magnetic potential of a magnetic dipole located at the center of the sphere and has a dipole moment of  $\vec{P}(\vec{r}_0) = (4\pi/3)R^3\vec{m}_0$ .

Several techniques developed in the space domain, to determine the magnetic field of an arbitrary-shaped body, have been used for forward modeling of an isolated magnetic anomaly (see Chapter 9 of Blakely, 1996 for details, also Telford et al., 1990). Many of the methods use the above-mentioned characteristics of the magnetic field of a uniformly magnetized body. Here I briefly explain two methods; one uses the above characteristics and the other does not. The first (e.g., Talwani, 1965) subdivides a magnetic body into thin horizontal slabs, thin enough to reliably assume the walls of the slab are vertical, thus reducing the integral in the z-direction of Eq. (4) to summation over the slabs. The method uses the divergence theorem, a twodimensional version of Eq. (5), to reduce the remaining surface integrals in Eq. (4) into a single line integral, the line describes the circumference of the slab, which is approximated by a polygon for easy integration. This method has been extensively used in aeromagnetic and satellite magnetic anomaly modeling (e.g., Plouff, 1976). A simple example of this method is the vertical prism discussed above. Because the magnetic body is divided into many thin slabs, the method can also handle a magnetic body with depth-dependent magnetization. The other method is the dipole array method where a magnetic body is subdivided into small volume elements, small enough to approximate the magnetization inside a volume element by a constant vector and the magnetic field of the volume element by that of a magnetic dipole located at the center of the volume element. This method does not require a uniform magnetic body, because it is always possible to subdivide the body into very many small volume elements of constant magnetization. Although the formulation in the rectangular coordinate system is straightforward, there has been some incorrect formulation in spherical coordinate system (see Dyment and Arkani-Hamed, 1998 for details). The dipole array method has been used in modeling satellite magnetic anomalies of Earth and Mars, where dipole arrays are placed on the surface of the planets (e.g., Mayhew, 1979; Purucker et al., 2000; Langlais et al., 2004). The space-domain methods, including the two explained, generally require a huge amount of mathematical manipulations and computer time. But the main problem with these methods is that they do not provide insight to the general relationship between the magnetic anomalies and the magnetization of the crust, that the magnetic anomalies arise from lateral variations of the vertically integrated magnetization. This is an important issue for understanding the resolving power of magnetic data. The advantage of the space-domain methods is the sharp boundaries of the model magnetic bodies. This enables us to integrate magnetic data with other geophysical data, such as seismic, and obtain a better model for a given magnetic anomaly. The Fourier domain methods, on the contrary, yield lateral variations of the magnetization where boundaries of the magnetic bodies are not sharply defined.

In the following I explain the Fourier domain technique used in forward modeling. The Fourier domain formulation better presents the relationship between the magnetization of the body and its magnetic field.

Consider a magnetic layer of magnetization  $\vec{M}(\vec{r}_0)$  with an upper surface  $S_2$  and a lower surface  $S_1$ . The surfaces are piecewise continuous. In a rectangular coordinate system with the *z*-axis upward, Eq. (4) is written as

$$V(\vec{r}) = -\frac{\mu_0}{4\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \left[ \int_{S_1}^{S_2} \vec{M}(\vec{r}_0) \cdot \nabla \frac{1}{|\vec{r} - \vec{r}_0|} dz_0 \right] dx_0 dy_0$$
(Eq. 9)

Taking two-dimensional Fourier transform of this equation yields (Arkani-Hamed and Strangway, 1986)

$$V_{\xi\eta} = -\frac{\mu_0}{2} \frac{\mathrm{e}^{-K_z}}{K} \vec{\beta} \cdot \vec{\alpha}_{\xi\eta}$$
 (Eq. 10)

where

$$\vec{\beta} = (i\xi, i\eta, -K) \tag{Eq. 11}$$

and

$$K = (\xi^2 + \eta^2)^{1/2}$$
 (Eq. 12)

is the two-dimensional wave number and  $\xi$  and  $\eta$  are wave numbers is the *x* and *y* directions.  $\vec{a}_{\xi\eta}$  is the Fourier transform of

$$\vec{\alpha} = \int_{S_1}^{S_2} \vec{M} e^{K_{Z_0}} dz_0.$$
 (Eq. 13)

Equations (10) and (13) show that the magnetic anomaly arises from the lateral variations of the bulk magnetization (the vertically integrated magnetization) of the source body, rather than detailed variations of magnetization with depth. In a local region where the Fourier domain formulation is applicable the core field has almost a constant direction  $\hat{B}_0$ . The Fourier transform of the magnetic anomaly is then reduced to

$$T_{\xi\eta} = -(\vec{B}_0 \cdot \vec{\beta}) V_{\xi\eta} \tag{Eq. 14}$$

Therefore, the main task is to determine the magnetic potential of a body.

Figure M10 shows the magnetic anomaly of a rectangular body with a square horizontal cross section of  $1 \times 1$  km and a thickness of 100 m. The top of the prism is at the surface and its sides are in the east and north directions. The body is located at the geomagnetic north pole (column 1), at 45°N geomagnetic latitude (column 2), and at the geomagnetic equator (column 3). It is magnetized in the direction of the core field with an intensity of 1 A  $m^{-1}$ . The magnetic anomalies are calculated at 100 m (row 1), 500 m (row 2), and 1 km (row 3) altitudes. The figure illustrates the complex characteristics of the magnetic anomaly that change drastically with the body location and the observation elevation. At the 100 m elevation the anomaly delineates the edges of the body, all the four edges at the north, only the north and south edges at the equator, and mainly the north and south edges at 45°N but slightly shifted. As the elevation increases the anomalies over the edges migrate toward the center and finally merge to give rise to a single positive anomaly at the north, a single negative anomaly at the equator, but a skewed anomaly at 45° N. The anomaly is directly over the body at the north and at the equator, but is significantly shifted toward the equator at 45°N. Moreover, the amplitude of the anomaly changes as the body moves from the pole toward the equator. This is due to the changes in the direction of the geomagnetic field, and thus the magnetization. In practice the magnetization intensity, which is assumed constant in these examples also decreases at lower latitudes, because of the decrease in the intensity of the magnetizing geomagnetic field.

The difficulty in relating the magnetic anomalies to their source bodies (Figure M10) is usually alleviated by applying a reduction-topole operator that reduces an anomaly to that as if the body is located at the north pole and is magnetized by the geomagnetic field there (e.g., Baranov, 1957; Bhattacharyya, 1965). That is, the anomalies seen in column 2 are reduced to those in column 1. On a regional scale where the core field direction and intensity change appreciably over the entire map a differential reduction-to-pole operator (Arkani-Hamed, 1988) is required to take into account these changes. However, all reduction-to-pole operators are singular at the geomagnetic equator and cannot be used to reduce the anomalies in column 3 to those in column 1.

### Inverse modeling

The inverse modeling of a local magnetic anomaly map is simplified because the core field is constant over the entire map. Blakely (1996) discusses this issue in a great detail. However, the inverse modeling of a global map is quite complicated. This is largely due to the fact that the direction and intensity of the core field drastically change over the globe (see Figure M10). Unlike the gravity anomaly of a body that attains the same maximum value directly over the body regardless of its location, the magnetic anomaly has quite complex characteristics, which is a source of great confusion among those who treat the magnetic anomaly maps similar to the gravity anomaly maps.

Here I briefly discuss major points of a generalized inversion technique developed by Arkani-Hamed and Dyment (1996) under the assumption that the anomalies arise from the induced magnetization, which is largely the case in the continents (e.g., Schnetzler and Allenby, 1983). It takes into account the global variations of the core field and transforms a global magnetic anomaly map into a global magnetic susceptibility contrast map of the lithosphere. Unlike the magnetic anomaly map, the magnetic susceptibility contrast map delineates the very nature of the magnetic properties of the lithosphere. Even a magnetization map does not delineate the nature of the magnetic lithosphere, because it is resulted from the multiplication of the magnetic susceptibility and the core field intensity which changes by more than a factor of 2 over the globe. The geomagnetic coordinate system is adopted throughout this inversion technique and the technique is based on spherical harmonic representations of the magnetic anomalies and the magnetic susceptibility distribution, which are the natural presentations on a global scale.

Let V be the magnetic potential of the lithosphere at an observation point  $\vec{r}$ , and  $\hat{B}$  denote the unit vector in the core field direction at that point. The magnetic anomaly T is

$$T = -\hat{B} \cdot \nabla V \tag{Eq. 15}$$

Let  $\hat{B}_1$  be the unit vector along the dipole component of the core field,

$$\hat{B}_1 = -\frac{(2\cos\theta\hat{r} + \sin\theta\hat{\theta})}{(1+3\cos^2\theta)^{1/2}}$$
(Eq. 16)

and write

$$\hat{B} = \hat{B}_1 + \vec{\delta}B \tag{Eq. 17}$$

where  $\hat{r}$  and  $\hat{\theta}$  are the unit vectors in the *r* and the colatitude  $\theta$  directions, respectively, and  $\vec{\delta B}$  denotes the contribution to  $\hat{B}$  from the nondipole part of the core field. Also, let

**Figure M10** Magnetic anomaly of a vertical prism of  $1 \times 1$  km square cross section and 100 m thickness, having  $1 \text{ A m}^{-1}$  magnetization. The first column shows the anomalies at the north pole, the second column shows the anomalies at 45° N latitude, and the third column shows the anomalies at the equator. The first row shows the anomalies at 100 m, the second row at 500 m, and the third row at 1000 m elevations.

$$\tau = (1 + 3\cos^2\theta)^{1/2}T$$
 (Eq. 18)

and

$$A = (1 + 3\cos^2\theta)^{1/2}\vec{\delta}B \cdot \nabla V \tag{Eq. 19}$$

*A* is a measure of the contribution to the magnetic anomalies arising from the coupling of the nondipole part of the core field with the magnetic potential of the lithosphere. Now expanding *V*,  $\tau$ , and *A* in terms of the spherical harmonics, and putting Eqs. (16)–(19) into Eq. (15) yields coupled equations that are solved iteratively to determine the spherical harmonic coefficients of the magnetic potential using those of the observed magnetic anomalies. It is worth noting, however, that the inversion from a global magnetic anomaly map to a magnetic potential map is unstable if the core field is dipolar (Backus, 1970). Although the entire core field is used in the calculations, the strong dominance of the dipole component of the core field still tends to enhance the sectorial harmonics of the potential, though slightly.

The next step is to calculate the magnetic susceptibility contrasts in the lithosphere from the magnetic potential thus obtained. Let  $\sigma(\vec{r}_0)$ denote the magnetic susceptibility of a volume element  $dv_0$  located at the point  $\vec{r}_0$  in the lithosphere, then the induced magnetization of the volume element  $\vec{M}(\vec{r}_0)$  is

$$\vec{M}(\vec{r}_0) = \frac{1}{\mu_0} \sigma(\vec{r}_0) \vec{B}'(\vec{r}_0) \mathrm{d}v_0 \tag{Eq. 20}$$

in which  $\vec{B}'(r_0)$  is the core field at that point. As mentioned earlier, the most one can achieve is to determine the vertically (radially) averaged magnetization of the lithosphere regardless of the technique used. This is the fundamental nonuniqueness of the inversion of magnetic anomalies. Therefore, we model the magnetic part of the lithosphere by a thin

magnetic spherical shell, and seek for a vertically averaged magnetic susceptibility, i.e., we let

$$\sigma(\vec{r}_0) = \sigma_0(\theta_0, \phi_0) \tag{Eq. 21}$$

Similarly, the core field is assumed to be constant with depth within the shell, i.e.,

$$\vec{B}'(\vec{r}_0) = \vec{B}'_0(\theta_0, \phi_0)$$
 (Eq. 22)

The core field intensity changes by less than 3% in the upper 50 km of the Earth and its direction hardly changes with depth in this region. Now decomposing  $\vec{B}'_0$  into a dipole part,  $\vec{B}'_1$ , and a nondipole part,  $\vec{\delta}B'$ ,

$$\vec{B}'_0 = \vec{B}'_1 + \vec{\delta}B'$$
 (Eq. 23)

and letting W denote the magnetic potential of the shell arising from the magnetization induced by the nondipole part of the core field, we obtain

$$W = \frac{1}{4\pi} \int \sigma_0(\theta_0, \phi_0) \vec{\delta} B'(\theta_0, \phi_0) \cdot \nabla \frac{1}{|\vec{r} - \vec{r}_0|} dv_0$$
 (Eq. 24)

Expanding  $\sigma$  and W in spherical harmonic and putting Eqs. (20)–(24) into Eq. (4) results again in coupled equations that are solved iteratively for the spherical harmonic coefficients of the magnetic susceptibility contrast from those of the magnetic potential.

The coupled equations that are iteratively solved for the magnetic potential using the magnetic anomaly, and for the magnetic susceptibility contrast using the magnetic potential, show that the spherical harmonic coefficients of different degrees of the magnetic susceptibility contrasts couple to those of the core field to produce a given spherical harmonic coefficient of the observed magnetic anomalies. This is a fundamental characteristic of a nonlinear inverse problem.

The above inversion technique is applied to the global magnetic anomaly map of the Earth (Figure M11/Plate 6a) derived from POGO and Magsat data that includes the spherical harmonics of degree 15–60 (Arkani-Hamed *et al.*, 1994). The harmonic coefficients of the magnetic anomalies with degree lower than 15 are dominated by the core field, and those higher than 60 are largely of nonlithospheric origin. The magnetic lithosphere is modeled by a spherical shell of thickness 40 km. Figure M12/Plate 6b shows the resulting vertically averaged magnetic susceptibility contrasts. Detailed interpretation of the features

seen in the figure is beyond the scope of this article. Here some basic characteristics of the susceptibility contrast map that illustrate the effects of the inversion process are briefly explained.

Comparison of Figures M11/Plate 6a and M12/Plate 6b shows the major effects of the inversion. The anomalies near the polar regions have retained their sign, whereas the anomalies in the equatorial region have changed their sign. The magnetic susceptibility contrasts associated with the magnetic anomalies in the midlatitudes are shifted poleward with respect to the magnetic anomalies. Moreover, the amplitude of the magnetic anomalies near the poles is significantly greater than those in the equatorial region, whereas the magnetic susceptibilities of their source bodies are comparable. Also, the inversion procedure in effect includes downward continuation. The higher degree harmonics of the resulting magnetic susceptibility contrast map have enhanced compared to the corresponding harmonics of the magnetic anomaly map at satellite altitudes. Consequently, some of the broad features in the anomaly map are divided into two or more small size features in the susceptibility contrast map.

It is worth reminding that Figure M12/Plate 6b shows the vertically averaged magnetic susceptibility contrasts within a spherical shell of 40 km thickness that can give rise to the magnetic anomalies seen in Figure M11/Plate 6a. Figure M12/Plate 6b shows the contrasts rather than the absolute magnetic susceptibility. The areas with positive and negative susceptibility contrasts should be regarded as the highand low-magnetic areas. A constant magnetic susceptibility is usually added to the resulting susceptibility contrast map to render all values positive, without affecting the observed magnetic anomalies. This is due to the fact that a spherical shell of uniform magnetic susceptibility produces no magnetic anomaly when magnetized by an internal magnetic field such as the core field (Runcorn, 1975). The nonuniqueness of the inverse problem in magnetic anomaly modeling, which is discussed in detail by Arkani-Hamed and Dyment (1996, see their Appendix B), concludes a large range of susceptibility distribution that give rise to no magnetic anomalies outside the lithosphere. The Runcorn model is one of the simple cases. These susceptibility distributions can be added to a resulting susceptibility map without affecting the resulting magnetic anomaly map.

### Conclusions

This article presents both forward and inverse modeling of magnetic anomalies. In the forward modeling the basic characteristics of the anomalies are discussed in some detail, and a Fourier domain technique is presented in detail. The magnetic anomaly of a vertical 490

prism of square cross section is shown at three elevations and at three latitude locations, to illustrate its complex behavior. The inversion of a global magnetic anomaly map into a global magnetic susceptibility contrasts map consists of two nonlinear operations. The first inverts a magnetic anomaly map into a magnetic potential map, while the second transforms the potential map into a magnetic susceptibility contrast map. The nonlinearity arises from the variations in the direction and intensity of the core field over the globe. The inversion technique removes the adverse effects of these variations, and results in the magnetic susceptibility contrasts that represent the very nature of the vertically averaged magnetic properties of the lithosphere.

# MAGNETIC DOMAINS

### Introduction

The existence of a paleomagnetic record testifies to the ability of magnetic minerals in rocks to retain their natural remanent magnetizations (NRMs) over geologic time. In the early days of paleomagnetism, it was thought that the stable components of NRM mainly resided in extremely small magnetic mineral grains, which occupied the singledomain (SD) state. However, it is now recognized that, due to their very small size and scarcity, SD particles may not be the major carriers of NRM in many rocks. Instead, it is more likely that much of the NRM is carried by grains which, by virtue of their larger sizes, are subdivided into two or more magnetic domains (Figure M13).

For a component of NRM to survive over geologic time, a particle's domain structure must remain stable in two ways. First, the initial domain state, whether it consists of a single domain or several domains, must resist being reset by the various physical and chemical forces which can affect a rock after emplacement, such as moderately elevated temperature, moderate pressure, slight chemical alteration, and shifts in the direction and magnitude of the Earth's field. In short, the fundamental domain structure-that is, the number of domains and the overall geometric style in which they are arranged in a crystal-should not change greatly over time. Second, in particles consisting of two or more domains, the domain walls (the transition regions between adjacent domains) present initially must remain locked in their positions, despite the aforementioned perturbations. Likewise, coercivities in a population of SD particles must remain sufficiently high over geologic time, so that paleomagnetic directions are not lost. Thus, magnetic domain structure lies at the heart of paleomagnetic stability.

In this article, we first discuss some of the fundamental principles and theoretical results of both classical magnetic domain theory and more recent micromagnetic models. Next, we discuss results of experiments to investigate how domain structure depends on grain size, applied field, and temperature in natural magnetic minerals and their synthetic analogs. Here, we focus on particles that contain two or more domains, such particles being prevalent in most rocks. For more detailed treatments of these subjects, the reader is referred to standard texts such as Chikazumi (1964), Cullity (1972), Stacey and Banerjee (1974), Dunlop and Özdemir (1997), and other references listed at the end of this article.

### Classical theory of magnetic domain structure

Theories of magnetic domain structure are based on three energies: exchange energy, anisotropy energy, and magnetostatic energy. In most

**Figure M13** Illustrations of (a) a multidomain cube containing four domains and (b) a single-domain cube of uniform magnetization.

classical theories, the first two energies produce the surface energy of the domain wall. Magnetostatic energy, the third energy, is the potential energy required to assemble an array of "magnetic free poles" where magnetic spins terminate at the domains' surfaces. Magnetostatic energy is the fundamental reason why particles subdivide into two or more domains because, in so doing, magnetostatic energy is reduced. However, as discussed below, this subdivision carries an energy "price": the energy of domain walls. Consequently, below a certain transition size particles occupy the SD state. Above this size, particles normally contain two or more domains, the number of which generally increases with the size of the particle. In this section, we discuss how traditional theories predict and how domain structure in a given material depends on grain size and temperature.

## Exchange energy

The origin of permanent magnetism was originally postulated by Weiss (1907) in terms of a "molecular field" that promotes the alignment of atomic spins in a ferromagnetic material. Subsequently, the molecular field was shown to be the phenomenological expression of a quantum-mechanical phenomenon, called the exchange interaction. Seminal calculations by Heisenberg (1928) demonstrated that the exchange energy between two adjacent spin vectors  $S_1$  and  $S_2$  is given by

$$E_{\rm ex} = -2J_{\rm ex}\boldsymbol{S}_1 \cdot \boldsymbol{S}_2 = -2J_{\rm ex}\boldsymbol{S}_1\boldsymbol{S}_2\cos\theta_{12}$$

Here,  $J_{ex}$  is the exchange integral of the specific material and  $\theta_{12}$  is the angle between the two adjacent spins. In the vast majority of natural and synthetic elements and compounds, the exchange integral is negative; in this case, adjacent spins which are antiparallel yield the configuration of lowest energy. Such materials are incapable of permanent magnetism. In those few materials whose exchange integral is positive, the configuration of lowest energy is achieved when neighboring spins are aligned. This gives rise to the rare phenomenon of spontaneous magnetization ( $M_s$ ) and remanence. Such materials possess a Curie temperature, at which spontaneous magnetism vanishes, because (a) thermal agitation disrupts the alignment of adjacent spins, and (b) thermal expansion of the lattice increases interatomic (or intermolecular) distances and thus reduces the effective strength of  $E_{ex}$ .

### Magnetocrystalline anisotropy energy

Magnetic anisotropy causes magnetic properties to depend on the direction in which they are measured. For example, due to magnetocrystalline anisotropy, it requires a lower field to saturate a magnetite crystal along the <111> directions than along <100>. Magnetocrystalline anisotropy arises from the coupling between spins and orbits of the electrons. Thus, work is required to rotate spins out of the directions of lowest energy determined by spin-orbit coupling. These crystallographic directions of lowest energy are often referred to as "easy" directions of magnetization, whereas the directions of highest energy are the "hard" directions. Easy and hard directions depend on the specific material and its crystal structure. In hexagonal crystals, for example, the work per unit volume required to rotate the spontaneous magnetization vector  $M_s$  away from the *c*-axis through an angle  $\theta$  is:

 $E = K_0 + K_1 \sin^2 \theta + K_2 \sin^4 \theta + \cdots$  higher order terms.

Here,  $K_0$ ,  $K_1$ ,  $K_2$  are the material's magnetocrystalline anisotropy constants (units of erg cm<sup>-3</sup> in cgs). When  $K_1 > 0$  and  $K_2 > -K_1$ , the *c*-axis is the easy direction of magnetization, as in cobalt.

In a cubic material, the magnetocrystalline anisotropy energy density is given by:

$$E = K_0 + K_1(\alpha_1^2 \alpha_2^2 + \alpha_2^2 \alpha_3^2 + \alpha_1^2 \alpha_3^2) + K_2(\alpha_1^2 \alpha_2^2 \alpha_3^2) + \cdots$$
  
higher order terms.

Here,  $\alpha_1$ ,  $\alpha_2$ , and  $\alpha_3$  are the direction cosines of the angles between the spontaneous magnetization vector  $M_s$  and the crystal axes [100], [010], and [001], respectively. Often,  $K_1$  is much larger than  $K_2$ , so that higher powers in the expression above can be neglected. In materials such as magnetite, both  $K_1$  and  $K_2$  are negative at and above room temperature; this results in <111> being easy directions. When  $K_1 > 0$  and  $K_2 = 0$ , then <100> are easy directions, as in iron (e.g., see Chikazumi, 1964; Cullity, 1972).

## Stress anisotropy

Also due to spin-orbit coupling, the lattice of a ferromagnetic material will spontaneously strain below the Curie temperature. Conversely, application of external stress or accumulation of internal strain can rotate the spontaneous magnetization away from the easy direction given by crystalline anisotropy. In a cubic material the energy resulting from an applied stress  $\sigma$  is

$$E = -3/2\lambda_{100}\sigma(\alpha_1^2\gamma_1^2 + \alpha_2^2\gamma_2^2 + \alpha_3^2\gamma_3^2) - 3\lambda_{111}\sigma(\alpha_1\alpha_2\gamma_1\gamma_2 + \alpha_2\alpha_3\gamma_2\gamma_3 + \alpha_3\alpha_1\gamma_3\gamma_1)$$

where  $\alpha_1$ ,  $\alpha_2$ , and  $\alpha_3$  are the direction cosines of  $M_s$  with respect to [100], [010], and [001], respectively. The  $\gamma_i$  are the equivalent direction cosines of  $\sigma$ ;  $\lambda_{100}$  and  $\lambda_{111}$  are the material's magnetostriction constants. Tension is assumed to be positive. When  $\lambda_{100} = \lambda_{111}$ , as in the case of isotropic magnetostriction, then the magnetoelastic energy reduces to the simple form

$$E = 3/2\lambda\sigma\sin^2\theta$$

where  $\theta$  is the angle between  $M_{\rm s}$  and  $\sigma$  and where  $\lambda = \lambda_{100} = \lambda_{111}$ . In this simple case, energy is minimum when (a)  $M_{\rm s}$  is parallel to  $\sigma$  and  $\lambda \sigma > 0$  or (b)  $M_{\rm s}$  is perpendicular to  $\sigma$  and  $\lambda \sigma < 0$ . Thus in case (a) the application of stress will cause  $M_{\rm s}$  to rotate toward the stress axis, whereas in case (b)  $M_{\rm s}$  will rotate toward the direction perpendicular to the axis of stress.

### Magnetostatic energy

The work, per unit volume, required to assemble a population of magnetic "free poles" into a particular configuration is called the magnetostatic energy. Magnetostatic calculations even for the simplest domain configurations are complex and usually require numerical methods. One of the simplest examples was addressed by Kittel (1949), who analyzed a semi-infinite plate of thickness L that contained lamellar domains of uniform width D, with spontaneous magnetizations normal to the plate surface (Figure M14). Walls were

**Figure M14** Illustration of the semi-infinite, magnetized plate of thickness *L*, whose magnetostatic energy was calculated by Kittel (1949). The plate contains domains of identical width *D*, with magnetizations perpendicular to the plate's surface. Walls are assumed to be infinitely thin.

assumed to be of negligible thickness with respect to the domains' widths and, therefore, the magnetostatic energies due to the walls' magnetic moments were not taken into consideration.

Using the magnetic potential and a Fourier series approach, Kittel obtained  $E_{\rm m} = 1.705 \ M_{\rm s}^2 D$ , where  $E_{\rm m}$  is the magnetostatic energy, per unit area of plate surface (erg cm<sup>-2</sup>, in cgs).

Note, however, that the expression above is an approximation, because Kittel did not account for magnetostatic interactions among all combinations of polarized slabs on the top and bottom surfaces of the plate. Subsequently, these extra energies were included in calculations by Rhodes and Rowlands (1954). Also, they relaxed the assumption of semi-infinite geometry and addressed finite, rectangular grains. Their numerical calculations yielded "Rhodes and Rowlands" functions, with which one may calculate the total magnetostatic energy of rectangular grains of specified relative dimensions.

### Energy and width of the domain wall

In the classical sense, a domain wall is the transition region where the spontaneous magnetization changes direction from one domain to the next. According to classical theories, each domain is spontaneously magnetized in one direction and is clearly distinct from the wall. (Micromagnetic theories relax this assumption and will be discussed in a later section.)

The two most important energies that affect the domain wall's energy and width are (1) exchange energy and (2) anisotropy energy, the latter being due either to magnetocrystalline anisotropy or stress. The magnetostatic energy of the wall itself also plays a role; this energy was first analyzed by Amar (1958) and grows especially important when the wall width approaches that of the particle.

Were magnetocrystalline energy acting alone, the spin vectors would change directions abruptly from one domain to the next. For example, if a substance possessed very strong, uniaxial crystalline anisotropy and exchange energy was very much weaker, then the lowest energy "transition" between two adjacent domains would virtually consist of two adjacent spins pointing 180° apart.

This kind of abrupt transition usually involves a large amount of exchange energy, however, because exchange energy is minimized when adjacent spins are parallel. Because minimization of anisotropy energy alone would produce an infinitely thin wall, while minimization of exchange energy alone would produce an infinitely broad wall, the spins in a wall rotate gradually from one domain to the next (Figure M15). This produces a wall with finite width.

By this model, spins in a wall reach an equilibrium configuration when magnetocrystalline and exchange energies are balanced. For the  $180^{\circ}$  Bloch wall shown in Figure M15 in which the spins rotate through  $180^{\circ}$ , the wall energy per unit area of wall surface is

$$E_w = 2(J_{ex}S^2\pi^2K/a)^{1/2} = 2\pi(AK)^{1/2}$$

**Figure M15** Illustration of spins in a 180° Bloch wall.  $\theta$  is the angle between a spin and the easy axis of magnetization;  $\phi$  is the angle between adjacent spins.

where  $J_{\text{ex}}$  is exchange integral, S is spin, K is anisotropy constant due to magnetocrystalline anisotropy energy and/or stress energy, A is exchange constant (equal to  $J_{\text{ex}}S^2/a$ ), and a is lattice constant. The width of a 180° wall is

$$\delta_{\rm w} = (JS^2 \pi^2 / Ka)^{1/2} = \pi (A/K)^{1/2}$$

In magnetite, values predicted for  $E_{\rm w}$  and  $\delta_{\rm w}$  are approximately 0.9 erg cm<sup>-2</sup> and 0.3 µm, respectively (e.g., see Dunlop and Özdemir, 1997).

### Domain width versus grain size

For the simple, planar domain structure illustrated in Figure M14, domain width D can be calculated for the lowest energy state by minimizing the sum of magnetostatic and wall energies per unit volume of material. One obtains the familiar half-power law derived originally by Kittel (1949):

$$D = (1/M_{\rm s})(E_{\rm w}L/1.705)^{1/2}$$

By this model, domain width increases with the half-power of crystal thickness, so long as the crystal occupies the state of absolute minimum energy. Experimental determinations of domain width versus grain thickness will be discussed in a subsequent section.

Rocks, however, rarely contain magnetic minerals in the shape of thin platelets that might be fair approximations to the semi-infinite plate of Kittel's model. Moskowitz and Halgedahl (1987) calculated the number of domains versus grain size in rectangular particles of x = 0.6 titanomagnetite ("TM60": Fe<sub>2.4</sub>Ti<sub>6</sub>O<sub>4</sub>) containing planar domains separated by 180° walls. Magnetostatic energy, including that due to the walls' moments, was determined with the method developed by Amar (1958), based on Rhodes and Rowlands' method (1954). It was assumed that grains occupied states of absolute minimum energy. The effects of two dominant anisotropies were investigated: magnetocrystalline anisotropy (zero stress) and a uniaxial stress ( $\sigma = 100$  MPa) which was strong enough to completely outweigh the crystalline term. Their calculations yielded two principal results: (1) particles encompassing a wide range of grain sizes can contain the same number of domains, and (2) a plot of N (number of domains) versus L (grain thickness) is fitted well by a power law  $N \propto L^{1/2}$ . It follows that domain width D also follows a half-power law in L. Thus, the general form of functional dependence of D on L is the same for finite, rectangular grains, and semi-infinite plates.

### Single-domain/two-domain transition size

Grains containing only two or three domains can rival the remanences and coercivities of SD grains, and such particles are referred to as being "pseudosingle-domain," or PSD. PSD grains can be common in many rocks and, in terms of interpreting rock magnetic behavior, it is important to know their size ranges in different magnetic minerals. The onset of PSD behavior begins at the single-domain–two-domain transition size,  $d_0$ .

In general, a particle will favor a two-domain over a SD state because the magnetostatic energy associated with two domains is much lower than that of a saturated particle. However, below  $d_0$  the energy price of adding a domain wall is too great to produce a state of minimum energy. At  $d_0$  the total energy of the two-domain state ( $E_{2D}$ ) and the SD state are equal; above  $d_0$ ,  $E_{2D} < E_{SD}$ , while  $E_{2D} > E_{SD}$  below it.

In zero applied field this transition size depends on the material's magnetic properties, its state of stress, the particle shape, and temperature. Moskowitz and Banerjee (1979) calculated total energies of SD, two-domain, and three-domain cubes of stress-free magnetite containing lamellar domains at room temperature. Magnetostatic energy of the walls was included in their calculations (Amar, 1958). They obtained  $d_0 \approx 0.08 \ \mu m$ .

Similar calculations for TM60 by Moskowitz and Halgedahl (1987) yielded  $d_0 \approx 0.5 \ \mu\text{m}$  for unstressed particles at room temperature. Raising the stress level to 100 MPa shifted  $d_0$  upward to 1  $\mu\text{m}$ .

### Domains and domain walls at crystal surfaces

In relatively thick crystals, domains and domain walls may change their geometric styles near and at crystal surfaces, in order to lower the total magnetostatic energy with respect to that of the "open" structure shown in Figure M14. The particular style depends largely on the dominant kind of anisotropy, as well as on the relative strengths of magnetostatic and anisotropy energies. When  $2\pi M_s^2/K \gg 1$  in a uniaxial material, prism-shaped closure domains bounded by 90° walls, in which spins rotate through 90° from one domain to the next, may completely close off magnetic flux at the crystal surface. Lamellar domains separated by 180° walls may fill the crystal's volume (Figure M16a). In this case, the two main energies originate from the walls and from magnetoelastic energy due to magnetostrictive strain where closure

**Figure M16** Three styles in which domains and domain walls may terminate at a crystal surface. (a) Illustration of prism-shaped surface closure domains at the surface of a material which is either uniaxial, with  $2\pi M_s^2/K \gg 1.0$ , or cubic, such as iron, whose easy axes are along <100>. Here, 90° walls separate closure domains from the principal "body" domains that fill most of the crystal. Arrows indicate the sense of spontaneous magnetization within the domains. (b) Illustration of wavy walls at the surface of a uniaxial material with  $2\pi M_s^2/K < 1.0$ . Waviness dies out with increasing distance from the surface. (c) Prism-shaped closure domains at the surface of a cubic material, such as magnetite, whose easy directions of magnetization are along <111>. Closure domains and body domains are separated by 71° and 109° walls.

domains abut body domains. Closure domain structures such as these can subdivide further into elaborate arrays of smaller closure and nested spike domains, if the crystal is sufficiently thick. Because closure domains can either greatly reduce or completely eliminate magnetostatic energy, the body domains can be several times broader than predicted for the Kittel-like, "open" structure.

When  $2\pi M_s^2/K \ll 1$  in a uniaxial substance like barium ferrite, a large amount of anisotropy energy results when  $M_s$  is perpendicular to the "easy" axis. Therefore, the style of surface closure shown in Figure M16a is energetically unfavorable. Instead, a very different style of surface domain structure may evolve in thick crystals. Walls which are planar within the body of the crystal can become wavy at the surface (Figure M16b). In extremely thick crystals, wavy walls can alternate with rows of reverse spikes. These elaborate surface domain structures lower magnetostatic energy by achieving a closer mixture of "positive" and "negative" free magnetic poles (e.g., see Szymczak, 1968).

Large crystals governed by cubic magnetocrystalline anisotropy reduce surface flux through prism-shaped closure domains at the surface. When <100> are easy directions, as in iron, closure domains are bounded by 90° walls (Figure M16a). When <111> are easy directions, as in magnetite, closure domains are bounded by 71° and 109° walls and, within the closure domains,  $M_s$  is canted with respect to the crystal surface (Figure M16c).

### Temperature dependence of domain structure

Understanding how domain structure evolves during both heating to and cooling from the Curie point is crucial to understanding the acquisition and thermal stability of thermal remanent magnetization (TRM). If the number of domains changes significantly during cooling from the Curie point, it is reasonable to hypothesize that TRM will not become blocked until the overall domain structure reaches a stable configuration.

According to Kittel's original model (Figure M14), grains will nucleate (add) domain walls and domains with heating in zero field, if the wall energy drops more rapidly with increasing temperature than does the magnetostatic term. Energywise, in this first case a particle can "afford" to add domains with heating. Conversely, during cooling from the Curie point a grain will denucleate (lose) domains and domain walls if wall energy rises more quickly than does  $M_s^2$  with decreasing temperature. If wall energy drops less rapidly with increasing temperature than does  $M_s^2$ , then the opposite scenarios apply. Of course, such behavior relies on the assumptions that the particle is able to maintain a global energy minimum (GEM) domain state at all temperatures and that the total magnetostatic energy of the walls themselves can be ignored.

Using Amar's (1958) model, Moskowitz and Halgedahl (1987) calculated the number of domains between room temperature and the Curie point in parallelepipeds of TM60. As discussed earlier, they investigated two cases: dominant crystalline anisotropy (zero stress) and high stress ( $\sigma = 100$  MPa). Magnetostatic energy from wall moments was included in the calculations. At all temperatures they assumed that particles occupied GEM domain states. Because the temperature dependences of the material constants A (exchange constant) and  $\lambda$  (magnetostriction constant) for TM60 had not been constrained well by experiments, they ran six models to bracket the least rapid and most rapid drops in wall energy with heating.

In TM60 grains larger than a few micrometers, most of their results gave an increase in the number of domains with heating. Exceptions to this overall pattern were cases in which walls broadened so dramatically with increasing temperature that they nearly filled the particle and rendered nucleation unfavorable. During cooling from the Curie point in zero field, the domain "blocking temperature"—that is, the temperature below which the number of domains remained constant—increased both with decreasing grain size and with internal stress.

## **Micromagnetic models**

In contrast to classical models of magnetic domain structure, micromagnetic models do not assume the presence of discrete domains that is, relatively large volumes in a crystal where the spontaneous magnetization points in a single direction. Instead, micromagnetic models allow the orientations of  $M_{\rm s}$ -vectors to vary among extremely small subvolumes, into which a grain is divided. A stable configuration is obtained numerically when the sum of exchange, anisotropy, and magnetostatic energies is minimum. To reduce computation time, all micromagnetic models for magnetite run to date assume unstressed, defect-free crystals.

Moon and Merrill (1984, 1985) were the first in rock magnetism to construct one-dimensional (1D) micromagnetic models for defect-free magnetite cubes. To simplify calculations, they assumed that magnetite was uniaxial. In their models, they subdivided a cube into K thin, rectangular lamellae. Within a Kth lamella, the spin vectors were parallel to the lamella's largest surface but oriented at angle  $\theta_k$  with respect to the easy axis of anisotropy. The distribution of angles was varied throughout the cube until a state of minimum energy was obtained. Because the  $\theta_k$ 's varied continuously across the grain, there was no sharp demarcation between domains and domain walls. For practical purposes, a wall's effective width was defined as the region in which the moments rotated most rapidly. Nucleation was modeled by "marching" a fresh wall from a particle's edge into the interior. A nucleation barrier was determined by calculating the maximum rise of total energy as the wall moved to its final location and as preexisting walls adjusted their positions to accommodate the new wall. The denucleation barrier was determined by reversing the nucleation process

Moon and Merill's major breakthrough was the discovery that a particle can occupy a range of local energy minimum (LEM) domain states. Each LEM state is characterized by a unique number of domains and is separated from adjacent states by energy barriers. As illustrated in Figure M17, the GEM state is the configuration of lowest energy but, owing to the energy barriers between states, a LEM state can be quite stable as well. Any given LEM can be stable over a broad range of grain sizes.

Several authors have extended micromagnetic calculations for magnetite to two- and three-dimensions (e.g., Williams and Dunlop, 1989, 1990; Newell et al., 1993; Xu et al., 1994; Fabian et al., 1996; Fukuma and Dunlop, 1998; Williams and Wright, 1998). In 2D models, grains are subdivided into rods. In 3D models, the crystal is subdivided into a multiplicity of extremely small, cubic cells (e.g.,  $\approx 0.01 \,\mu\text{m}$  on a side), within each of which  $M_s$  represents the average magnetization over several hundred atomic dipole moments. Each cell's  $M_{\rm s}$ -vector is oriented at angle  $\theta$  with respect to the easy axis, and the  $\theta$ 's are varied independently with respect to their neighbors until an energy minimum is achieved. Owing to the extremely large number of cells and the even larger number of computations, energy calculations begin with an initial guess of how the final, minimum energy structure might appear. To date, the largest magnetite cubes addressed by 3D models are only a few micrometers in size, due to limitations of computing time (e.g., Williams and Wright, 1998).

2D and 3D micromagnetic models yield a variety of exotic, nonuniform configurations of magnetization, such as "flower" and "vortex" states. Analogous to Moon and Merrill's results, these models yield both LEM and GEM states, although very different in their  $M_{\rm s}$ -structures from those of 1D models. For example, Figure M18 illustrates a "flower" state in a cube magnetized parallel to the z-axis. The flower state is reminiscent of a classical SD state of uniform magnetization, except that the  $M_s$ -vectors are canted at and near the crystal surface. Increasing the cube size makes other nonuniform states energetically favorable (e.g., Fabian et al., 1996). For example, according to 3D models of magnetite cubes between 0.01 and 1.0 µm in size, the flower state is the lowest energy state between about 0.05 and 0.07 µm (Williams and Wright, 1998). Further increase of cube size yields a vortex state, in which the  $M_s$ -vectors circulate around a closed loop within the grain. By Williams and Wright's calculations, both flower and vortex states are stable between about 0.07 and 0.22 µm, although the vortex state has the lower energy. Raising the cube size to the 0.22-1.0 µm range results in the flower state becoming unstable, so that the vortex state is the only possible state. In relatively large cubes of magnetite—e.g., 4 or 5  $\mu m$ —2D and 3D models yield Ms-configurations closely approaching those of

**Figure M17** Diagram illustrating the relative energies and energy barriers associated with local energy minimum (LEM) domain states. Each LEM state is characterized by a unique number of domains and is separated from adjacent states by nucleation and denucleation energy barriers. In this diagram, the global energy minimum, or GEM, domain state has five domains.

**Figure M18** Illustration of a "flower" state obtained through three-dimensional micromagnetic modeling of a cube largely magnetized along the cube's *z*-axis.

classical domain structures expected for magnetite; some models predict "body" domains separated by domain walls, with closure domains at the surface (e.g., Xu *et al.*, 1994; Williams and Wright, 1998).

According to several micromagnetic models of hysteresis in submicron magnetite, magnetization reversal can occur through LEM-LEM transitions (e.g., flower to vortex state). Reversal can take place through almost independent reversals of the particle's core and outer shell (e.g., Williams and Dunlop, 1995).

Dunlop *et al.* (1994) used 1D micromagnetic models to investigate transdomain TRM. Transdomain TRM—that is, acquisition of TRM through LEM-LEM transitions—had been proposed earlier by Halgedahl (1991), who observed denucleation of walls and domains in titanomagnetite during cooling (see below for a discussion of these results). In particular, Halgedahl's observations strongly suggested that denucleation could give rise to SD-like TRMs in grains that, after other magnetic treatments, contained domain walls. Furthermore, Halgedahl (1991) found that a grain could "arrive" in a range of LEM states after replicate TRM acquisitions.

To determine whether transdomain TRM could be acquired by stress-free, submicron magnetite particles free of defects, Dunlop *et al.* (1994) calculated the energy barriers for all combinations among single domain-two-domain-three-domain transitions with decreasing temperatures from the Curie point of magnetite in a weak external field. They assumed that LEM-LEM transitions were driven by thermal fluctuations across LEM-LEM energy barriers and that thermalequilibrium populations of LEM states were governed by Boltzmann statistics. According to their results, after acquiring TRM most populations would be overwhelmingly biased toward GEM domain states, and an individual particle should not exhibit a range of LEM states after several identical TRM runs.

Using renormalization group theory, Ye and Merrill (1995) arrived at a very different conclusion. According to their calculations, shortrange ordering of spins just below the Curie point could give rise to a variety of LEM states in the same particle after replicate coolings.

These conflicting theoretical results are discussed below in the context of experiments.

### Methods of imaging domains and domain walls

Rock magnetists have mainly used three methods to image domains and domain walls: the Bitter pattern method, the magneto-optical Kerr effect (MOKE), and magnetic force microscopy (MFM). Two other methods—transmission electron microscopy (TEM) and off-axis electron holography—have been used in a very limited number of studies on magnetite.

The Bitter method images domain walls through application of a magnetic colloid to a smooth, polished surface carefully prepared to eliminate residual strain from grinding (e.g., see details in Halgedahl and Fuller, 1983). Colloid particles are attracted by the magnetic field gradients around walls, giving rise to Bitter patterns. When viewed under reflected light, patterns appear as dark lines against a grain's bright, polished surface. With liquid colloid, this method can resolve details as small as about 1 µm. If colloid is dried on the sample surface and the resultant pattern is viewed in a scanning electron microscope (SEM), features as small as a few tenths of one micrometer can be resolved (Moskowitz *et al.*, 1988; Soffel *et al.*, 1990).

The MOKE is based on the rotation of the polarization plane of incident light by the magnetization at a grain's surface. Unlike the Bitter method, the MOKE images domains themselves, rather than domain walls. Domains appear as areas of dark and light, the result of their contrasting magnetic polarities (Hoffmann *et al.*, 1987; Worm *et al.*, 1991; Heider and Hoffmann, 1992; Ambatiello *et al.*, 1999). The MOKE has the same resolving power as the Bitter method.

In the MFM, a magnetized, needle-shaped tip is vibrated above the highly polished surface of a magnetic sample. Voltage is induced in the tip by the magnetic force gradients resulting from domains and domain walls. The effects of any surface topography are removed by scanning the surface with the nonmagnetic tip of an atomic force microscope. The MFM can resolve magnetic features as small as 0.01  $\mu$ m (Williams *et al.*, 1992; Proksch *et al.*, 1994; Moloni *et al.*, 1996; Pokhil and Moskowitz, 1996, 1997; Frandson *et al.*, 2004).

# Styles of domains observed in magnetic minerals of paleomagnetic significance

In rock magnetism, the majority of domain observation studies have focused on four magnetic minerals, all important to paleomagnetism: pyrrhotite (Fe<sub>7</sub>S<sub>8</sub>), titanomagnetite of roughly intermediate composition (near Fe<sub>2.4</sub>Ti<sub>6</sub>O<sub>4</sub>, or TM60), magnetite (Fe<sub>3</sub>O<sub>4</sub>), and hematite (Fe<sub>2</sub>O<sub>3</sub>).

Owing to its high magnetocrystalline anisotropy constant and relatively weak magnetostriction constant, pyrrhotite behaves magnetically as a uniaxial material. When studied with the Bitter method, pyrrhotite often exhibits fairly simple domain patterns, which suggest lamellar domains separated by 180° walls (Figure M19a) (Soffel, 1977; Halgedahl and Fuller, 1983).

Despite being cubic, intermediate titanomagnetites rarely, if ever, exhibit the arrays of closure domains, 71°, and 109° walls that one would predict. Instead, these minerals usually display very complex patterns of densely spaced, curved walls. Possibly, these complex structures result from varying amounts of strain within the particle (Appel and Soffel, 1984, 1985). Occasionally, grains exhibit simple arrays of parallel walls, such as that shown in Figure M20 (e.g., Halgedahl and Fuller, 1980, 1981), but it is not unusual to observe wavy walls alternating with rows of reverse spikes (Halgedahl, 1987; Moskowitz et al., 1988). Both simple and wavy patterns suggest a dominant, internal stress that yields a uniaxial anisotropy, although the origin of this stress is still unclear. On one hand, it could originate from the mechanical polishing required to prepare samples for domain studies. Alternatively, in igneous rock samples stress could be generated during cooling, due to differences in the coefficients of thermal expansion among the various minerals.

Small magnetite grains randomly dispersed in a rock or a synthetic rock-like matrix generally display simple arrays of straight domain walls, if the domains' magnetizations are sufficiently close to being parallel to the surface of view (e.g., Worm *et al.*, 1991; Geiß *et al.*, 1996) (Figure M21). In such samples, however, there appears to be a paucity of closure domains, perhaps the result of observation surfaces being other than {100} planes.

In an early study by Bogdanov and Vlasov (1965), Bitter patterns of  $71^{\circ}$  and  $109^{\circ}$  walls were observed on cleavage planes of a few small magnetite particles obtained by crushing a natural crystal. Similarly, from Bitter patterns Boyd *et al.* (1984) found both closure domains and networks of  $180^{\circ}$ ,  $71^{\circ}$ , and  $109^{\circ}$  walls in several magnetite particles in a granodiorite. Body domains accompanied by closure domains were also reported by Smith (1980), who applied the TEM method to a

In this particular state of magnetization, the grain contains four walls, whose lengths are commensurate with the particle's length. few small magnetite crystals in rock. Note that this method images domains through deflection of the electron beam by the magnetizations within domains. Consequently, the TEM method reveals volume domains, not just their surface manifestations. Similarly, large magnetite crystals cut and polished on {100} planes almost invariably exhibit the closure domains bounded by 71° and 109° walls expected for truly multidomain magnetite (e.g., Bogdanov and Vlasov, 1966; Özdemir and Dunlop, 1993, 1997; Özdemir *et al.*, 1995).

To date, domain studies on hematite have been limited to large (e.g.,  $100 \ \mu\text{m}-1 \ \text{mm}$ ) platelets. Even large crystals such as these

contain very few walls and a fairly simple domain structure, owing to hematite's weak spontaneous magnetization (about 2 emu cm<sup>-3</sup>) and low magnetostatic energy (Figure M22) (Halgedahl, 1995, 1998).

### Observed number of domains versus grain size

Both Kittel's original model of domains in a semi-infinite platelet and calculations for finite grains by (e.g., Moskowitz and Halgedahl, 1987) lead to the prediction that domain width  $D \propto L^{1/2}$ , where *L* is plate or particle thickness. These predictions are supported by domain studies of natural magnetic minerals, which generally yield a power-law dependence of *D* on *L*, although the power may differ somewhat from 0.5.

In rock magnetism, Soffel (1971) was the first to study the grainsize dependence of the number of domains in a paleomagnetically important magnetic mineral. From Bitter patterns on grains of natural, intermediate ( $x \approx 0.55$ ) titanomagnetite in a basalt, Soffel determined that, on average, N (number of domains)  $\propto L^{1/2}$ , where L is the average particle size. This relation translates to D (domain width)  $\propto L^{1/2}$ . Extrapolation of these data to N = 1 (or, equivalently, to D = L) yielded a single domain-two domain transition size of 0.6 µm for this composition. By assuming that Kittel's model could be applied to roughly equidimensional grains without serious errors and that  $M_s = 100$  emu cm<sup>-3</sup> for  $x \approx 0.55$ , Soffel obtained a wall energy density of about 1 erg cm<sup>-2</sup>.

Bitter patterns on natural pyrrhotite in the Bad Berneck diabase from Bavaria were studied both by Soffel (1977) and by Halgedahl and Fuller (1983). Halgedahl and Fuller determined the dependence of domain width on grain size for three states of magnetization: NRM, after alternating field demagnetization (AFD) in a peak field of 1000 Oe, and saturation remanence imparted in a field of 15 kOe. Particles that contained walls in these three different states yielded similar power-law dependences of *D* on *L*:  $D \propto L^{0.43}$  (NRM),  $D \propto L^{0.40}$  (AFD), and  $D \propto L^{0.45}$  (saturation remanence). The single domain-two-domain boundary sizes estimated for the three states also were similar, falling between 1.5 and 2  $\mu$ m. These results were consistent with those of Soffel (1977).

Likewise, Geiß *et al.* (1996) obtained  $D \propto L^{0.45}$  from Bitter patterns on synthetic magnetite particles grown in a glass-ceramic matrix (Worm and Markert, 1987). They obtained a single domain-twodomain transition size for magnetite at approximately 0.25 µm.

In contrast to the results discussed above for titanomagnetite, pyrrhotite, and glass-ceramic magnetite, one of Dunlop and Özdemir's (1997) data compilations for magnetite samples from several very different provenances yielded  $D \propto L^{0.25}$ . The cause of the discrepancy between this result and those obtained from other samples is not understood.

### Domain wall widths

When studied in the SEM, patterns of dried magnetic colloid afford high-resolution views of domain walls—or, more precisely, the colloid accumulations around walls. Moskowitz *et al.* (1988) applied this method to polycrystalline pellets of synthetic titanomagnetite substituted with aluminum and magnesium (Fe<sub>2.2</sub>Al<sub>0.1</sub>Mg<sub>0.1</sub>Ti<sub>0.6</sub>O<sub>4</sub>). Henceforth, this composition is referred to as "AMTM60." Dried Bitter patterns on unpolished surfaces were virtually identical in style to those common to materials controlled by strong uniaxial anisotropy, such as barium ferrite. Patterns indicated closely spaced stripe domains, sinusoidally wavy walls, and elaborate wavy walls, which alternated with nested arrays of reverse spikes. Direct measurements from SEM photographs yielded wall widths between 0.170 and 0.400 µm.

In the same study, Moskowitz *et al.* (1988) also measured the wavelengths, amplitudes, and domain widths of the sinusoidally wavy patterns. Using these parameters and the experimental value of spontaneous magnetization for AMTM60, they applied Szymczak's (1968) model to estimate the exchange constant and the uniaxial anisotropy constant, the latter presumably due to residual stress generated, while the pellet cooled from the sintering temperature.

Very high-resolution images of domains and domain walls have been obtained with MFM on magnetite. The first images were reported by Williams *et al.* (1992) from a {110} surface on a large crystal of natural magnetite. They recorded a magnetic force profile across a  $180^{\circ}$  wall. This record indicated that the spins within the wall reversed their polarity of rotation along the length of the wall, demonstrating that walls in real materials can be much more complex than those portrayed by simple models.

In a study of glass-ceramic magnetite particles with MFM, Pokhil and Moskowitz (1996, 1997) found that, along its length, an individual wall can be subdivided into several segments of opposite polarity. The segments are separated by Bloch lines, the transition regions where polarity changes sense. Rather than being linear, subdivided walls zigzag across a grain. Analogous to wavy walls, the zigzags help to reduce a grain's total magnetostatic energy. The number of Bloch lines within any specific wall was found to vary with repeated AF demagnetization treatments. Thus walls, like particles, can occupy LEM states.

Owing to its high-resolution capabilities, the MFM can provide estimates of wall width. Proksch *et al.* (1994) obtained MFM profiles across a  $180^{\circ}$  wall on a {110} surface of natural magnetite. The deconvolved signal yielded a half-width, assumed to be commensurate with wall width, of about 0.21 µm.

# Experimental evidence for local energy minimum domain states

In their study of Bitter patterns on natural pyrrhotite, Halgedahl and Fuller (1983) noted that grains of virtually identical size could contain very different numbers of domains, despite these same particles having undergone the same magnetic treatments. Moreover, they found that an individual particle could arrive in very different domain states—i.e., with different numbers of walls—after different cycles of minor

hysteresis. Clearly, such particles did not always occupy a domain state of absolute minimum energy.

These observations led Halgedahl and Fuller (1983) to the conclusion that a particle could occupy domain states other than the ground state. Shortly thereafter, Moon and Merrill (1984, 1985) dubbed these states as LEM states, on the basis on their one-dimensional micromagnetic results for magnetite. Subsequent domain observation studies by Geiß *et al.* (1996) provided strong evidence for LEM states in magnetite as well.

#### LEM states and thermomagnetic treatments: hysteresis

A particularly unexpected type of LEM state in pyrrhotite and intermediate titanomagnetite is a SD-like state that certain particles can occupy after being saturated in a strong external field, even though these same particles readily accommodate walls in other states of magnetization. Bitter patterns on intermediate ( $x \approx 0.6$ ) titanomagnetite in oceanic basalt and on natural pyrrhotite in diabase were studied during hysteresis by Halgedahl and Fuller (1980, 1983). An electromagnet was built around the microscope stage for these experiments, permitting one to track the evolution of walls continuously, while varying the applied field. In states of saturation remanence, most particles in a large population contained one or more walls, as expected on the basis of previous theories. However, a significant percentage-nearly 40%—of the finer (5–15  $\mu$ m) particles observed appeared saturated after the maximum field was shut off (Figure M19a and b). Within a large population of such grains it was found that the number of domains was described well by a Poisson distribution. Halgedahl and Fuller (1980, 1983) proposed that grains, which failed to nucleate walls, could make a substantial contribution to saturation remanence. Furthermore, such grains might explain much of the known decrease in the ratio of saturation remanent magnetization to saturation magnetization with increasing particle size. This hypothesis was extended to the case of weak-field TRM.

Particles in SD-like states remained saturated, until nucleation was accomplished by applying a back-field of sufficient magnitude. In some cases, the nucleating field was strong enough to sweep a freshly nucleated wall across the particle and thereby result in a state of saturation (or near-saturation) in the opposite sense. In other cases, the new wall moved until it was stopped by a pinning site. In the smaller grains studied (e.g., smaller than 20  $\mu$ m) the nucleation field dropped off with increasing grain size *L* according to a power law in  $L^{-1/2}$ .

Boyd *et al.* (1984) reported Bitter patterns on natural magnetite grains carrying saturation remanence, and these patterns suggested SD-like states. These results were surprising, in view of magnetite's strong tendency to self-demagnetize.

Subsequent domain observations and hysteresis studies of hematite platelets from Elba, Italy demonstrated that, after exposure to strong fields, even large crystals could arrive in states suggesting near-saturation. Often, however, small, residual domains clung to the platelet's surface in these states. Back-fields were necessary to nucleate principal domains, and these nucleation fields also followed a power-law in  $L^{-1/2}$  (Halgedahl, 1995, 1998).

Results from titanomagnetite and pyrrhotite were interpreted by Halgedahl and Fuller (1980, 1983) in light of previous theoretical and experimental work on high-anisotropy, industrial materials synthesized to produce magnetically hard, permanent magnets. In such materials, nucleation of walls is an energetically difficult process (Brown, 1963; Becker, 1969, 1971a,b, 1976). According to Brown's original theory, the nucleation of a fresh wall requires the following condition to be fulfilled:

$$2K/M_{\rm s} < |\overrightarrow{H}_{\rm appl} = \overrightarrow{H}_{\rm d}|$$

Here,  $2K/M_s$  is the local anisotropy field at the nucleation site;  $H_d$  is the local demagnetizing field at the site, assumed to be opposite in sense to  $M_s$ ; and  $H_{appl}$  is the field applied to the sample. In samples

where back-fields are necessary to accomplish nucleation,  $H_{appl}$  is opposite to the sample's original saturation magnetization. Wall nucleation may occur either at crystal defects where  $2K/M_s$  is anomalously low or where the local demagnetizing field  $H_d$  is anomalously high, as at shape defects on a crystal's surface. Note that Brown's theory of nucleation differs from the kind of "global" nucleation resulting from micromagnetic models. Brown-type nucleation may depend on the presence of defects, which fulfill the above condition. By contrast, micromagnetic models assume that particles are defect-free.

However, SD-like states also can result from submicroscopic walls being trapped by surface and volume defects (Becker, 1969, 1971a,b, 1976). There are two cases. First, when a saturating field is shut off, a submicroscopic, virgin wall can nucleate but remain pinned at a local defect. In the second case, a strong applied field may be insufficient to completely saturate a particle. When this occurs, preexisting domain walls may be driven into surface or volume defects and become trapped. In both cases, the particle appears to be saturated at the top of a hysteresis loop. Experimentally, the saturation remanent state appears to be SD-like. A back-field, opposite in sense to the maximum field, is required to break free these residual walls and the submicroscopic domains which they enclose.

These two phenomena can be distinguished by observing both the position where a reverse nucleus first appears in a grain and the field required for its appearance. If complete saturation of a grain, followed by nucleation of a fresh wall, has occurred, then the nucleus will always appear at the same location and in the same back-field, regardless of the maximum field's polarity. Of course, the submicroscopic nucleus could have been trapped by a defect just after it was nucleated initially. If the grain was not saturated completely, then both the location where the nucleus appears and the field required to expand this nucleus and make it visible depend on the direction in which a wall was driven in the first place and on the back-field's magnitude—that is, on the specific trapping site (Becker, 1969, 1971a,b, 1976; Halgedahl and Fuller, 1983).

The style of domain structure and the range of LEM states that a particle can occupy can depend on thermomagnetic history. In a study of Bitter patterns on natural, polycrystalline pyrrhotite, Halgedahl and Fuller (1981) discovered that crystallites displayed arrays of undulating walls on their surfaces after acquiring TRM in a weak external field. By contrast, after AF demagnetization in a strong peak field the same crystallites exhibited planar walls. Evidently, cooling through the TRM blocking temperature locked in a high-temperature configuration of walls, whose curved shapes promoted lower magnetostatic energy than did a planar geometry.

As indicated by Moon and Merrill's theoretical results for magnetite, a particular LEM state can be stable across a broad range of grain size. This prediction is born out by experiments and calculations by Halgedahl and Ye (2000) and Ye and Halgedahl (2000), who investigated the effects of mechanical thinning on domain states in natural pyrrhotite particles. In their experiments, several individual pyrrhotite grains in a diabase were mechanically thinned and their Bitter patterns observed after each thinning step. Despite some grains being thinned to about one-fourth of their initial diameter, the widths of surviving domains and positions of surviving walls remained unaffected (Figure M23). Neither nucleations nor denucleations were observed, although calculations indicated that thinning would cause significant changes in GEM domain states.

Bitter patterns on crystallites of polycrystalline AMTM60 were studied after many replicate TRM acquisition and AF demagnetization experiments (Halgedahl, 1991). In each particle, the number of domains varied from one experiment to the next, describing a distribution of TRM states. For states of weak-field TRM, this distribution could be broad and could include SD-like states (Figure M24). After replicate AF demagnetizations, however, typical distributions were narrow and clustered about a most probable state, possibly the GEM state.

**Figure M23** Bitter patterns on a grain of natural pyrrhotite in a diabase before and after mechanical thinning. (a) Initial state, before thinning, (b) after thinning the particle to about one-half of its original length along a direction parallel to the trends of the Bitter lines, and (c) final state, after the particle has been thinned to about one-fourth of its original length.

# Thermal evolution of magnetic domain structures observed at elevated temperatures

The manner in which domain structure evolves with temperature carries clear implications for TRM. In very early models of TRM, such changes were either ignored or were assumed not to occur. Instead, some models assumed that the number of domains remained constant from the Curie point to room temperature in a weak external field, and that the blocking of TRM was controlled solely by the growth of energy barriers associated with defects which, eventually, locked walls in place.

Yet changes in the number of domains with temperature could profoundly affect how pseudosingle-domain and multidomain particles acquire TRM. Temperature-induced nucleations or denucleations of walls should trigger sudden changes of the internal demagnetizing field. As a result, preexisting walls, which survive a domain transition, could be dislodged from imperfections where they were pinned initially at higher temperatures.

In rock magnetism, domain observation experiments to study the thermal response of domain structure have focused on two magnetic minerals: (a) magnetite, owing to its great importance to the paleomagnetic

**Figure M24** Bitter patterns on a crystallite of titanomagnetite ("AMTM60": see text) after each of eight replicate TRM acquisition runs in the Earth's field.

signal carried by many rocks, and (b) intermediate titanomagnetite, owing to its significance to marine magnetic anomalies and to its moderately low-Curie temperature, which renders study of Bitter patterns feasible at moderate temperatures. High-temperature experiments have yielded highly variable results.

The first domain observations on magnetite above room temperature in the Earth's field were made by Heider *et al.* (1988), using particles of hydrothermally recrystallized magnetite embedded in an epoxy matrix. Depending on the particle, Bitter patterns could be followed to approximately  $200^{\circ}$ C, above which temperature the patterns grew too faint to distinguish against a grain's bright background. Surprisingly, heating to very moderate temperatures drove certain walls across much of a particle; in some cases, denucleation occurred. Upon cooling, walls reassembled in a similar, though not identical, arrangement to that observed initially at room temperature. In some cases repeated thermal cycling between room temperature and about  $200^{\circ}$ C produced different numbers of domains in the same particle.

Ambatiello *et al.* (1995) used the MOKE to study domain widths versus temperature in several large (>5 mm) crystals of natural magnetite cut and polished on {110} planes. At room temperature, these planes were dominated by broad (40–90  $\mu$ m), lamellar domains separated by 180° walls, terminating in closure domains at crystal edges. On {111} planes they found complex, nested arrays of very small closure domains, which finely subdivided the main closure structure.

Unlike the Bitter technique, the MOKE is applicable to the Curie point of magnetite (580°C), at least in theory. In practice, the amount

of Kerr rotation in magnetite is very small even at room temperature; this rotation decreases progressively as  $M_s$  drops with heating. As the Curie point is approached, the contrast between adjacent domains grows exceedingly faint. For this reason, Ambatiello and colleagues successfully imaged domains to 555°C, but no higher.

According to their observations, domain widths generally increased with heating, and such changes were thermally reversible. However, the temperature that triggered changes depended on the provenance of the sample. In some samples, domain widths remained nearly constant until significant broadening of domains occurred above 400°C. In other samples, domains began to broaden at far lower temperatures.

To explain the overall character of their results, Ambatiello *et al.* (1995) calculated the thermal dependence of domain widths on the basis of the closed, "Landau-Lifshitz"-type structure shown in Figure M16c. Their calculations included the magnetoelastic energy associated with closure domains, as well as the " $\mu$ \*" correction to magnetostatic energy, originating from small deviations of spins away from the easy axis near a crystal surface. There were several discrepancies between experimental and model results. One mechanism which they put forth to explain these discrepancies was that heating promoted an even finer subdivision into small domains at the crystal surface. This would cause a greater collapse of magnetostatic energy than predicted from their model and thus a more pronounced broadening of body domains than expected.

Bitter patterns observed at elevated temperatures on natural, intermediate titanomagnetites have been reported by Soffel (1977), Metcalf and Fuller (1987a,b, 1988), and Halgedahl (1987). Because the magnetic force gradients around a wall weaken rapidly with heating, walls attract increasingly less magnetic colloid as the Curie point is approached. Consequently, these authors could follow patterns from room temperature to about 10° to 20° below their samples' Curie points (Soffel, 1977:  $T_c = 105$ °C; Metcalf and Fuller, 1987a,b, 1988, Halgedahl, 1987:  $T_c$  approximately 150°C). During heating, patterns gradually faded to obscurity, with few significant changes in domain structure.

Remarkably, some titanomagnetite particles studied by Metcalf and Fuller (1987a,b, 1988) displayed no Bitter lines after cooling from the Curie point in the Earth's field. This observation provided supporting evidence for Halgedahl and Fuller's (1983) proposal that weak-field TRM acquired by populations of pseudosingle-domain grains could, in part, be attributable to particles which failed to nucleate walls during cooling.

The possible importance of LEM states to TRM acquisition was raised by work on synthetic, polycrystalline AMTM60 (Halgedahl, 1991). Observations focused on grains that displayed simple "Kittel-like" patterns suggesting lamellar domains (Figure M14). The sample was cycled repeatedly between room temperature and the Curie point of 75°C in the Earth's field, although patterns lost definition near 70°C. Bitter patterns were observed continuously throughout heatings and coolings.

As discussed above and shown in Figure M24, replicate TRM experiments often produced different numbers of domains in the same particle. Some of these domain states suggested that the particle was entirely saturated, with no visible Bitter lines, or nearly saturated, with only small spike domains at grain boundaries.

During heating, few changes in domain patterns were observed, except for the usual fading as the Curie temperature was approached. SD-like states were quite thermally stable, exhibiting no changes during thermal cycling until the sample was heated nearly to, or above, the Curie point. As a result of heating above a certain critical temperature, followed by cooling, a SD-like state could be transformed to a LEM state with several domain walls.

Continuous observation of Bitter patterns on AMTM60 during cooling revealed that denucleation was the mechanism by which a particle arrived in a final LEM state. Walls which initially nucleated just below  $T_c$  grew visible after the sample cooled slightly through just a few degrees. With further cooling, however, the number of domains often

decreased either through contraction of large, preexisting spike domains, or by straight walls moving together and coalescing into spikes. In both cases, the spikes often would collapse altogether. Nucleations were never observed during cooling, once Bitter patterns grew visible. In some cases, denucleation left behind large volumes which, apparently, contained no walls, although walls were present elsewhere in the grain. In other cases, denucleation left behind a grain that appeared nearly saturated, but for small edge domains. In both cases denucleation appeared to produce anomalously large moments in particles that contained several walls after other TRM runs (Halgedahl, 1991).

Results of the experiments described above on AMTM60 lend further support to the hypothesis that particles in metastable SD states can make significant contributions to stable TRM acquired in weak fields. Furthermore, particles which do contain domain walls can carry anomalously large TRM moments, if denucleation leaves behind large volumes in which walls are absent.

These experimental results are at odds with theoretical results by Dunlop et al. (1994) for LEM-LEM transitions in magnetite at high temperatures. At present this disagreement has not been explained fully. However, it is important to note that the model of Dunlop et al. (1994) assumes that (1) such transitions are driven by thermal fluctuations, and that (2) occupation frequencies of LEM states follow Boltzmann statistics for thermal equilibrium, before domains are blocked in. It is reasonable to expect that thermally activated jumps among LEM states occur very rapidly and discontinuously during times on the order of 1 s or less; rapid transitions such as these are impossible to track under a microscope. By contrast, many of the denucleations observed by Halgedahl (1991) occurred via continuous wall motions easily tracked over laboratory time scales of several seconds. It is questionable, therefore, whether the changes exhibited by AMTM60 were driven by the thermal fluctuation mechanism modeled by Dunlop et al. (1994). Perhaps the denucleations observed are not stochastic processes. Additional analyses and experiments are needed to determine the controlling mechanisms.

# Observed temperature dependence of magnetic domain structure: low temperatures

Magnetite undergoes two types of transitions at low temperatures, which can profoundly affect domain structure and remanence (e.g., see detailed discussions in Stacey and Banerjee, 1974; Dunlop and Özdemir, 1997). First, at the isotropic point (approximately 130 K) the first magnetocrystalline anisotropy constant,  $K_1$ , passes through zero as it changes sign from negative at temperatures above the transition to positive below it. Second, at the Verwey transition,  $T_v$  (approximately 120 K), magnetite undergoes a crystallographic transition from cubic to monoclinic.

At the isotropic point domain walls should broaden dramatically, because wall width is proportional to  $K^{-1/2}$ , K being the crystalline anisotropy constant. It follows that, by cooling through the isotropic point, walls may break free of narrow defects, which pinned them at higher temperatures. At the Verwey transition the easy axis of magnetization changes direction. In multidomain and pseudosingle-domain magnetite, this thermal passage should cause domain structure and domain magnetizations to reorganize completely, so that much of an initial remanence acquired at room temperature would be demagnetized by cooling below  $T_{v}$ . Low-temperature demagnetization has proved useful in removing certain spurious components of NRM, which are surprisingly resistant to thermal demagnetization above room temperature. Thus, it is important to determine how these transitions affect domain structure.

Using an MFM specially adapted to operate at low temperature, Moloni *et al.* (1996) were the first to image domains in magnetite at temperatures near the two transitions. Their sample was a synthetic magnetite crystal cut and polished on a  $\{110\}$  surface. At room temperature, the crystal displayed 180°, 71°, and 109° walls on {110}, as expected for multidomain magnetite. At 77 K—that is, below the Verwey transition—they observed both straight, 180° walls separating broad, lamellar domains, and wavy walls accompanied by reverse spikes. Both types of domain structure were consistent with a uniaxial anisotropy arising from monoclinic crystal structure and for which  $2\pi M_s^2/K < 1$ . They interpreted the broad, "body" domains as being magnetized along <100> easy axes within {110} planes. The wavy walls were interpreted to indicate domains with magnetizations directed along an easy axis that lay out-of-plane. This mixture of domain styles was thought to reflect lateral variations in the easy axis, due to *c*-axis twinning below  $T_v$ . As the crystal was warmed to a few degrees below  $T_v$  the domain structure disappeared entirely below the instrument's noise level, evidently undergoing a complete reorganization.

# Ultrahigh-resolution imaging of micromagnetic structures

Very recently, off-axis electron holography in the TEM has been used to image magnetic microstructures in submicron magnetite intergrown with ulvospinel (Harrison *et al.*, 2002). This method enables one to image the magnetization vectors within very small, single particles, at a resolution approaching nanometers. Harrison *et al.* (2002) discovered that clusters of magnetically interacting blocks of magnetite could assume both vortex and multidomain-like states. This promising method should prove highly fruitful in future experimental tests of micromagnetic models.

# MAGNETIC FIELD OF MARS

### Introduction

Strong magnetic anomalies have been detected over the south hemisphere of Mars. The Mars missions prior to Mars Global Surveyor (MGS) detected no appreciable magnetic field around the planet, which led to the conclusion that the Martian core field is weaker than Earth's by more than an order of magnitude. However, orbiting at elevations as low as 100–200 km during the science phase and aerobreaking phase, MGS detected a very strong crustal magnetic field, as strong as 200 nT, over the ancient southern highlands (Acuna *et al.*, 1999), indicating that the Martian crust is more magnetic than Earth's by more than an order of magnitude.

There is evidence from the Martian meteorites that a magnetic field as strong as  $\sim$ 3000 nT has existed on the surface of Mars. The oldest Martian meteorite (ALH84001) formed before 4 Ga (e.g., Collinson, 1997; Kirschvink *et al.*, 1997; Weiss, *et al.*, 2002; Antretter *et al.*, 2003) and the young Martian meteorites that have crystallization ages ranging from 0.16 to 1.3 Ga (Nyquist *et al.*, 2001) are magnetized in a weak field of less than 3000 nT (e.g., Cisowski, 1986; Collinson, 1997; McSween and Treiman, 1998). Whether the meteorites were magnetized by a weak core field or by the local crustal field is still debated. There is good evidence that the strong anomalies of the crust have existed for the last ~4 Ga (Arkani-Hamed, 2004a).

The magnetometer on board of MGS has provided immense amount of magnetic data since it resumed its mapping phase when its highly elliptical orbit was reduced to an almost circular polar orbit at a mean elevation of ~400 km. Besides the magnetometer, MGS carried an electron reflectometer, which has also indirectly provided data on the magnetic field of Mars (e.g., Mitchell *et al.*, 2001). This article is concerned with the magnetometer data. The first section presents a spherical harmonic model of the magnetic field of Mars that is derived from the mappingphase magnetic data. The second section is concerned with the firstorder interpretation of the anomalies. The final section summarizes the major points of the article.

## The spherical harmonic model of the magnetic field

The first magnetic anomaly map of Mars was derived by Acuna *et al.* (1999) from the low-altitude MGS data acquired at 100–200 km elevations during the science phase and aerobreaking phase. It was presented without altitude corrections. Subsequently, Purucker *et al.* (2000) reduced the radial component anomalies to a constant elevation of 200 km, and Arkani-Hamed (2001a) derived a 50° spherical harmonic model of the magnetic potential at 120 km altitude using all three vector components of the magnetic field. The later magnetic field models of Mars by Arkani-Hamed (2002), Cain *et al.* (2003), and Langlais *et al.* (2004) were obtained using all three components of the magnetic field acquired at the low- and high-altitude phases.

A highly repeatable and reliable magnetic anomaly map of Mars is essential for the investigation of the relationship between the tectonic features and the magnetization of the Martian crust. MGS has provided a huge amount of high-altitude magnetic data acquired within 360-420 km altitudes. Although the high altitude of the spacecraft limits the resolution of the data (e.g., Connerney et al., 2001; Arkani-Hamed, 2002), the huge amount of the data provides an opportunity to derive a highly repeatable and accurate magnetic anomaly map at that altitude. For this purpose Arkani-Hamed (2004b) used the nighttime radial component of the high-altitude data, which is least contaminated by noncrustal sources, and selected the most common features on the basis of covariance analysis. The vast amount of the data allowed him to divide the entire data into two almost equal sets, acquired during two different periods separated by more than a year, and to derive two separate spherical harmonics models of the magnetic field. The spherical harmonic model of the radial component of the magnetic field R is expressed as

$$R(r,q,j) = \sum_{n=1}^{N} (n+1)(a/r)^{n+2}$$
$$\sum_{m=0}^{n} (C_{nm}\cos m\varphi + S_{nm}\sin m\varphi)P_m^n(\cos \theta)$$

where *a* is the mean radius of Mars (3393 km); *r*,  $\theta$ , and  $\varphi$  are distance from the center, colatitude, and east longitude (the coordinate system is centered at the center of mass of Mars);  $P_m^n(\cos \theta)$  is the Schmidtnormalized associated Legendre function of degree *n* and order *m*;  $C_{nm}$  and  $S_{nm}$  are the Gauss coefficients; and *N* denotes the highest degree harmonics retained in the model. The covariance analysis of the two models showed that the covarying coefficients of the models are almost identical over harmonics of degree up to 50, with correlation coefficients greater than 0.95. These harmonics are highly repeatable and hence reliable. Figure M25/Plate 13a shows the radial component of the magnetic field of Mars at 100 km altitude, derived by averaging the covarying harmonic coefficients of the two models up to degree 50 and downward continuing from 400 to 100 km altitude. The color bar is saturated to better illustrate the weak anomalies.

## Interpretation of the magnetic anomalies

Figure M25/Plate 13a shows strong magnetic anomalies arising from the remanent magnetization of the crust. This section provides first-order interpretation of the anomalies.

The magnetic anomalies in the northern lowlands are very weak compared to those in the south. Many buried impact craters in the lowlands suggest similar ages for the crust in the north and south (Frey *et al.*, 2001). There is no striking evidence that the composition of the Martian crust had a distinct north-south dichotomy before the formation of the lowlands that would have prevented the formation of strong magnetic bodies in the north. The weak anomalies in the lowlands are most likely the relicts of stronger ones that existed before the formation of the lowlands. Zuber *et al.* (2000) disputed the impact origin of the lowlands and suggested crustal thinning due to a giant mantle plume. According to this hypothesis, the magnetic source bodies must have been partially demagnetized by the thermal effects of the plume, and to a lesser extent by near-surface low-temperature hydration (e.g., Arkani-Hamed, 2004a).

Figure M25/Plate 13a shows that the giant impact basins Hellas (41°S, 70°E), Argyre (50°S, 316°E), and Isidis (13°N, 88°E) are almost devoid of magnetic anomalies. These basins were formed by large impacts  $\sim$ 4 Ga, which resulted in strong shock pressures and high temperatures, capable of demagnetizing the crust beneath the basins (Hood et al., 2003; Mohit and Arkani-Hamed, 2004; Kletetschka et al., 2004). The crust beneath these basins is completely demagnetized to a distance of ~0.8 basin radius, where the shock pressure exceeded  $\sim$ 3 GPa, and partially demagnetized to  $\sim$ 1.4 radius where the pressure exceeded 2 GPa. This observation together with the fact that many intermediate-size impacts that created craters of 200-500 km diameter have little demagnetization effect led Mohit and Arkani-Hamed (2004) to suggest that the magnetic carriers of Martian crust have high coercivity. The resulting demagnetization depends on the coercivity of the magnetic minerals, magnetite, hematite, and pyrrhotite, suggested for the Martian crust (e.g., Kletetschka et al., 2000, 2004; Hargraves et al., 2001). Cisowski and Fuller (1978) found that remanence with a coercivity of 70 mT was  $\sim 20\%$ demagnetized after a shock of 1 GPa and 70% after a shock of 4 GPa. Under a shock of 1 GPa, the remanence of the multidomain hematite and magnetite are reduced by 20% and 68%, respectively (Kletetschka et al., 2002, 2004). Shock experiments on high coercivity (300 mT) single-domain pyrrhotite samples showed that a shock of 1 GPa removed 50% of the magnetization at room temperature, and they were completely demagnetized by shocks exceeding 2.75 GPa, undergoing a transition to a paramagnetic phase (Rochette et al., 2003). The high-pressure magnetic measurements in a diamond anvil cell showed that magnetite behaved as single domain with high coercivity at high pressures (Gilder et al., 2002). The survival of the magnetic anomalies beneath intermediate-size craters can be partly due to the increase of the coercivity of already high-coercive magnetic carriers of the Martian crust during the passage of the shock wave.

The magnetic anomalies over Tharsis bulge are much weaker than those in the south. The bulge formed through major volcanic activities in Noachian and Early Hesperian, although minor volcanism likely continued to the recent past (e.g., Hartmann and Neukum, 2001).

Figure M25/Plate 13a The radial component magnetic map of Mars at 100 km altitude derived from the high-altitude MGS data using the spherical harmonic of degree up to 50. The color bar is saturated to better illustrate the weak anomalies. Units are in nanotesla.

There are many lines of evidence that the volcanic layers of Tharsis are not significantly magnetized, they are formed either in the absence of a core dynamo or in the waning period of the dynamo (Arkani-Hamed, 2004b). Many places of Tharsis have been punctured by tectonic processes, which could have created detectable magnetic anomalies if the Tharsis plains were appreciably magnetized. Here two major features, Valles Marineris and shield volcanoes, are discussed in some detail.

Figure M25/Plate 13a shows no distinct magnetic edge effects associated with Valles Marineris, a canyon of over 5 km mean depth, 100-400 km width, and  $\sim$ 3500 km length. The models proposed for the formation of this giant canyon (e.g., Schultz, 1997; Tanaka, 1997; Wilkins and Schultz, 2003) indicate a vast amount of mass wasting. Many of the proposed models imply that upper strata of the canyon floor are porous. The porous floor and possible long-existing water make the rocks more susceptible to demagnetization by low-temperature hydration. The magnetization of mid-ocean ridge basalt on Earth declines from  $\sim 20$  to  $\sim 5$  A m<sup>-1</sup> in the first  $\sim 30$  Ma, likely a result of low-temperature hydration by circulating pore water (e.g., Bliel and Petersen, 1983). Also a positive Bouguer anomaly of ~150 mGal is associated with the central part of the canyon, implying crustal thinning and mantle uplift of ~15 km. If the Tharsis crust were strongly magnetized before the formation of the canyon, it is to be expected that the crust in the canyon would be partly demagnetized, giving rise to detectable magnetic edge effects. The absence of the expected edge effects indicates that the preexisting Tharsis plains were not significantly magnetized. Figure M25/Plate 13a shows that the formation of the canyon has ruptured the magnetic anomalies in the eastern part of the canyon between 290°E and 320°E. The anomalies must have existed before the formation of Valles Marineris that occurred during Late Noachian to Early Hesperian (e.g., Anderson et al., 2001). Figure M25/Plate 13a also shows no magnetic signature associated with the shield volcanoes Olympus, Arsia, Pavonis, and Ascreaus, suggesting that the underlying preexisting Tharsis plains had not been appreciably magnetized. Otherwise, the thermal effects of the shield volcanoes could have demagnetized part of them and created low-magnetic patches in the magnetized plains, giving rise to detectable magnetic anomalies.

There was no active core dynamo during the formation of the shield volcanoes, from Early Hesperian to Late Amazonian. Hood and Hartdegen (1997) estimated the magnetic anomaly that would have been produced by the entire volcanic structure if were magnetized by a core field an order of magnitude weaker than the Earth's core field. The lack of such a magnetic anomaly indicates that no core dynamo existed during the formation of shield volcanoes to magnetize the volcanic flows.

Many lines of evidence suggest that the core dynamo decayed during Early Noachian. The lack of magnetic anomalies associated with giant impact basins, the absence of magnetic edge effect of Valles Marineris, and the fact that the huge amount of volcanic flows of Syria Planum, occurred from Noachian to Early Amazonian (e.g., Anderson *et al.*, 2001) and those of Olympus and Tharsis mounts, occurred from Early Hesperian to Late Amazonian, show no magnetic signatures strongly argue against an active core dynamo since Early Noachian (Arkani-Hamed, 2004b).

Attempts have been made to estimate the paleomagnetic pole position of Mars. Arkani-Hamed (2001b) modeled 10 widely distributed relatively isolated small magnetic anomalies. Assuming that the source bodies were magnetized by a dipole core field, he found that most of the pole positions were clustered within a 30° circle centered at 25° N, 230°E. Moreover, both north and south magnetic poles were found in the cluster, suggesting reversal of the core field polarity. Using the two weak magnetic anomalies near the geographic north pole, Hood and Zacharian (2001) found paleomagnetic poles in general agreement with Arkani-Hamed (2001b). Arkani-Hamed and Boutin (2004) used magnetic profiles from the low- and high-altitude data to model nine anomalies. The magnetic pole positions determined from their models showed clustering of the poles at the same general region, but not as tightly as those of Arkani-Hamed (2001b).

The magnetic field of Mars provides information about the rotational dynamics of the planet. None of the paleomagnetic poles are close to the present rotation pole. If the axis of dipole core field were close to the axis of rotation at the time the magnetic sources acquired magnetization, which is the case for the terrestrial planets at present, the paleomagnetic pole positions suggest appreciable,  $20^\circ - 60^\circ$ , polar wander since the magnetic bodies were magnetized. Polar wander of 20° to 120° were proposed on the basis of geological features (Murray and Malin, 1973; Schultz and Lutz-Garihan, 1982; Schultz and Lutz-Garihan, 1988). Approximating the topographic mass of Tharsis bulge by a surface mass, Melosh (1980) predicted polar wander of up to 25° from the effects of the bulge on the moment of inertia of the planet. Willeman (1984) suggested that compensation of Tharsis bulge would limit the amount of polar wander to less than 10°. The theoretical studies of polar wander by Spada et al. (1996) showed that Mars could have undergone polar wander by as much as 70°, in response to surface loads such as Olympus and Tharsis mounts.

### Summary

Figure M25/Plate 13a presents the most recent and highly accurate spherical harmonic model of the radial component of the magnetic field of Mars derived from the high-altitude mapping-phase magnetic data from MGS, using harmonics of degree up to 50. It shows that the northern lowland formation and the large impacts that created the giant basins Hellas, Isidis, and Argyre have significantly demagnetized the crust and there was no active core dynamo to remagnetize the crust. The absence of magnetic edge effects associated with Valles Marineris, and the lack of magnetic signatures of the large shield volcanoes Olympus and Tharsis mounts imply that core dynamo did not exist from Late Noachian to Late Amazonian, and likely to the present. The fact that intermediate-size craters, with diameters 200-500 km, show no sign of demagnetization of the underlying crust indicates that the magnetic carriers of the Martian crust have high coercivity. The clustering of the paleomagnetic poles far from the present rotation axis implies polar wander of Mars by about 20°-50° since the magnetic source bodies were magnetized. Finally, the presence of both north and south paleomagnetic poles in the cluster suggests that the core field of Mars had polarity reversals.

# MAGNETIC FIELD OF SUN

The Sun has been observed to exhibit a breathtaking variety of magnetic phenomena on a vast range of spatial and temporal scales. These vary in spatial scale from the solar radius down to the limit of present resolution of the most powerful satellite instrumentation, and with durations varying from minutes to hundreds of years, encompassing the famous 11-year sunspot cycle. This dynamic and active field, which is visible in extreme ultraviolet wavelengths as shown in Figure M26/Plate 14a, is responsible for all solar magnetic phenomena, such as sunspots, solar flares, coronal mass ejections and the solar wind, and also heats the solar corona to extremely high temperatures. These have important terrestrial consequences, causing severe magnetic storms and major disruption to satellites, as well as having a possible impact on

**Figure M26/Plate 14a** Compound extreme ultraviolet (171 Å) full-disk image of the Sun taken by the Transition Region and Coronal Explorer (TRACE) satellite. The two bands on either side of the Sun's equator contain bright features indicating magnetic activity.

the terrestrial climate. The magnetic field also plays a major role in the evolution of the Sun as a star, with magnetic braking drastically reducing the angular momentum of the star as it evolves over its lifetime (Mestel, 1999).

This article will review the observations of the solar magnetic field and briefly indicate the features that need to be understood in order to formulate a theory for the generation and evolution of such a field.

## The large-scale solar field

Although magnetic fields in the Sun are observed on a whole spectrum of length-scales, it is usual to classify magnetic phenomena either as large- or small-scale events. Here the large-scale magnetic field is defined to be that which is observed on scales comparable to the solar radius, with systematic properties, spatial organization, and temporal coherence.

The most obvious manifestation of the large-scale solar magnetic field is the appearance of sunspots at the solar surface. Sunspots have been systematically observed in the West since the early 17th century when Galileo utilized the newly invented telescope to document the passage of dark spots across the solar surface. Although the 11-year period for the cycle of sunspot activity was discovered by Schwabe in 1843, the connection between sunspots and the magnetic field of the Sun was only determined when Hale in 1908 used the Zeeman splitting of spectral lines to establish the presence of a strong magnetic field in sunspots (Hale, 1908). By then it could clearly be seen that sunspots appear in bipolar pairs, with a leading and trailing spot nearly aligned with the solar equator. Magnetic observations of sunspots indicate that they have systematic properties-often described as Hale's polarity laws. These state that the magnetic polarities of the leading and trailing spots are opposite, with the sense of the polarity being opposite in each hemisphere of the Sun (see Figure M27). Moreover, the polarities of the bipolar sunspot pairs that are observed at the solar surface reverse after each minimum in sunspot activity. Finally, Joy's law states that there is a systematic tilt (of the order of  $4^\circ$ ) in the alignment of sunspot pairs with respect to the solar equator, with the leading spot being closer to the equator. Taken together, these indicate that

**Figure M27** Hale's polarity law: Magnetogram of the solar surface as a function of longitude and latitude. White indicates strong radial field pointing out of the solar surface, while black indicates strong radial field pointing into the solar surface. Notice that the sense of the active regions is opposite in the northern and southern hemispheres.

sunspots are the surface manifestation of an underlying magnetic field with an opposite sense in each hemisphere. This magnetic field is cyclic, with a mean period of 22 years.

Sunspot pairs are interpreted as an indicator for an azimuthal (toroidal)  $B_{\phi}$  field. A radial (poloidal) component of the magnetic field,  $B_{\rm r}$ , may also be detected. The radial field is particularly visible at the solar poles with a distinct and opposite polarity at each pole. This polar field reverses at the *maximum* of sunspot activity and the polarity is such that between solar maximum and solar minimum the radial field has the same polarity as the trailing spots of the sunspot pairs in the same hemisphere. Hence  $B_{\phi}$  and  $B_{\rm r}$  fields are nearly in antiphase with  $B_{\phi}B_{\rm r} < 0$  for most of the time (Stix, 1976). Also particularly visible at high latitudes are ephemeral active regions. These are small regions that do not systematically obey Hale's polarity laws (although they do show a preference for the same orientation as sunspots) and have a lifetime of a few days. It is now believed that these ephemeral active regions are either reprocessed flux from active regions or the result of local regeneration in the solar convection zone.

An important measure of the topology of the large-scale solar magnetic field is given by the current helicity of the magnetic field  $\mathcal{H}_j = \langle \mathbf{j} \cdot \mathbf{B} \rangle$ , where  $\mathbf{j} = 1/\mu_0 \nabla \times \mathbf{B}$  is the electric current. This is a difficult quantity to measure, although some information about the radial contribution to the current helicity  $\langle j_r B_r \rangle$  can be estimated from vector magnetograms of active regions. The measurements are consistent with the premise that magnetic structures possess a preferred orientation corresponding to a left-hand screw in the northern hemisphere (with an opposite sense in the southern hemisphere). Another crucial topological measure of the magnetic field is the magnetic helicity  $\mathcal{H} = \langle \mathbf{A} \cdot \mathbf{B} \rangle$  (where  $\mathbf{B} = \nabla \times \mathbf{A}$ ). Although some estimates have been made of the magnetic helicity from vector magnetograms, it is almost impossible to measure this important property of the solar magnetic field with any great certainty.

## Spatiotemporal variability

In addition to the systematic properties of the solar magnetic field indicated by Hale's and Joy's laws, these large-scale features follow a systematic spatiotemporal pattern. At the beginning, of a cycle spots appear on the Sun at latitudes of around  $\pm 27^{\circ}$ ; as the cycle progresses the location of activity drifts toward the equator and the spots then die out (at a latitude of around  $\pm 8^{\circ}$ ) in the next minimum. It is important to note that it is the location of magnetic activity rather than individual sunspot pairs—which have a lifetime of at most a few months—that migrates toward the solar equator. This migration of activity produces the familiar butterfly diagram first exhibited by Maunder (1913). An up-to-date version showing the incidence of sunspots as a function of colatitude is in Figure M28a. It is clear from this figure that the level of sunspot activity has been approximately the same in each hemisphere, and that the solar magnetic field has a high degree of symmetry. The above observations indicate that the solar field is primarily axisymmetric and dipolar, although a small nonaxisymmetric component of the solar field has been observed.

In addition to the basic solar cycle, sunspot activity undergoes further significant temporal variability. By using the (arbitrarily defined) sunspot number (e.g., Eddy, 1976), the variation in magnetic activity over the past 400 years may be obtained. An up-to-date record of sunspot numbers is shown in Figure 28b. This figure shows that an average cycle is temporally asymmetric, with a sharp rise from minimum to maximum of duration 3-6 years being followed by a gradual decay lasting between 5 and 8 years. The amplitude of the cycle has been shown to be anticorrelated with the length of the rise time and that of the solar cycle itself. The solar cycle appears to be chaotic with an amplitude that is modulated aperiodically. Despite the shortness of the time sequence, the existence of a characteristic timescale for the modulation of approximately 90 years (the Gleissberg cycle) has been postulated-although this is open to debate. What is clear, however, is the presence in the record of an episode with a dearth of sunspots, which lasted for about 70 years at the end of the 17th century. This interruption is known as the Maunder minimum. There is no doubt that this is a real phenomenon, and this is not due to the lack of awareness on the part of the observers (see Ribes and Nesme-Ribes, 1993). It is also interesting to note that at the end of the Maunder minimum large-scale solar magnetic activity started again primarily in the southern hemisphere of the Sun and hence the field was not dipolar for a cycle. Although small asymmetries between sunspot activity in the northern and southern hemispheres have been observed since the Maunder minimum, when the field is strong the field is largely dipolar, with only a small quadrupole component as noted above. It is only when the field is weak and the dipole component is small that a comparable quadrupolar contribution can be seen.

More useful information about the temporal variability of the solar magnetic activity can be gained by the use of proxy data (see e.g., Beer, 2000). Magnetic fields in the solar wind modulate the cosmic ray flux entering the Earth's atmosphere. These high-energy particles lead to the production of radioisotopes, including <sup>10</sup>Be and <sup>14</sup>C,

and so the abundance of these isotopes can act as a measure of solar magnetic activity-the abundance is anticorrelated with magnetic activity. The isotope <sup>10</sup>Be is preserved in polar ice-cores and its production rate, together with the sunspot number, is shown in Figure M29. The figure clearly shows the presence of the Maunder minimum and that, although sunspot activity is largely shut off during this period, cyclic magnetic activity continued with a period of approximately 9 years. The <sup>10</sup>Be record extends back over 50 ka and analysis of this record clearly shows both continued presence of the 11-year solar cycle. Moreover analysis indicates that the Maunder minimum is not an isolated event, with regularly spaced minima (termed grand minima) interrupting the record of activity with a significant recurrent timescale of 205 years (Wagner et al., 2001). The variations in <sup>14</sup>C production confirm this pattern of recurrent grand minima with a timescale of about 200 years. Moreover, both of these radioisotope records show significant power at a frequency that corresponds to roughly 2100 years. It appears as though grand minima occur in bursts, with this as a well-defined period of recurrence (J. Beer, private communication).

Taken together, these data indicate that the solar magnetic field undergoes a considerable amount of temporal variability on scales varying from days to hundreds of years.

### The small-scale solar magnetic field

In addition to the large-scale magnetic field with systematic properties described above, magnetic field is also observed on scales comparable with the solar convective scales and smaller. The magnetic network is seen to coincide largely with the network forming the boundaries of supergranular convection. The network has a different form at solar maximum and minimum. At solar minimum it consists of mixed polarity, vertically oriented bundles of magnetic flux, while at solar maximum the network is dominated by the presence of large unipolar regions in close proximity to the bipolar active regions. The magnetic network is therefore only weakly linked to the solar magnetic cycle. The flux bundles in the magnetic network are dynamic and are observed to move randomly across the solar surface, with a motion that is consistent with two-dimensional diffusion.

The magnetic network is also interspersed with weak stochastic magnetic fields of random orientations. This intranetwork field is

**Figure M28** (a) Solar butterfly diagram: Location of sunspots as a function of time (horizontal axis) and latitude (vertical axis). As the cycle progresses sunspots migrate from midlatitudes to the equator. (Courtesy of D.N. Hathaway). (b) Time series for yearly sunspot group numbers. Notice the Maunder minimum at the end of the 17th century.

**Figure M29** Comparison of the proxy <sup>10</sup>Be data from the dye 3 ice core (measured in 10000 atoms  $g^{-1}$ ), filtered using a low pass (6 year) filter, with the filtered (6 year) sunspot group number as determined by Hoyt and Schatten (1998). Note that the <sup>10</sup>Be is anticorrelated with sunspot activity.

weaker than the network field and has a significantly shorter dynamical timescale associated with it (on the scale of days as opposed to months). There appears to be little or no correlation of this field with the solar cycle and the behavior of this field is consistent with it being generated by the action of a local dynamo (see *Dynamo, solar*) situated in the upper reaches of the solar convection zone. All these small-scale magnetic features visible at the solar surface migrate slowly toward the solar pole with a velocity of between 1 and 10 m s<sup>-1</sup>. This migration is due to the presence of a systematic large-scale meridional flow at the solar surface. The meridional flow has also been detected by helioseismic inversions of the solar interior and is believed to continue poleward to a depth of  $0.9R_{\odot}$ , where  $R_{\odot}$  is the solar radius.

# Solar cycle indices—irradiance, flows and the shape of the corona

The solar magnetic cycle can not only be detected in the large-scale magnetic features such as sunspots. Many other solar indices follow the 11-year activity cycle. Of particular interest terrestrially is the variation in the solar luminosity (the so-called solar constant) that occurs over the solar cycle. Total solar irradiance does vary systematically in phase with the solar cycle. In the visible spectrum the modulation varies only weakly, with the effect of bright magnetic faculae nearly exactly canceling out (but just overcoming) that of dark sunspots. However in the far-ultraviolet and X-ray part of the spectrum the modulation is large and systematic (see e.g., Frölich, 2000). The shape of the solar cycle, and these in turn interact with the geomagnetic field and are measurable in the AA and AP geomagnetic indices and visible in the record of aurorae.

In addition, the presence of the magnetic field is also responsible for driving flows that are correlated with the solar activity cycle. This pattern of parallel belts of faster slower rotation was initially discovered by Doppler measurements of the solar surface and dubbed torsional oscillations. It is now known from helioseismic inversions for the internal solar rotation (Vorontsov *et al.*, 2002) that these oscillations have an amplitude of approximately  $5-10 \text{ m s}^{-1}$  and that they extend deep into the solar interior—reaching at least halfway into the solar convective zone (see Figure M30/Plate 14b). These bands of zonal flows, which have an equatorward and poleward propagating branch, have a period of 11 years, which is consistent with them being driven by the Lorentz force associated with the magnetic field.

**Figure M30/Plate 14b** *Top panel*: The rotational variation as a function of time and latitude at radius  $r = 0.98R_{\odot}$  are shown for the first nearly 6 years, and thereafter the time series is continued by exhibiting the 11-year harmonic fit. Shown to the right are the residuals from the fit, on the same color scale. *Bottom panel*: As for above, but showing the rotation variation as a function of depth instead of latitude, at latitude 20°. ## Stellar magnetic fields

The Sun is just one example of a moderately rotating star whose magnetic properties can be observed in detail. Much can be learned about the magnetic behavior of the Sun, by examining the properties of nearby magnetically active stars that have similar properties (e.g., age and rotation rate). The most important results indicating magnetic activity in stars are obtained by measuring the level of Ca<sup>+</sup>, H, and K emission. The rate of Ca<sup>+</sup> emission in the Sun is well-known to be correlated with solar magnetic fields. Results from the Mount Wilson Survey indicate the level of magnetic activity in a relatively large sample of slow and moderate rotators. It is now clear that, for stars of a fixed spectral type, there is a range of activity, but that this scatter is a function of age. It can be shown that the level of activity in a star can be represented as a function of the inverse Rossby (or Coriolis) number  $\sigma = \Omega \tau_c$ , where  $\Omega$  is the angular velocity of the star and  $\tau_c$  is a suitable convective timescale (Brandenburg *et al.*, 1998).

For slow rotators, cyclic magnetic activity may be deduced from variations in the Ca<sup>+</sup> emission and it is clear that the cycle period of activity decreases with increasing rotation rate. Moreover as the rotation rate is increased the magnetic activity of the stars becomes more disordered, with a transition between cyclic, doubly periodic and chaotic activity occurring as the rotation rate is increased. On studying this relationship in greater detail it becomes apparent that the stars fall into two distinct groups, an active and an inactive branch (Brandenburg *et al.*, 1998). This is enough to discourage the extension of the properties of slowly rotating stars to cover those with a greater angular momentum.

Direct measurement of magnetic fields in stars is also possible using a variety of techniques, including broadband polarimetry and photometry (see e.g., Rosner, 2000). The luminosity of a highly active star may vary by up to 30%, whereas the known variation in solar luminosity is only 0.2%. Whether an increase in magnetic activity in a star is positively or negatively correlated with an increase in luminosity depends upon the absolute level of activity in the star. It is also found

200

-10 Dve3

that the level of magnetic activity is proportional to the inverse Rossby number of the star—a result that is consistent with the emission data. Clearly, as there is a small sample of stars for which we have a detailed record of magnetic activity and this record is comparatively short, there is a need to continue these observations as they give us great understanding of the magnetic properties of our nearest star—the Sun.

# MAGNETIC INDICES

Magnetic indices are simple measures of magnetic activity that occurs, typically, over periods of time of less than a few hours and which is recorded by magnetometers at ground-based observatories (Mayaud, 1980; Rangarajan, 1989; McPherron, 1995). The variations that indices measure have their origin in the Earth's ionosphere and magnetosphere. Some indices having been designed specifically to quantify idealized physical processes, while others function as more generic measures of magnetic activity. Indices are routinely used across the many subdisciplines in geomagnetism, including direct studies of the physics of the upper atmosphere and space, for induction studies of the Earth's crust and mantle, and for removal of disturbed-time magnetic data in studies of the Earth's deep interior and core. Here we summarize the most commonly used magnetic indices, using data from a worldwide distribution of observatories, those shown in Figure M31 and whose sponsoring agencies are given in Table M1.

## Range indices K and K<sub>p</sub>

The 3-h K integer index was introduced by Bartels (1938) as a measure of the range of irregular and rapid, storm-time magnetic activity. It is designed to be insensitive to the longer term components of magnetic variation, including those associated with the overall evolution of a magnetic storm, the normal quiet-time diurnal variation, and the very much longer term geomagnetic secular variation arising from core convection. The K index is calculated separately for each observatory, and, therefore, with an ensemble of K indices from different observatory sites, the geography of rapid, ground level magnetic activity can be quantified.

When it was first implemented, the calculation of K relied on the direct measurement of an analog trace on a photographic record. Today, in order to preserve continuity with historical records, computer programs using digital data mimic the original procedure. First, the diurnal and secular variations are removed by fitting a smooth curve to 1-min horizontal component (H) observatory data. The range of the remaining data occurring over a 3-h period is measured. This is then converted to a quasilogarithmic K integer,  $0, 1, 2, \ldots, 9$ , according to a scale that is specific to each observatory and which is designed to normalize the occurrence frequency of individual K values among the many observatories and over many years.

A qualitative understanding of the *K* index and its calculation can be obtained from Figure M32. There we show a trace, Figure M32a, of the horizontal intensity at the Fredericksburg observatory recording magnetically quiet conditions during days 299–301 of 2003, followed by the sudden commencement in day 302 and the subsequent development of the main and recovery phases of the so-called great Halloween Storm. In Figure M32b we show, on a logarithmic scale, the range of the Fredericksburg data over discrete 3-h intervals, and in Figure M32c we show the *K* index values themselves. Note the close correspondence between the magnetogram, the log of the range and the *K* index. This storm is one of the 10 largest in the past 70 years since continuous measurements of storm size have been routinely undertaken. For more information on this particular storm, see the special issue of the *Journal of Geophysical Research*, A9, **110**, 2005.

Planetary-scale magnetic activity is measured by the  $K_p$  index (Menvielle and Berthelier, 1991). This is derived from the average of fractional K indices at 13 subauroral observatories (Table M1) in such a way as to compensate for diurnal and seasonal differences between the individual observatory K values. The final  $K_p$  index has values 0, 0.3, 0.7, 1.0, 1.3, ... etc. For illustration, in Figure M33 we show magnetograms from the 13 observatories contributing to  $K_{\rm p}$ , recording the Halloween Storm of 2003, along with the  $K_p$  index itself. The distribution of observatories is far from uniform, with a predominant representation from North America and Europe, and very little representation from the southern hemisphere. In fact, in Figure M33, it is easy to see differences during the storm in the magnetograms among the different regional groupings of observatories. Although geographic bias is an obvious concern for any index intended as a measure of planetary-scale magnetic activity,  $K_p$  has proven to be very useful for scientific study (e.g., Thomsen, 2004). And, since it has been continuously calculated since 1932, Kp lends itself to studies of magnetic disturbances occurring over many solar cycles.

There are several other indices related to the *K* and  $K_p$ .  $A_k$  and  $A_p$  are linear versions of *K* and  $K_p$ .  $K_n$ ,  $A_n$ ,  $K_s$ , and  $A_s$  are similar to  $K_p$  and  $A_p$  except that they use, respectively, northern and southern hemisphere observatories; their global averages are  $K_m$  and  $A_m$ . The *aa* index is like the  $K_p$  except that it utilizes only two, roughly antipodal, observatories, one in the northern hemisphere and one in the southern hemisphere. *aa* has been continuously calculated since 1868, making it one of the longest historical time series in geophysics.

## Auroral electrojet indices AU, AL, AE, AO

During magnetic storms, particularly during substorms, magnetospheric electric currents are often diverted along field lines, with

current closure through the ionosphere. To measure the auroral zone component of this circuit, Davis and Sugiura (1966) defined the auroral electrojet index AE. Ideally, the index would be derived from data collected from an equally spaced set of observatories forming a neck-lace situated underneath the northern and southern auroral ovals.

Unfortunately, the southern hemispheric distribution of observatories is far too sparse for reasonable utility in calculating AE, and the northern hemispheric observatories only form a partial necklace, due to the present shortage of reliable observatory operations in northern Russia. Progress is continuing, of course, to remedy this shortcoming, but for

now the partial necklace of northern hemisphere observatories is used to calculate an approximate AE.

The calculation of AE is relatively straightforward. One-min resolution data from auroral observatories are used, and the average horizontal intensity during the five magnetically quietest days is subtracted. The total range of the data from among the various AE observatories for each minute is measured, with AU being the highest value and AL being the lowest value. The difference is defined as AE = AU - AL, and for completeness the average is also defined as AO = 1/2(AU - AL). For illustration, in Figure M34, we show magnetograms from the eight auroral observatories contributing to AE, during the Halloween Storm of 2003, along with the AE and its attendant relatives.

## Equatorial storm indices $D_{st}$ and $A_{sym}$

One of the most systematic effects seen in ground-based magnetometer data is a general depression of the horizontal magnetic field as recorded at near-equatorial observatories (Moos, 1910). This is often interpreted as an enhancement of a westward magnetospheric equatorial ring current, whose magnetic field at the Earth's surface partially cancels the predominantly northerly component of the main field. The storm-time disturbance index  $D_{\rm st}$  (Sugiura, 1964) is designed to measure this phenomenon.  $D_{\rm st}$  is one of the most widely used indices in academic research on the magnetosphere, in part because it is well motivated by a specific physical theory.

The calculation of  $D_{\rm st}$  is generally similar to that of AE, but it is more refined, since the magnetic signal of interest is quite a bit smaller.

**Figure M33** Example of (a) magnetometer data, horizontal intensity (*H*), from the observatories used in the calculation of the  $K_p$  index, together with (b) the corresponding  $K_p$  index. The observatories have been grouped into North American, European, and southern hemisphere regions in order to highlight similarities of the data within each region and differences in the data across the globe.

One-min resolution horizontal intensity data from low-latitude observatories are used, and diurnal and secular variation baselines are subtracted. A geometric adjustment is made to the resulting data from each observatory so that they are all normalized to the magnetic equator. The average, then, is the  $D_{\rm st}$  index. It is worth noting that, unlike the other indices summarized here,  $D_{\rm st}$  is not a range index. Its relative  $A_{\rm sym}$  is a range index, however, determined by the difference between the largest and smallest disturbance field among the four contributing observatories.

In Figure M35 we show magnetograms from the four observatories contributing to  $D_{st}$  and  $A_{sym}$ , for the Halloween storm of 2003, along with the indices themselves. The commencement of the storm is easily identified, and although the magnetic field is very disturbed during the first hour or so of the storm, the disturbance shows pronounced longitudinal difference, and hence a dramatically enhanced  $A_{svm}$ . With the subsequent worldwide depression of H through to the beginning of day 303 the storm is at its main phase of development. During this time  $D_{\rm st}$  becomes increasingly negative. It is of interest to note that it is during this main phase that AE is also rapidly variable, signally the occurrence of substorms with the closure of magnetospheric electric currents through the ionosphere. AE diminishes during the recovery period of the storm as D<sub>st</sub> also pulls back for its most negative values and  $A_{sym}$  is diminished. Toward the end of day 303 the second act of this complicated storm begins, with a repeat of the observed relationships of the various indices.

### Availability

Magnetic indices are routinely calculated by a number of different agencies. Intermagnet agencies routinely calculate K indices for their observatories (www.intermagnet.org). The GeoForschungsZentrum in Potsdam calculates  $K_p$  (www.gfz-potsdam.de). The Kyoto World Data Center calculates AE and  $D_{st}$  (swdcwww.kugi.kyoto-u.ac.jp). Other agencies supporting the archiving and distribution of the indices include the World Data Centers in Copenhagen (web.dmi.dk/fsweb/ projects/wdcc1) and Boulder (www.ngdc.noaa.gov), as well as the International Service of Geomagnetic Indices in Paris (www.cetp. ipsl.fr).

# MAGNETIC MINERALOGY, CHANGES DUE TO HEATING

Mineralogical alterations occur very often in rocks subjected to thermal treatment. Laboratory heating may cause, in many cases, not only magnetic phase transformations, but also changes in the effective magnetic grain sizes, the internal stress, and the oxidation state. The presence or absence of such alterations is crucial to the validity and success of numerous magnetic studies.

The basic assumption in paleointensity determinations in the measurement of anisotropy of thermoremanent magnetization is that the rock is not modified during the different successively applied heating treatments. For simple thermal demagnetization, the occurrence of mineralogical alteration can introduce errors in the determination of the magnetic carrier if the latter had undergone transformation a at lower temperature than its unblocking temperature. Acquisition of parasitic chemical remanent magnetization is also possible if the heating was not made in a perfectly zero magnetic field. Formation of magnetic grains with very short relaxation times can lead to a large variation in the magnetic viscosity, making the stable components of the remanent magnetization sometimes immeasurable during thermal demagnetization. The interpretation of the results obtained by the Lowrie's method (1990) of identification of magnetic minerals by their coercivity and unblocking temperatures can be biased by mineralogical alteration, because rock can undergo mineralogical alteration instead of thermal demagnetization.

Analysis of the Curie curve (the measurement of the susceptibility in the low- or high magnetic field as a function of the temperature) is a key method for the identification of magnetic minerals, because each mineral has its Curie temperature (corresponding to a change from a ferrimagnetic to a paramagnetic state). On a Curie curve with increasing temperature, the Curie temperature is shown as a strong decrease in the susceptibility, sometimes preceded by an increase in susceptibility (a Hopkinson peak). However, mineralogical alteration can also increase or decrease susceptibility so it is not possible to discriminate the Curie temperature or the Hopkinson peak from mineralogical alteration from the shape of a simple curve directly until the highest temperature is reached, except if the heating and cooling curves are identical.

# Example of mineralogical transformations due to heating

The increase of susceptibility during heating is mainly due to the formation of iron oxides. A decrease in susceptibility is often related to transformation of these oxides, such as in the oxidation of magnetite to hematite. Magnetite growth between 500 and 725°C (susceptibility increase) and the hematization of the magnetite at a higher temperature (susceptibility decrease) have been pointed out in a study of biotite granites (Trindade et al., 2001). Furthermore, magnetic oxides can be formed from iron sulfides (pyrite, pyrrhotite, greigite, troilite), carbonates (siderite, ankerite), silicates, other iron oxides or hydroxides (e.g., Schwartz and Vaughan, 1972; Dekkers, 1990a,b). During heating, hexagonal pyrrhotite (antiferromagnetic) can be transformed first, to monoclinic pyrrhotite (ferrimagnetic) by partial oxidation to magnetite (Bina et al., 1991). Pyrrhotite oxidizes mostly to magnetite at higher temperatures. Siderite oxidizes to magnetite or magnemite when exposed to air, even at room temperature but the oxidation is faster during heating (Ellwood et al., 1986; Hirt and Gehring, 1991). Maghemite converts to hematite in the temperature range from 250 to 750°C, depending on the grain size, degree of oxidation, and the presence of defects in the crystallographic lattice (Verwey, 1935; Özdemir, 1990). In the range 250-370°C, goethite is transformed generally to very fine grains of hematite (Gehring and Heller, 1989; Dekkers, 1990b). Lepidocrocite starts to transform into superparamagnetic (SP) maghemite at  $\sim 175^{\circ}$ C, with further conversion of this maghemite into hematite at around 300°C (Gehring and Hofmeister, 1994). In an oxidative atmosphere, ferrihydrite transforms into hematite (Weidler and Stanjek, 1998). But, ferrihydrite heated in the presence of an organic reductant forms magnetite and/or maghemite, or magnetitemaghemite intermediates (Campbell et al., 1997). Exsolved magnetite has been found in plagioclases, pyroxene, and micas. With increasing temperature phyllosilicates undergo different reactions (Murad and Wagner, 1998). Thus, new phases developed at high temperatures depend on the composition of the original clay minerals, the firing temperature, and the atmosphere around the samples (Osipov, 1978).

During thermal treatment, ferrimagnetic minerals can also be affected by changes in the magnetic grain size (alteration, grain growth, or grain breaking due to fast heating and cooling). Therefore, grain size dependence of magnetic susceptibility is weak for pseudosingle-domain (PSD) and multidomain (MD) magnetite grains (Hartstra, 1982), but becomes important if the grain size variation is a transformation into SP—Single-Domain (SD) or a SD—PSD transformation. The susceptibility of the SD grains is lower than for the other grain sizes (Stacey and Banerjee, 1974). Homogenization of the distribution of crystal defects can also have significant effects, leading to an increase in the susceptibility of large grains and in the redistribution of the domain wall. Inversion by filling up by new cations of the vacancy sites within the crystal lattice (Bina and Henry, 1990) can give significant susceptibility variations. This last mechanism and grain breaking could be at the origin of susceptibility variation since the heating takes place at relatively low temperatures.

# Methods of analysis

A change of color of the sample is an indication of mineralogical alteration, but not all mineralogical transformations of magnetic minerals do lead to such color changes. Moreover, such change can be limited to a very fine surface layer and concern only to paramagnetic or diamagnetic minerals. Different investigations are therefore necessary to determine the magnetic mineralogy characteristics.

To investigate the mineralogical alteration of magnetic minerals due to heating, as a first possibility the simple observation of a thin section or conduct a microprobe analysis. In practice, such an approach is often difficult since alteration can have affected a limited part of the magnetic minerals, which can be moreover of a very small size. It is therefore easy to miss the modified minerals. However, when it works, this method yields precise indications about the affected minerals.

Transformation of a nonferrimagnetic mineral to another nonferrimagnetic mineral does not introduce a significant variation in susceptibility. Since the mineralogical change of the ferrimagnetic phase mostly corresponds on the contrary to the susceptibility change, measurement of susceptibility is generally a simple, fast, and efficient method to point out the alteration of the ferrimagnetic part. The least time consuming and common approach uses the monitoring of the variations of bulk magnetic susceptibility measured at room temperature and then after subsequent thermal steps, for example during thermal demagnetization.

The different parts of Curie curve measured during heating and cooling respectively, are similar if no alterations have occurred. The nonreversibility of the curve, on the contrary, indicates mineralogical changes. Hrouda *et al.* (2003) proposed to make several Curie curves for the same sample, with increasing maximum temperature, until obtaining a nonreversible curve. A faster approach is to apply cooling as soon as a significant susceptibility change occurs during heating. If the cooling curve is similar to the heating curve, the sample can be then heated again until the next significant susceptibility variation, etc. (Figure M36). Comparison of the heating and cooling curves can yield key information about the affected and altered minerals. If a Curie point occurs only on the heating curve, the corresponding mineral not disappeared. On the other hand, if this Curie point appears on the heating curve at a higher temperature than a transformation, it is

**Figure M36** Thermomagnetic curve (low field normalized susceptibility  $K/K_0$  as a function of the temperature T in °C) of a dolerite sample during heating (thick line) and cooling (thin line). Partial loop "a" corresponds to an absence of mineralogical alteration (reversible curve) contrary to the final part "b" of the loop (irreversible curve).

often difficult or even impossible to determine if this Curie temperature was associated with the preexisting or the newly formed mineral. A Curie temperature occuring only on the cooling curve is related to a newly formed mineral.

Van Velzen and Zijderveld (1992) proposed a complementary method for monitoring mineralogical alteration by using not only the susceptibility but several remanent magnetization characteristics. This timeconsuming method allows a much more precise study of the effect of heating. However, if several different alterations had occurred during the same thermal treatment, they cannot be distinguished using these approaches.

Hysteresis loop analysis is another classical method in rock magnetism, giving, in particular, data on grain size and coercivities of the magnetic minerals. The sample is first subjected to a strong magnetic field to obtain the saturation of the magnetization. The total magnetization is then measured during progressive decrease of the field followed by the application of an increasing field in the opposite direction until obtaining the saturation of the magnetization in this opposite direction ("descending" curve d, Figure M37). The "ascending" curve a is then obtained by measurement of the total magnetization during a decrease of the field in the opposite direction followed by an increase in the field in the direction of the initial field. To further investigate the mineralogical alteration, hysteresis loops at room temperature are measured before and after heating (Figure M37a). Difference hysteresis loops  $(J_{b-a})$  are obtained by subtraction for a same field (H) value of the measured magnetization value before  $(J_b)$  and after  $(J_a)$  heating in curves d and a, respectively (Figure M37b). They are sometimes relatively complicated curves, but using the separation method proposed by Von Dobeneck (1996) in two curves (half-difference and half-sum), the interpretation becomes much easier (Figure M37c). In particular, it is possible to discriminate characteristics (coercivity, magnetic field for saturation) of disappearing and occurring magnetic components, even during the same thermal treatment (Henry et al., 2005).

## Applications

If heating at a temperature T applied in laboratory introduces a mineralogical change, previous heating at the same temperature T should have given the same transformation. The studied rocks in their present state were therefore not subjected to this temperature before being sampled. The minimum temperature to develop mineralogical change, therefore, corresponds to the maximum temperature possibly undergone by the rock in the past (Hrouda *et al.*, 2003). This is therefore the maximum paleotemperature since the rock has the present mineralogical composition, i.e. sometimes relatively recently in case of weathering and low-temperature oxidation.

Modification of the magnetic fabric as a result of heating has been applied to different types of rocks (see Magnetic susceptibility, anisotropy, effects of heating). The outcome was sometimes a simple enhancement of the fabric, but significant changes of the fabric have also been obtained. It is moreover possible to determine the anisotropy of magnetic susceptibility of the ferrimagnetic minerals formed or that have disappeared during successive heatings. To this aim, the tensor resulting from the subtraction of the tensors measured before and after heating is used (Henry et al., 2003). When a same magnetic fabric is obtained from several following thermal steps, it cannot be related to the randomly oriented ferrimagnetic minerals. Instead, the newly formed fabric must be related to characteristics of the preexisting rock. By comparing this ferrimagnetic mineral fabric with the initial whole rock fabric, it is possible to distinguish cases where heating simply enhances of preexisting fabric from those where thermal treatment induces a different fabric. Relative to the preheated fabric, this different fabric may simply be an inverse fabric or one whose principal susceptibility axes are oriented in a different direction, relative to petrostructural elements other than those defining the initial magnetic fabric.

Important applications concerning all the methods, assumes that no transformation occurred during heating. It is fundamentally important to

**Figure M37** Example of hysteresis loops (ascending—a and descending—d curves) measured at room temperature on dolerite sample after heating at 400 and at 550°C (a) and corresponding difference loop (b). From curves (c) obtained from half-sum and half-difference of the curves b, transformation of a magnetic component with low coercivity and saturation field to another magnetic phase with higher coercivity and saturation field can be inferred (Henry *et al.*, 2004): Part of the curves pointing out disappearance (in grey) of component with low coercivity (1) and moderate saturation field (2), and occurrence (in black) of component with higher coercivity (3) and high saturation field (4). verify this assumption when paleointensity or anisotropy of thermoremanent magnetization studies are carried out. It is important to point out that mineralogical alteration can also have important implications for all the studies using heating, such as Lowrie's (1990) method of identification of magnetic minerals (using corercivity and unblocking temperatures) or even simple thermal demagnetization.

## MAGNETIC PROPERTIES, LOW-TEMPERATURE

#### Introduction

Use of magnetic measurements at cryogenic temperatures for characterizing magnetic mineralogy of rocks was initiated in the early 1960s, when it was realized that several minerals capable to carry natural remanent magnetization (NRM), e.g., magnetite and hematite, show distinctive magnetic phase transitions below room temperature. In the last decade, low-temperature magnetometry of rocks and minerals has seen a new boost due to increasing availability of commercial systems capable to carry out magnetic measurements down to and below 4.2 K. Low-temperature magnetometry has the potential to complement conventional high-temperature methods of magnetic mineralogy while offering an advantage of avoiding chemical alteration due to heating. This is especially important in the case of sedimentary rocks, which alter much more readily upon heating. However, additional complications may arise because of a possible presence in a rock of mineral phases showing ferrimagnetic or antiferromagnetic ordering below room temperature. On the other hand, these minerals are often of a diagnostic value by themselves, being the signature of various rock-forming processes. In all, low-temperature magnetometry is a valuable new tool in rock and environmental magnetism.

Several factors control low-temperature behavior of remanent magnetization and low-field susceptibility of minerals and rocks. Phase transitions, which may occur below room temperature, have the most profound effect. Also of importance is the temperature variation of the intrinsic material properties such as magnetocrystalline anisotropy and magnetostriction. Low-temperature magnetic properties of minerals are also affected by their stoichiometry and degree of crystallinity. Last but not least, low-temperature variation of remanence and magnetic susceptibility is generally grain-size dependent. In particular, ultrafine (say, <20 nm) grains show the distinct behavior called superparamagnetism, which manifests itself in a nearly exponential decrease of remanence with increasing temperature due to a progressive unblocking of magnetization by thermal activation. On the other hand, all the above factors have relatively little effect on saturation magnetization, which is primarily determined by chemical composition of the material.

Measurements that can be used to characterize low-temperature magnetic properties of minerals and rocks include the following. Thermal demagnetization of a saturation isothermal remanent magnetization (SIRM) given at a low temperature, typically 10 K, is a relatively rapid experiment and the most frequently used. Low-temperature magnetic phase transitions generally manifest themselves in SIRM vs temperature curves and are most useful as diagnostic features. However, in some cases signature of a magnetic-phase transition can be confused with that of a ferrimagnetic to paramagnetic transition if the transition temperatures are in the same range. An example is the 34-K phase transition in mineral pyrrhotite, which is fairly close to Néel temperatures of
minerals siderite and rhodochrosite (38 and 32 K, respectively). It is thus advised to use SIRM demagnetization only for a reconnaissance study of mineral phases present. A useful method to distinguish between the two above cases is to measure a SIRM acquired at room temperature during a zero-field cycle to a low temperature. Magnetic phase transitions will be recorded in this experiment, while Néel temperatures will not.

For some materials low-temperature magnetic properties measured on warming may depend on the mode of preceding cooling, i.e., on whether a sample has been cooled in a zero (zero-field cooling, ZFC) or in a strong magnetic field (field cooling, FC). In particular, this is the case for magnetically hard minerals, in which thermoremanent magnetization (TRM) acquired during cooling in a strong field to a given low temperature is much higher than a SIRM, which can be induced by a single application of the same field at the same temperature. Demagnetization curves of the two remanences will then be strongly discrepant but converge near room temperature. Another variant of ZFC vs FC measurements, which must not be confused with the former one, consists in measuring magnetization during warming in a relatively weak, usually 2-20 mT, DC field, after sample being cooled once in a zero and second time in the DC field equal to the measurement field. This method can be used to characterize the superparamagnetic behavior. The two magnetization vs temperature curves would diverge if the blocking of superparamagnetic moments occurs below room temperature.

Measurements of magnetic hysteresis loops as a function of temperature potentially would yield the most detailed information on the magnetic mineralogy of the sample. However, this is a rather timeconsuming experiment, and relatively little has been reported so far on low-temperature hysteresis properties of minerals and rocks.

Variation of AC susceptibility at low temperatures is also a useful characteristics of the magnetic mineralogy. An important advantage of susceptibility measurements is that they allow to detect minerals that show antiferromagnetic ordering below Néel temperatures. On the other hand, low-temperature susceptibility signal due to ferrimagnetic and antiferromagnetic phases is progressively masked by a contribution from paramagnetic minerals which increases proportionally to 1/T.

The remainder of this article presents an overview of lowtemperature magnetic properties of most common iron minerals found in terrestrial rocks.

#### Magnetite and maghemite

Magnetite (Fe<sub>3</sub>O<sub>4</sub>), iron ferrite, is the longest known and most ubiquitous natural magnetic material and probably also the most extensively studied. It occurs, in a varying concentration, in most volcanic, sedimentary, and metamorphic rocks, and forms economically significant iron ore deposits. Furthermore, magnetite can be formed biogenically by a wide variety of organisms, from prokaryotes to humans (cf. Kirschvink *et al.*, 1985).

Low-temperature anomalies in the magnetic susceptibility and magnetization of magnetite were discovered in 1910-1920s (Weiss and Renger, 1914; Weiss and Forrer, 1929). However, only much later it was proposed (Verwey, 1939; Verwey and Haayman, 1941) that these anomalies, together with those in electrical properties, heat capacity, etc., are due to the phase transition, which is now called the Verwey transition. The transition is accompanied by a slight monoclinic distortion of the cubic spinel crystalline lattice of magnetite stable at ambient temperature, which results in a large, by over an order of magnitude, increase of the magnetocrystalline anisotropy. The transition temperature  $(T_V)$  is 125 K in stoichiometric crystals with low internal stress (Walz, 2002). Substitution of iron with vacancies (Aragón et al., 1985; Aragón, 1992; Özdemir et al., 1993) and foreign metal cations (Miyahara, 1972; Kozłowski et al., 1996a,b; Brabers et al., 1998) are known to lower the  $T_{\rm V}$  and eventually suppress the transition. Stresses have the same effect (Samara, 1968; Rozenberg et al., 1996). The low-temperature behavior of the magnetic properties, and particularly of a remanent magnetization during cooling from room

temperature in zero magnetic field, is also strongly affected by the isotropic point at about 130 K, the temperature where the first constant of magnetocrystalline anisotropy  $K_1$  momentarily turns zero (Bickford, 1950; Syono, 1965). The isotropic point temperature appears much less sensitive to nonstoichiometry than the  $T_V$  (Kąkol and Honig, 1989; Kąkol *et al.*, 1994). A review of low-temperature magnetic properties of magnetite from the point of view of rock magnetism has been recently given by Muxworthy and McClelland (2000a).

The Verwey transition is easily recognizable in the demagnetization curves of a SIRM acquired at a low temperature (e.g., 10 K), as a sharp drop of magnetization (Figure M38). The temperature where the magnetization decrease rate is maximal is usually taken as a transition temperature. This has a justification in studies on large nearly perfect synthetic magnetite crystals (Aragón, 1992), where the magnetization drop occurs within 1 K. However, in fine grains magnetization decreases more gradually, particularly when magnetite is slightly oxidized (Figure M39, Özdemir et al., 1993), and such an assignment of the transition temperature may be somewhat arbitrary. Perhaps for this reason the exact values of  $T_{\rm V}$  in rocks are seldom reported, and the observation of the transition is taken as only a qualitative test for the presence of magnetite. Meanwhile, actual values of transition temperatures can be of interest because of their sensitivity to minute variations of oxygen stoichiometry and metal substitution, thus providing information inaccessible with other methods. Recent examples that illustrate use of the low-temperature magnetometry of magnetite to solve magnetomineralogical problems include: (i) a method to detect the presence of biogenic magnetite produced by magnetotactic bacteria, showing a distinctive difference between the demagnetization curves of SIRMs given below the Verwey transition after ZFC and FC, respectively (Moskowitz et al., 1993); (ii) a model explaining the magnetic susceptibility signal in Chinese loess by the effect of natural grass fires (Kletetschka and Banerjee, 1995); and (iii) tracing of chemical alteration of goethite (a-FeOOH) during heating (Özdemir and Dunlop, 2000).

Magnetite and magnetite-bearing rocks can be further characterized by a variation of a remanence acquired at room temperature during a zero-field cycle crossing the Verwey temperature. On initial cooling,

**Figure M38** Change in the remanent moment obtained by cooling in a magnetic field of 1 T to 4.5 K during warming in a zero field, for samples of  $Fe_{3-\delta}O_4$  with  $\delta = 0.000$  (squares), 0.003 (triangles), and 0.006 (circles). magnetization is lost between ca. 200 K and the  $T_{\rm V}$ ; demagnetization is grain-size dependent, being by far the most effective in large multidomain grains, where it is essentially complete at the isotropic point (Dunlop, 2003). Below the transition temperature, magnetization is nearly constant until on warming the temperature reaches the vicinity of  $T_{\rm V}$ . The behavior on crossing the  $T_{\rm V}$  from below depends primarily on stress: in low-stress samples remanence tends to be further lost (Muxworthy and McClelland, 2000b), while highly stressed ones show a rebound (Heider et al., 1992; King and Williams, 2000). In the paleomagnetic practice, cycling the rock sample through the isotropic point and Verwey temperature is known as the low-temperature cleaning (LTC, Ozima et al., 1964). LTC should at least partly remove the unwanted secondary components of NRM carried by large multidomain grains of magnetite. However, perhaps because physical mechanisms of remanence demagnetization during LTC remained elusive for so long (Muxworthy and McClelland, 2000b; Dunlop, 2003), it has been seldom used in paleomagnetic studies.

Magnetic properties of the low-temperature monoclinic phase of magnetite, although of no direct importance in paleomagnetism, proved to be an interesting subject of study itself, receiving much recent interest (Schmidbauer and Keller, 1996; Muxworthy, 1999; Özdemir, 2000; Kosterov, 2001, 2002; Özdemir *et al.*, 2002; Smirnov and Tarduno, 2002; Kosterov, 2003). In particular, it appears that below the Verwey transition temperature dependences of the magnetic hysteresis parameters are qualitatively different in truly multidomain and in smaller, pseudosingle-domain grains, respectively: in multidomain

grains both  $M_{\rm rs}$  and the coercive force are much higher after a ZFC while a more complex relationship between ZFC and FC hysteresis parameters is observed in pseudosingle-domain grains (Kosterov, 2001, 2002). Magnetic properties of the low-temperature phase also strongly depend on magnetite stoichiometry (Özdemir *et al.*, 1993; Kosterov, 2002, 2003), which is a result of the variation of the magnetocrystalline anisotropy with the degree of oxidation (Kąkol and Honig, 1989). Memorizing the value of a small to moderate magnetic field (<100 mT) applied during cooling through the Verwey transition has been demonstrated (Smirnov and Tarduno, 2002).

Maghemite ( $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>) is a fully oxidized analog of magnetite, in which 1/9 of iron cations in the spinel lattice are replaced with vacancies. It is a common constituent of soils (Taylor and Schwertmann, 1974) and also has been found in deep-sea sediments (Harrison and Peterson, 1965). Unlike magnetite, maghemite does not show phase transitions below room temperature, and remanence given at a given low temperature decreases monotonously on warming (Morrish and Watt, 1958; Moskowitz *et al.*, 1993). SIRM given at room temperature changes reversibly on ZFC to a low temperature (de Boer and Dekkers, 1996).

#### Titanomagnetites

Titanomagnetites are spinel iron-titanium oxides of the composition  $Fe_{3-x}Ti_xO_4$ . Stable single-phase oxides exist for *x* between 0 (magnetite) and 0.96 (Kąkol *et al.*, 1991a). The end member with nominal composition  $Fe_2TiO_4$  is known as mineral ulvöspinel. A titanomagnetite with  $x \sim 0.6$  (TM60) is the dominant magnetic mineral in fresh submarine basalts; in subaerial basalts, unoxidized titanomagnetites typically have compositions TM60-TM70 (Dunlop and Özdemir, 1997, Section14.4). Ti-rich titanomagnetites have only a local significance in sediments, where the eroded material from volcanic rocks is readily available. Titanomagnetites of intermediate compositions are found relatively less frequently in nature than those close to magnetite and TM60, respectively.

Titanomagnetites with compositions richer in Ti than TM04 do not exhibit the Verwey transition (Kozłowski *et al.*, 1996a). However, the variation of the magnetocrystalline anisotropy remains similar to that in magnetite for the wide range of compositions. At room temperature,  $K_1$  is negative; with the decrease of temperature its absolute value first increases and then starts to decrease approaching the isotropic point. With the increase of *x* the isotropic point temperature first shifts toward lower temperatures, being below 77 K for the material in the TM18-TM36 range (Syono, 1965; Kąkol *et al.*, 1991b), and then starts to increase again, so that the material with the nominal composition TM41 has the isotropic point of about 125 K, very close to that of magnetite (Kąkol *et al.*, 1991b). For even more Ti-rich compositions,  $K_1$  is positive at all temperatures below 300 K (Syono, 1965; Kąkol *et al.*, 1991b) and increases sharply to very high values below 200 K.

Low-temperature dependences of SIRM and low-field susceptibility for millimeter-size single crystals of titanomagnetite in the composition range from TM0 to TM60 have been reported by Moskowitz et al. (1998, Figure M40). Titanomagnetites from TM05 to TM28 show a sharp decrease of SIRM between 40 and 80 K. Low-field susceptibility of these titanomagnetites increases rapidly in this temperature range. For TM05 it reaches a maximum at about 90 K and then slightly decreases; for TM19 and TM28 the susceptibility increase just becomes considerably slower above ~110 K. Since the material under study is multidomain, this behavior is likely controlled by the temperature variation of magnetocrystalline anisotropy. Compositions around TM40 show a somewhat more complex behavior: SIRM first drops rapidly in about the same range as for more Ti-poor compositions, and then shows further, less pronounced decrease between 120 and 150 K. The latter should be due to the isotropic point at about 125 K (Kakol et al., 1991b). In even more Ti-rich titanomagnetites TM55-TM60 SIRM decreases rapidly between 50 and 70 K, and more

**Figure M40** Normalized saturation isothermal remanence (SIRM) curves of synthetic titanomagnetites during zero-field warming from 5 to 300 K: (a) TM0-TM41 and (b) TM55-TM61. SIRM was given in a 2.5 T field at 5 K. Single-crystal samples are denoted by solid symbols and polycrystalline samples are denoted by open symbols. (c) Normalized in-phase susceptibility curves of synthetic titanomagnetites during warming from 15 to 300 K. gradually above this temperature, bearing some resemblance to the behavior of ultrafine superparamagnetic grains.

Magnetic hysteresis of intermediate titanomagnetites as a function of low temperature has been studied only on millimeter-sized singlecrystal samples, for a rather limited number of compositions from TM40 to TM80, and in the magnetic fields not exceeding 1.5 T, which is likely to be too low to fully saturate the samples, especially more Ti-rich ones (Tucker, 1981; Schmidbauer and Readman, 1982). The most distinctive feature of these compounds is a large increase of the coercive force with decreasing temperature, which is due to the sharp rise of the magnetocrystalline anisotropy. For compositions from TM50 to TM80 the rise of the  $H_c$  starts at about 150 K and for TM40 at 70 K (Schmidbauer and Readman, 1982). In addition, both  $M_{\rm rs}$  and the coercive force appear to depend on the mode of preceding cooling, the latter being much higher and the former considerably lower after ZFC.

It must be borne in mind that the above experiments were done on large crystals, necessarily multidomain. To the best of author's knowledge, no low-temperature magnetic studies have been carried out on synthetic intermediate titanomagnetites of micron to submicron grain size. The low-temperature data on rocks, which contain such grains, are also scarce. Moskowitz et al. (1998) have reported contrasting low-temperature SIRM(T) curves for basaltic samples from the center and a chilled margin of an Icelandic dike, respectively. Samples from the center of the dike yielded curves closely resembling those for synthetic Ti-rich (x > 0.4) titanomagnetites, while samples from the dike margin showed curves with a break-in-slope around 50 K. It may be suggested that rapid cooling of the dike margin had produced a titanomagnetite phase with  $x \sim 0.2$ , and the discrepancy between SIRM(T) curves of these samples and those of synthetic titanomagnetite of similar composition is due to a difference in grain size. Similar SIRM(T) curves have been observed in late Pleistocene to Holocene sediments from Zacapu basin in central Mexico, where the abundant titanomagnetite of composition ranging from TM20 to TM55 comes from nearby volcanic activity (Ortega et al., 2002). Further complications are likely to arise if titanomagnetites are oxidized to form titanomaghemites, as is the case for most submarine basalts older than several millions of years. In such rocks, Matzka et al. (2003) have observed even a self-reversal of SIRM given at room temperature during a low-temperature cycle in zero field. Magnetization crossed to negative values around 70 K during the cooling leg but returned reversibly to initial values upon the subsequent warming. In summary, much has yet to be done to fully understand the low-temperature behavior of naturally occurring intermediate titanomagnetites.

#### Titanohematites

The composition of minerals belonging to the titanohematite series can be described by the chemical formula  $Fe_{2-\nu}Ti_{\nu}O_3$ , the end members being minerals hematite ( $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>) and ilmenite (FeTiO<sub>3</sub>), respectively. These minerals crystallize in the rhombohedral system; the space group describing crystal symmetry is  $R\overline{3}C$  for v < 0.5 and  $R\overline{3}$  for v > 0.5. Compositions close to both hematite and ilmenite are quite common in igneous rocks, while truly single-phase titanohematites of an intermediate composition (0.2 < y < 0.8) can be obtained only in the laboratory by quenching from high temperatures. Natural intermediate titanohematites of nominal composition  $0.5 \le y \le 0.7$ , found in rapidly chilled dacitic pyroclastic rocks, received much interest in rock magnetism due to the ability to acquire a self-reversed TRM (Uyeda, 1958; Hoffman, 1992). Magnetic properties of titanohematites are determined by their composition: (i) for  $0 \le y < 0.5$  an overall ordering is antiferromagnetic with a weak parasitic ferromagnetism due to a spin canting (Dzyaloshinsky, 1958; Moriya, 1960); (ii) compositions with 0.5 < y < 0.7 are ferrimagnetic; (iii) titanohematites with  $0.7 < y \le$ 0.93 show rather complex magnetic structures, which will be discussed in more detail below; (iv) compositions with y greater than about 0.93 show antiferromagnetism. Curie temperatures of titanohematites decrease approximately linearly with increasing ilmenite content up to  $y \sim 0.93$ , reaching the values below room temperature at  $y \sim 0.75$ (Nagata, 1961).

Hematite is the most stable iron oxide in oxidizing conditions and, as such, is found in many sedimentary and in some highly oxidized volcanic rocks. Its small net saturation moment of about  $0.4 \text{ Am}^2 \text{ kg}^{-1}$  (Morrish, 1994) results primarily from a spin canting. Another mechanism that can produce a magnetic moment is a presence of defects or impurity atoms in the hematite crystalline lattice (Bucur, 1978). Since hematite is much less strongly magnetic than magnetite or maghemite, the two latter minerals dominate the NRM in the case when concentrations of these minerals are comparable. However, in an important class of sedimentary rocks called red beds, NRM is almost entirely carried by hematite.

Below room temperature, bulk hematite exhibits the so-called Morin transition (Morin, 1950). At the Morin transition spin directions change from the basal plane to the rhombohedral *c*-axis, and the spin canting, and the magnetic moment associated with it, seems to vanish. The defect moment, however, remains largely intact. This explains, at least qualitatively, the peculiar behavior of room temperature remanence being cycled in a zero field through the Morin transition (Haigh, 1957; Gallon, 1968; Bucur, 1978): magnetization lost on cooling is largely, but not completely, restored on warming (Figure M41). Still unresolved is an existence of the transition temperature hysteresis during magnetization cycling in a zero field. Transition temperatures determined from cooling curves are often lower than those determined from warming curves, sometimes by as much as 20°.

Alike the Verwey transition in magnetite, the Morin transition is sensitive to impurities. Titanium is known to suppress the transition in concentrations as low as less than 1% (Kaye, 1962), while the transition exists until 10% of Al substitution (da Costa *et al.*, 2002). The transition becomes more gradual for highly aluminous hematites, in the sense that low- and high-temperature phases appear to coexist over a considerable range of temperatures, and the effective transition temperature is lowered to about 180 K for hematite with ~10% Al. The transition temperature is lowered and the transition itself appears considerably suppressed in fine grains (Bando *et al.*, 1965; Schroeer and Nininger, 1967; Nininger and Schroeer, 1978; Amin and Arajs, 1987). This may be the reason why the Morin transition is rarely found in hematite-bearing rocks (Dekkers and Linssen, 1989).

Titanohematites with y up to about 0.7 do not show any distinctive low-temperature magnetic properties (Ishikawa and Akimoto, 1957).

On the contrary, more Ti-rich compositions show fairly complex behavior (Figure M42). At very low temperatures, a spin glass structure seems to arise (Arai and Ishikawa, 1985; Arai *et al.*, 1985a,b; Ishikawa *et al.*, 1985), the spin glass transition temperatures  $T_{sg}$  being considerably lower than the respective Curie temperatures. Between these two transition points compositions with  $y \sim 0.8-0.9$  show superparamagnetic behavior (Ishikawa *et al.*, 1985). The spin glass phase is capable to carry a relatively strong remanence, which disappears at the  $T_{sg}$ . The coercive force also increases sharply below this temperature reaching 300–600 mT at 4.2 K. It must be noted, however, that the above studies have been carried out using the synthetic materials. Whether their natural analogs would show similar magnetic properties remains largely unknown.

The second end member of the titanohematite series, ilmenite, orders antiferromagnetically below its Néel temperature of  $57\pm 2$  K (Senftle *et al.*, 1975). Antiferromagnetism in the low-temperature phase persists up to about 6.6% of Fe<sup>3+</sup> substitution, while Néel temperatures shift to below 50 K (Thorpe *et al.*, 1977). Ilmenite therefore contributes only to induced magnetization. A susceptibility peak at 45 K, which may be due to ilmenite, has been reported for a basalt sample from the Hawaiian deep drill hole SOH-1 (Moskowitz *et al.*, 1998).

#### Iron hydroxides

Hydrous iron oxides are produced commonly by weathering of iron-bearing rocks in ambient conditions. They are also ubiquitous in

**Figure M42** Low-temperature magnetic-phase diagram of ilmenite-rich part of the FeTiO<sub>3</sub>-Fe<sub>2</sub>O<sub>3</sub> system. Down triangles indicate the temperature where TRM disappears, up triangles the temperature of the susceptibility peak. marine sediments (Murray, 1979). Of various iron hydroxides, the orthorhombic form, goethite ( $\alpha$ -FeOOH), is the most stable. Goethite is an antiferromagnet but, like hematite, often carries a small magnetic moment believed to be of defect origin (Strangway et al., 1968; Hedley, 1971). Below its Néel temperature of 120°C (in wellcrystalline samples) goethite is extremely magnetically hard, requiring fields in excess of 10 T to approach the magnetic saturation. An intense TRM, nearly equal to the spontaneous magnetization  $J_s$ , can be acquired by cooling from  $T_N$  in a strong field. Upon warming in a zero field it is demagnetized almost linearly with temperature until fully vanishing somewhat below  $T_N$ , but on the consequent cooling in a zero field a considerable part of TRM is restored (Figure M43a, Rochette and Fillion, 1989). TRM is far greater than an IRM that could be acquired by application of the same field at a low temperature. Therefore, FC and ZFC warming curves of goethite are very strongly different for both bulk and nanocrystalline goethite (Figure M43b, Guyodo et al., 2003). Both features can be used as a discriminatory criterion for this mineral.

Other iron hydroxides often found in sediments and soils include lepidocrocite ( $\gamma$ -FeOOH) and ferrihydrite (5Fe<sub>2</sub>O<sub>3</sub>·9H<sub>2</sub>O). These minerals are paramagnetic at room temperature and do not contribute to NRM; however, both can transform to ferrimagnetic phases (maghemite) on moderate heating. Recent studies of the lowtemperature magnetic properties (Zergenyi *et al.*, 2000; Hirt *et al.*, 2002) have revealed that below their ordering temperatures (~100 K for ferrihydrite and 50–60 K for lepidocrocite) these minerals can acquire a considerable, on the order of several tenths of A m<sup>2</sup> kg<sup>-1</sup>, remanence which decays nearly exponentially on heating in zero field, mimicking the superparamagnetic behavior of ultrafine particles of strongly magnetic minerals, e.g., magnetite or maghemite (Figure M44).

#### Iron sulfides

Of a variety of iron sulfides occurring in nature, monoclinic 4C pyrrhotite ( $Fe_7S_8$ ) is the most extensively studied. The magnetic transition at 30-34 K, initially discovered in early 1960s (Besnus and Meyer, 1964), has been since found in a number of natural and synthetic pyrrhotites (Rochette, 1988; Dekkers, 1989; Dekkers et al., 1989; Rochette et al., 1990). Phenomenologically, the behavior of the SIRM and the coercive force on crossing the transition has much in common with the much more extensively studied Verwey transition in magnetite. Part of a SIRM given at some temperature below the transition is demagnetized at the latter. A SIRM acquired above the transition, when cycled through the transition in zero magnetic field is also partly demagnetized, and a rebound of magnetization at the transition is observed during warming (Figure M45). The latter feature is grain-size dependent, becoming progressively less pronounced in finer grains. Pyrrhotite grains several tens of microns in size show an irreversible loss of remanence even during a zero-field cycle to 77 K (Dekkers, 1989). The  $M_{\rm rs}/M_{\rm s}$  ratio and the coercive force increase sharply below the transition, indicating that the low-temperature phase is in the single-domain magnetic state. These properties can serve as discriminatory criteria for monoclinic pyrrhotite in the case when heating the sample above room temperature is impossible or undesirable.

Thiospinel of iron, mineral greigite (Fe<sub>3</sub>S<sub>4</sub>) once thought to be rare, is being identified in growing number of environments, contributing to NRM of sediments and soils (see e.g., Snowball and Torii, 1999 and references therein). Its low-temperature magnetic properties have been the subject of several recent studies (Roberts, 1995; Snowball and Torii, 1999; Dekkers *et al.*, 2000); however, no distinctive features between 4.2 K and room temperature have been observed. Generally, SIRM given at a low temperature decreases monotonously on warming in zero-field albeit at different rates (Roberts, 1995), while room-temperature SIRM hardly show any changes on cooling to 4 K (Dekkers *et al.*, 2000, Figure M46). The latter study also reported on the magnetic hysteresis measurements on synthetic greigite. A peak

The upper curve of  $J_{rs}$  (triangles) is obtained by heating peak TRM at 4.2 K and the lower one (dots) by cooling peak TRM from 290 K. in  $M_{\rm rs}$  was found at 10 K, and both the coercive force and coercivity of remanence increased significantly below at about 30 K. Reasons for this behavior are not clear.

Pyrite (FeS<sub>2</sub>) is often found in sediments affected by diagenesis. Theoretical calculations show that pyrite and its polymorph marcasite are low-spin paramagnets whose magnetic susceptibility is temperature independent (Hobbs and Hafner, 1999). However, in practice an increase of susceptibility is often observed in both compounds below

10 K (Burgardt and Seehra, 1977; Seehra and Jagadeesh, 1979). Most likely it is due to otherwise undetectable impurities showing usual Curie-Weiss paramagnetism.

Pyrrhotites richer in iron than  $Fe_7S_8$  are antiferromagnetic at room temperature, but transform to a ferrimagnetically ordered phase at ~200°C, and eventually to monoclinic pyrrhotite on further heating. Other Fe-S minerals (mackinawite, smythite) have been often considered metastable in ambient conditions. These minerals received so far a limited interest in rock magnetism, and their magnetic properties at low temperatures are largely unknown.

#### Siderite and rhodochrosite

Siderite (iron carbonate, FeCO3) and rhodochrosite (manganese carbonate, MnCO<sub>3</sub>) usually precipitate jointly in anoxic sedimentary environments when iron and manganese are present in soluble form. The two compounds may form solid solutions spanning the entire range of intermediate compositions. Although paramagnetic at room temperature, siderite has some importance in paleomagnetism, since secondary maghemite is produced by weathering siderite-bearing rocks, and also because siderite easily converts to magnetite at heating to  $\sim$ 400°C, thereby putting an effective limit to thermal demagnetization (Ellwood et al., 1986, 1989). Siderite orders antiferromagnetically below the Néel temperature of 37-40 K (natural samples of varying purity, cf. Jacobs, 1963; Robie et al., 1984). MnCO3 is a canted antiferromagnet with slightly lower Néel temperature of 32 K (synthetic crystal, Borovik-Romanov et al., 1981). Both compounds can acquire remanence below  $T_N$ , which is lost quite sharply on warming in zero field. These minerals could be thus confused with pyrrhotite, which shows the magnetic transition in the same temperature range. However, siderite and rhodochrosite can still be distinguished from pyrrhotite since both minerals show a large (over one order of magnitude for siderite) difference between SIRMs acquired after FC and ZFC, respectively (Housen et al., 1996; Frederichs et al., 2003), not observed for pyrrhotite (Figure M47). It might be expected that cycling of room-temperature SIRM in siderite- and pyrrhotite-bearing samples will also distinguish between the two minerals.

#### Vivianite

Vivianite, iron hydrophosphate (Fe<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>·8H<sub>2</sub>O), usually precipitates in moderately to highly productive, iron-rich sedimentary environments. At low temperatures, vivianite shows antiferromagnetic ordering in each of two sublattices formed by Fe<sup>2+</sup> ions occupying nonequivalent positions (van der Lugt and Poulis, 1961). The two sublattices are canted by approximately  $42^{\circ}$  (Forsyth *et al.*, 1970). However, conflicting results have been reported on changes of the antiferromagnetic order with temperature. Forstat *et al.* (1965) have

**Figure M46** (a) Thermal demagnetization of IRM acquired at 5 K in a 2.5 T field for four greigite samples. (b) Behavior of IRM (1.2 T) acquired at room temperature for synthetic greigite during zero-field cooling to 4 K. found two sharp anomalies in the specific heat at 9.60 and 12.40 K, respectively, which were attributed to two distinct antiferromagneticparamagnetic transitions. On the other hand, in a neutron diffraction experiment Forsyth *et al.* (1970) found only one antiferromagneticparamagnetic transition at 8.84  $\pm$  0.05 K. A recent rock magnetic study (Frederichs *et al.*, 2003) has confirmed previous data on the magnetic susceptibility, and found that below 10 K vivianite can acquire only a small remanence on the order of  $10^{-3}$  A m<sup>2</sup> kg<sup>-1</sup>.

#### Iron silicates

Silicates are the most abundant minerals in the Earth's crust. They often contain iron in either ferrous (Fe<sup>2+</sup>) or ferric (Fe<sup>3+</sup>) form. At low temperatures, iron-rich silicates typically order antiferromagnetically, and the observed Néel temperatures range from <10 K to about 100 K (Coey *et al.*, 1982; Coey and Ghose, 1988). Examples are fayalite (Fe<sub>2</sub>SiO<sub>4</sub>) and ferrosilite (FeSiO<sub>3</sub>), iron-rich end members of olivine and pyroxene series, respectively. For the former Néel temperature is 65 K (Santoro *et al.*, 1966), and for the latter 43 K (Sawaoka *et al.*, 1968). However, iron-rich silicates are rare in nature and in most cases iron cations are diluted with nonmagnetic cations such as Mg<sup>2+</sup> and Al<sup>3+</sup>. With increasing nonmagnetic dilution, Néel temperatures are progressively lowered and the magnetic ordering eventually suppressed. In the olivine series (Fe<sub>x</sub>Mg<sub>1-x</sub>)<sub>2</sub>SiO<sub>4</sub> the antiferromagnetic transition disappears for  $x \sim 0.3$  (Hoye and O'Reilly, 1972). Some sheet silicates, while having the antiferromagnetic ground

state, can exhibit the magnetic hysteresis and acquire remanent magnetization at low temperatures. An example is mineral minnesotaite, or ferrous talc, of chemical formula  $Fe_3Si_4O_{10}(OH)_2$ , which acquires an IRM(2 T) of about 40 A m<sup>2</sup> kg<sup>-1</sup> at 4.2 K (Ballet *et al.*, 1985). The underlying mechanism of this behavior is that in minnesotaite the metamagnetic transition from an antiferromagnetic to a ferromagnetic state occurs in an anomalously low field of about 0.5 T. After once being subjected to fields higher than the metamagnetic threshold, the sample follow hysteresis loop never to return to the antiferromagnetic state (Coey and Ghose, 1988). In summary, silicate minerals may have certain potential to contribute to the low-temperature magnetic signal of rocks, particularly to the magnetic susceptibility; whether and how often this is really the case remains to be seen.

#### MAGNETIC PROXY PARAMETERS

#### Introduction

As a rule, a natural system is complex and the result of the interplay of numerous constituting parameters. To fully describe such systems, ideally each (independent) parameter must be known. However, their mere number would imply a substantial analytical operation and in practice one should look for parameters that describe the essential parts of the system. Because these parameters can only describe the system in an approximate fashion they are termed "proxy parameters" or "proxies." There exists a myriad of proxies including the chemical analysis of inorganic or organic compounds, the number and types of living and fossil biota, and the physical properties of a sample, such as grain-size distribution, porosity, magnetic properties, etc. Basically, each physical, chemical, or biological parameter that is measurable reasonably quickly at reasonable cost may serve as proxy to describe a complete system. One should realize that up to over several thousands of data points are rapidly gathered in a case study. Combinations of two or more of those parameters may yield valuable proxies as well. Another important condition for a parameter to serve as proxy is that its meaning must be understood. This pertains to the analytical point of view as well as to its functioning in the natural system. In the following, we outline the merit and potential of the so-called mineralmagnetic proxies.

From the analytical viewpoint, the assets of mineral-magnetic or rock-magnetic proxy parameters are manifold. They include sensitivity, rapidity, ease of sample preparation, comparatively modestly priced instrumentation for data acquisition, nondestructiveness, and in particular the ability to sense grain-size variation in the ultrafine grain-size range. Magnetic properties refer to bulk sample properties in contrast to (electron) microscopical techniques where often only a small fraction of a sample can be analyzed. Therefore, mineral-magnetic parameters are well suited as proxy parameters. As drawbacks should be mentioned that some of the parameters are nonunique, and that their scales are most often utilized in a relative sense. Often ratios of several parameters are used to reduce nonuniqueness. The meaning of a ratio may change depending on the absolute values of numerator and denominator; hence, may vary among case studies. Proper interpretation of a mineral-magnetic data set therefore requires expert training and a feel for potential variability in the data cloud.

#### Magnetism

Mineral-magnetic parameters refer to the concentration and properties of iron oxides (and some iron sulfides), minerals that occur in trace amounts in any rock, soil, or even organic tissue. In quantum mechanics, electrons are assigned orbital and spin magnetic moments. For magnetism, the spin moment is most important: each electron can be regarded as a microscopic magnet. In most compounds electrons act independently and consequently a very low-magnetic moment is measured in applied magnetic fields and no permanent or remanent magnetic moment can exist. This is the case in diamagnetic and paramagnetic substances. Diamagnetism-occurring in compounds with no unpaired electron spins-is characterized by a small but negative magnetic moment in applied fields. It is a property of all matter because all paired electrons yield a diamagnetic moment. Paramagnetism-characteristic of compounds with unpaired electron spinsyields a positive magnetic moment that outweighs diamagnetic moments very quickly.

By virtue of exchange interaction, a property described also by quantum mechanics, the outermost electrons of transition elements may act collectively in some compounds, provided that their orbitals sufficiently overlap. For the first row transition elements, this situation occurs in metal oxides. In nature, iron is the most important element and the collective electron behavior is termed ferromagnetism (*sensu lato*). Several classes of ferromagnetism are distinguished: ferromagnetism, ferrimagnetism, and antiferromagnetism (Figure M48).

Ferromagnetic and ferrimagnetic materials have very large magnetic moments in applied fields, several orders of magnitude larger than a typical paramagnet. Antiferromagnetic materials ideally would have a net magnetic moment of zero but in reality usually a weak moment persists. Collective spin behavior gives rise to the existence of permanent or remanent magnetization, i.e., magnetic moments that remain after removal of an external magnetic field. The magnetic properties 526

of ferromagnets (*sensu lato*) are dependent on mineral type, temperature, grain size, and strain state of the grain. Subtle variations in magnetic properties can thus be interpreted in terms of changing concentration, grain size, or strain state of the magnetic materials. In a geoscientific context, in turn, these can be interpreted along the lines of changes in catchment area, in climate, in diagenesis, or in oxidation degree when dealing with a series of lava flows. This is exploited when utilizing magnetic properties as proxy parameters.

#### Magnetic minerals

In nature, magnetic minerals are largely restricted to iron-titanium oxides that may contain minor amounts of substituted aluminum, chromium, manganese, and magnesium. The most important terrestrial magnetic mineral is magnetite (Fe<sub>3</sub>O<sub>4</sub>), one of the endmembers of the titanomagnetite solid-solution series (the other endmember is ulvöspinel, Fe<sub>2</sub>TiO<sub>4</sub>). Hematite ( $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>) is another important

**Figure M48** Classes of magnetism. The resultant magnetic moment is indicated below.

mineral; it is one of the endmembers of the titanohematite solid-solution series (the other endmember is ilmenite, FeTiO<sub>3</sub>). Goethite ( $\alpha$ -FeOOH), pyrrhotite (Fe<sub>7</sub>S<sub>8</sub>), and greigite (Fe<sub>3</sub>S<sub>4</sub>) are often referred to as minor magnetic minerals. Some copper minerals show magnetic properties as well but their occurrence is restricted to certain iron types. Metallic iron is very rare in terrestrial environments but occurs prominently in meteorites. Magnetic minerals can be distinguished from each other by their Curie point temperature, the temperature above which collective behavior is lost and a paramagnetic substance remains. When dealing with antiferromagnetic minerals the temperature at which collective behavior is lost, is referred to as Néel point temperature. In practice Curie and Néel temperature are used interchangeably. When cooling below the Curie or Néel temperature, collective spin coupling sets in again. For most magnetic minerals the Curie (Néel) temperature is several hundreds of degree Celsius, i.e., far above room temperature (see Table M2). If we would extend the measurement range down to a few Kelvin, many silicate minerals will order magnetically as well. However, this is not routinely done because it requires specific instrumentation that is not widely available.

#### Grain-size indicators

Small grains have a different number of magnetic domains—zones with a uniform magnetization direction within a grain—than large grains of the same magnetic mineral. Hence, magnetic properties that reflect somehow the number of domains, are grain-size indicative. From the smallest grain size to the largest, four main domain structure types are distinguished: superparamagnetic, single-domain, pseudosingle-domain, and multidomain (Figures M49 and M50). The boundaries between these domain types are gradual, but the change in domain-state dependent properties essentially forms a continuum. Superparamagnetic grains are that small that they cannot support a stable domain configuration: upon a changing external field the spin configuration

**Table M2** Some natural magnetic minerals, Curie ( $T_C$ ) or Néel temperature ( $T_N$ ) and magnetic structure below  $T_C$  or  $T_N$ . More detailed descriptions of the magnetic properties of most of these phases are given by Hunt *et al.* (1995), Dunlop and Özdemir (1997), Maher and Thompson (1999), or Evans and Heller (2003)

Mineral name	Composition	$T_{\rm C}$ or $T_{\rm N}$	Magnetic structure

Magnetite-jacobsite	Fe <sub>3</sub> O <sub>4</sub> -Fe <sub>2</sub> MnO <sub>4</sub>	578°C to 350°C	Ferrimagnetic
Magnetite-chromite	Fe <sub>3</sub> O <sub>4</sub> -Fe <sub>2</sub> CrO <sub>4</sub>	578°C to 30°C	Ferrimagnetic
Hematite-ilmenite	$\alpha$ -Fe <sub>2</sub> O <sub>3</sub> -FeTiO <sub>3</sub>	675°C to -170°C	Canted antiferromagnetic-ferrimagnetic <sup>a</sup>
Maghemite	$\gamma$ -Fe <sub>2</sub> O <sub>3</sub>	645°C <sup>b</sup>	Ferrimagnetic
Goethite	α-FeOOH	120°C	Antiferromagnetic
Akagenéite	$\beta$ -FeOOH	26°C	Antiferromagnetic
Bernallite	Fe(OH) <sub>3</sub>	154°C	Canted(?) antiferromagnetic <sup>c</sup>
Feroxyhite	$\delta'$ -FeOOH	177°C	Ferrimagnetic
Pyrrhotite	$Fe_7S_8-Fe_{11}S_{12}$	325°C	Ferrimagnetic-antiferromagnetic <sup>d</sup>
Greigite	$Fe_3S_4$	350°C ?e	Ferrimagnetic
Iron	Fe	770°C	Ferromagnetic
Lepidocrocite	γ-FeOOH	-196°C	Antiferromagnetic <sup>f</sup>
Siderite	FeCO <sub>3</sub>	-238°C	Antiferromagnetic <sup>f</sup>
Ferrihydrite	Fe <sub>5</sub> HO <sub>8</sub> ·4H <sub>2</sub> O	$-158^{\circ}C$ to $-248^{\circ}C^{f}$	Speromagnetic <sup>f,g</sup>

<sup>a</sup>Above the Morin transition, hematite has a canted antiferromagnetic structure which results in a macroscopic magnetic moment, its structure becomes ferrimagnetic with increasing Ti-content. As in the titanomagnetite solid-solution series, high Ti-contents yield Curie temperatures below room temperature.

<sup>b</sup>Most maghemites invert to hematite before their Curie temperature is reached.

<sup>c</sup>The structure of bernallite is not known with certainty.

 $^{d}$ Only monoclinic pyrhotite (Fe<sub>7</sub>S<sub>8</sub>) is ferrimagnetic at room temperature, the other pyrhotite structures become ferrimagnetic on heating above ~200 °C.

<sup>e</sup>On heating, greigite decomposes before it reaches its Curie temperature. Therefore, the temperature listed should be regarded with great caution.

<sup>f</sup>The last three minerals listed are paramagnetic at room temperature but they order magnetically at low temperatures, so their presence can be demonstrated with magnetic methods. Furthermore, on heating a sample above room temperature these paramagnetic minerals chemically alter into magnetic minerals.

<sup>g</sup>Speromagnetism is characterized by short-range antiferromagnetic spin coupling. On longer ranges the magnetic ordering is random. The range of ordering temperatures of ferrihydrite is related to its crystallinity.

**Figure M49** Examples of magnetic hysteresis loops (left, central). (*Left*) Hysteresis loop of an ensemble of single-domain grains. Single-domain grains are characterized by square hysteresis loops; loops of pseudosingle-domain and multidomain grains are increasingly slender and have inclined slopes. (*Central*) So-called "wasp-waisted" hysteresis loop. The central section is smaller than the outer parts. Wasp-waisted loops are typically of mixed ensembles with contrasting coercivities: either a mixture of two magnetic minerals (magnetite and hematite in the present case) or a mixture of superparamagnetic and larger grains of the same mineral. (*Right*) Determination of an IRM acquisition curve and the remanent coercive force.

**Figure M50** An example of a so-called Day plot. The solid lines represent the experimental calibration by Day *et al.* (1977). SD, single domain; PSD, pseudosingle-domain; MD, multidomain. Data points are from Icelandic lava with stable (open circles) and unstable (closed circles) behavior of the natural remanent magnetization. Dunlop (2002) showed that SP grains plot upward and to the right of the calibrated band.

conforms to the new situation rapidly (= on laboratory timescale). At room temperature, magnetite grains smaller than 20–25 nm in size are superparamagnetic. Single-domain grains contain one magnetic domain and are paleomagnetically most stable (25–80 nm). The stability can be expressed in terms of relaxation time. Pseudosingle-domain grains (80 nm— $\sim 10-15 \mu \text{m}$ ) contain "a few" domains (up to  $\sim 10$ ); they are paleomagnetically very stable. Multidomain grains (>10–15  $\mu$ m) contain many domains (>~10); they are paleomagnetically less stable.

The number of domains is a function of the grain's size and shape, and of the saturation magnetization of the magnetic material. In essence, a grain of a material with a high-saturation magnetization like magnetite will contain (much) more domains than a grain with the same size but of material with a low-saturation magnetization like hematite (see Table M3). Therefore we need to know the magnetic mineralogy before we can make a proper grain-size estimate with magnetic methods. Macroscopically, the domain state is reflected in the so-called hysteresis loop (Figure M49 left and central panels), the response of a sample to a cyclic applied magnetic field. If remanent magnetization occurs, the loops are open (the surface area corresponds to the energy contained in the magnetic system). The maximum value of the magnetization is the saturation magnetization ( $M_{\rm s}$  or  $\sigma_{\rm s}$ ), the corresponding remanent magnetization (when the external field is reduced to zero) is termed the remanent saturation magnetization (SIRM or saturation isothermal remanent magnetization, also  $M_{\rm rs}$  or  $\sigma_{\rm rs}$ ). The field values where M is zero are termed coercive force ( $B_c$  or  $H_c$ ). The field value where the remanence corresponds to zero is labeled remanent coercive force ( $B_{cr}$  or  $H_{cr}$ , cf. Figure M49 right panel).  $B_c$ and  $B_{\rm cr}$  go up with decreasing grain size. The  $M_{\rm rs}/M_{\rm s}$  and  $B_{\rm cr}/B_{\rm c}$  ratios are grain-size indicative, their plot against each other is referred to as "Day" plot (Figure M50). Ferro- and ferrimagnetic materials have lower values for their coercive forces than antiferromagnetic materials (see Table M3). Minerals with low coercivity values are termed magnetically "soft" while those with high values are "hard."

It is important to note that coercive force values are concentration independent when magnetic interaction can be neglected. To a firstorder description, this is warranted in many natural situations. Under this condition, values of magnetizations and various remanences scale linear with the concentration of the magnetic mineral. By dividing two concentration-dependent parameters, a concentration-independent ratio is obtained that contains information on grain size or the oxidation degree of the magnetic mineral. This idea of correcting for concentration forms the basis of many magnetic proxies.

#### Magnetic proxy parameters

The concept of using magnetic properties as proxy parameters and correlation tool in a geoscientific context was put forward in the late 1970s mostly by Oldfield and his coworkers; the article in *Science* (Thompson *et al.*, 1980) is often considered as the formal definition of "environmental magnetism" as a subdiscipline. Before briefly highlighting some magnetic proxies, we need to introduce two other important mineral-magnetic parameters, the low-field or initial susceptibility ( $\chi_{in}$  or  $\kappa_{in}$ ) and the anhysteretic remanent magnetization (ARM).

The initial susceptibility is the magnetization of a sample in a small applied field (up to a few times the intensity of the geomagnetic field,  $30-60 \mu$ T) divided by that field. Measurement takes a few seconds and requires no specific sample preparation; instrumentation is sensitive. This makes initial susceptibility an attractive proxy parameter, especially for correlation purposes. All materials have a magnetic susceptibility, also paramagnets and diamagnets. The initial susceptibility

Mineral	Saturation magnetization (A $m^2 kg^{-1}$ )	Coercive force <sup>a</sup> (mT)	Remanent coercive force <sup>a</sup> (mT)	Saturation field (T)
Magnetite	92 <sup>b</sup>	5-80	15-100	<0.3 <sup>c</sup>
Maghemite	$\sim 65-74^{\circ}$	5-80	15-100	< 0.3 <sup>d</sup>
Hematite	0.1-0.4	100-500	200-800	$\sim 1 - \sim 5$

Goethite	0.01-1	>1000	>2000	~10->20
Pyrrhotite	18	8-100	9–115	up to 1 <sup>d</sup>
Greigite	$\sim 30^{\rm e}$	15-40	35-70	<0.3 <sup>d</sup>

**Table M3** Saturation magnetization, typical coercive forces, remanent coercive forces and field required to reach saturation of some magnetic minerals (at room temperature)

<sup>a</sup>In the indicative ranges given the smallest number refers to multidomain particles and the largest to single-domain particles. Needle-shaped particles of strong magnetic material can have higher values for the coercivity than quoted in the ranges above.

<sup>b</sup>With increasing substitution of Ti, the saturation magnetization decreases

<sup>c</sup>The ideal maghemite composition has a saturation magnetization of 74 A m<sup>2</sup> kg<sup>-1</sup>, in practice lower values are often determined.

<sup>d</sup>Oxidized coatings and differential composition often increase coercivity and fields in which saturation is reached.

<sup>e</sup>The purity of greigite samples is problematic, the saturation magnetization value should be considered a minimum.

of a geologic sample is therefore a composite of the diamagnetic, paramagnetic, and ferromagnetic (*sensu lato*) contributions, something which should be kept in mind when interpreting susceptibility profiles. Ferro- and ferrimagnetic materials have very high initial susceptibilities so that for concentrations larger than  $\sim 1\%$  the measured susceptibility may be equated to the ferromagnetic susceptibility. For lower concentrations—the rule in sediment and soil samples—the paramagnetic and diamagnetic contributions can be substantial. Superparamagnetic grains have a high value for the initial susceptibility, much higher than the bulk value of the same material. The variation of initial susceptibility with grain size is small for single domain and larger grains. The superparamagnetic threshold size is dependent on the measurement frequency. By measuring at different frequencies the frequency dependence of the initial susceptibility can be calculated. This is a proxy for the relative amount of superparamagnetic grains.

The ARM is induced by an asymmetric alternating field, which is reduced from a peak value to zero. Often equipment for alternating field demagnetization is used, the asymmetry is created by a small direct current bias field. Typical values for the peak alternating field are 100–300 mT, whereas the bias field can vary between 30 and 100  $\mu$ T. The ARM intensity is a function of the bias field, for low bias fields (say <100  $\mu$ T) it scales linearly. Hence, by dividing the ARM intensity by the bias field value, a field-independent parameter is created, referred to as ARM susceptibility ( $\chi_{ARM}$ ) through its analogy with the low-field susceptibility. Some instruments allow to have the bias field switched on in desired windows of the decreasing alternating field to sense particular coercivity windows, such ARMs are referred to as partial ARM, labeled pARM. ARM is considered to be a good analog of thermoremanent magnetization created by cooling through the Curie temperature in a small magnetic field. Single-domain grains are sensed in particular by ARM.

Most proxy parameters are based on combinations of low-field susceptibility and/or various remanent magnetizations because they are most quickly measured (measurement of a complete hysteresis loop still takes 3 min on dedicated instrumentation, operator attendance is, however, required). Instrumentation that can measure ARMs and IRMs in a fully automated fashion has meanwhile developed, a distinct advantage (Table M4).

**Figure M51** Magnetic properties from the last 140 ka of a loess-paleosol sequence at Xining, western Loess Plateau, China (simplified after Hunt *et al.* 1995). (a) (*Outermost left*): Lithological column with ages for the paleosols. *S*, soil; *L*, loess, numbering starts from the Holocene soil *S*<sub>0</sub>. In the *S*<sub>1</sub> complex three subunits are distinguished: *SS*<sub>1</sub>, *SS*<sub>2</sub>, and *SS*<sub>3</sub>. (*Left-hand panel*): Susceptibility.  $\chi_{pr}$ , the susceptibility of paramagnetic minerals (measured in a high-magnetic field), appears to be relatively constant in this profile.  $\chi_{total}$  refers to the low-field susceptibility. The ferrimagnetic contribution to the low-field susceptibility equals  $\chi_{total} - \chi_{pr}$ . (*Central panel*): Saturation magnetization which is used as a normalizer to remove concentration effects. (*Right-hand panel*): The ratio  $\chi_{t}/\sigma_{s}$ , indicative of SP grains, increases in the paleosols. It is also slightly increased in a zone in *L*<sub>1</sub>, which probably indicates a warmer period in the glacial period in which *L*<sub>1</sub> was deposited. Note that no soil is visually evident in this zone. (b) (*Outermost left*): see Figure M51 (*Left-hand panel*): ARM intensity expressed on a mass-specific basis ( $\sigma_{rs}$ ). Note that the pattern is noisier than that of the ARM and that is differs from that of  $\sigma_s$  (see a) above. (*Right-hand panel*): Higher ratios of  $\sigma_{ARM}/\sigma_r$  indicate greater abundances of SD and PSD particles in the soils. Not only the SP fraction, but also the SD and the PSD fractions increase in soils. Subtle paleoclimatic variations can also be traced within and between lithological units, e.g., paleosol *S*<sub>1</sub>*SS*<sub>3</sub> is much more developed than *S*<sub>1</sub>*SS*<sub>1</sub> and, in particular, than *S*<sub>1</sub>*SS*<sub>3</sub> are present.

The eccentricity component from the Laskar (1990) solution is displayed for comparison with the longer term trends observed within the loess record. Correlation points linking warm features are shown with full lines while those for cold features are shown with dashed lines.

#### Some examples

The loess-paleosol climate archive was studied numerous times since Heller and Liu (1982) reported reliable magnetostratigraphic data from the Chinese Loess Plateau (CLP). The climatic conditions on the CLP are broadly determined by the relative intensities of the summer and winter monsoons. The summer monsoon delivers moisture toward the CLP, so strong summer monsoons indicate a wetter (and warmer) climate whereas strong winter monsoons (more and coarser dust) herald dry and cold climate conditions. Hunt et al. (1995b) utilized the magnetic proxy approach to highlight subtle differences within loess-paleosol profiles on the CLP (see Figure M51). Mainly qualitative observations in the loess-soil profile were confirmed whereas very subtle differences within the loess horizons were detected. Soils that are indicative for a wetter climate are characterized by higher values for  $\chi_{in}$ , in line with earlier observations. By using  $\chi_{in}$  as proxy for the intensity of the summer monsoon and the grain-size ratio as proxy for the winter monsoon, Heslop et al. (2000) were able to tune the entire "yellow" loess record (2.6 Ma) to the astronomical solution of Laskar (1990) providing a high-resolution timescale for the loess-paleosol deposits (Figure M52). With this high-resolution timescale, climatic and environmental changes can be put into a regional and also global perspective.

Mineral-magnetic proxy studies from the marine realm are numerous as well. Many studies report on the sensitivity of magnetic proxies to climate change since the mid-1980s. Robinson (1986) showed for North Atlantic sediments fairly close to the Mid-Atlantic spreading ridge west from Spain that concentration-dependent and -independent magnetic parameters and ratios reflect changes in climate caused by

changes in provenance of the sediment flux. He argued for an eolian source and found indications for ice-rafted debris. Later work among others by Stoner and colleagues (1996) documented the sensitivity of North Atlantic sediments, in particular from higher latitudes, to record Heinrich events, short-duration rapid climate variations. The minor importance of reductive diagenetic processes in most of these sediments and distinct magnetic properties of the source areas allow interpretation of subtle variations in the record in terms of climate change. Reductive diagenesis obscures the magnetic fingerprint of source areas (e.g., Bloemendal et al., 1992). The presence of pyrite (FeS<sub>2</sub>) and magnetic sulfides testifies anoxic conditions. Joint mineralmagnetic and geochemical analysis can be used to evaluate the extent of diagenesis (e.g., Dekkers et al., 1994; Passier et al., 2001). Oxidative diagenesis has a typical magnetic signature (Passier et al., 2001), which was utilized by Larrasoaña et al. (2003a) to provide a proxy for bottom-water ventilation in the Mediterranean Sea during sapropel formation (Figure M53). They distinguish three types of sapropel environment: (i) sapropels without oxidation fronts with high organic matter contents inferred to be deposited under severely anoxic conditions; (ii) sapropels with both dissolution and oxidation fronts, the mostly occurring situation referred to as "anoxic"; and (3) sapropels without dissolution front but with a well-developed oxidation front, referred to as "less anoxic." The third group implies no excess sulfide being generated within the sapropel for a dissolution front formed below it. These sapropels are most prone to be reoxidized completely and therefore easily escape visual detection. They can, however, be traced with magnetic (and other) proxies.

**Figure M53** A series of geochemical and magnetic proxies measured on samples from ODP Site 967 (Eastern Mediterranean) with their meaning underneath the abscissas (after Larrasoaña *et al.*, 2003a). Sediments constitute an alternation of marly limestones and marls with sapropels intercalated (sapropels are sediments with more than 2% organic matter and therefore dark-brown to black colored). Sapropeletic sediments are indicated by darkest gray shading, dissolution zones with intermediate gray, and reoxidized zones with lightest gray. The insolation cycle (i-cycle) codification implies an age range from ~2.9 to ~2.5 Ma. The sapropels class into groups (2) and (3). Arrows indicate the position of completely reoxidized (missing, m) sapropels on the basis of magnetic and geochemical proxies. In cases where assignment to a sapropel type is not certain because of lack of magnetic data due to unavailability of the core segment for rock magnetic analysis, a question mark is put.

Mixed magnetic mineralogy, magnetic interaction, and thermal relaxation

Often magnetite-like minerals dominate the magnetic signal. However, more detailed analysis has shown that the occurrence of mixed magnetic mineralogy is the rule rather than the exception. The absolute values of HIRM ("hard" IRM) as an indicator for the amount of hematite have been used as a proxy for dust input by Larrasoaña *et al.* (2003b). They gave the samples at 0.9 T IRM which was demagnetized at 120 mT peak AF to cope with the limited dynamic range of the magnetometer.

Also the S-ratio is an example of a parameter to distinguish between "magnetite" and "hematite" ("soft" IRM and "hard" IRM; with respect to a saturating forward IRM and various back field IRMs). In particular,  $S_{300}$  is being used as indicator for the magnetite-hematite ratio.  $S_{300}$  equals 1 (or -1 depending on the definition, see Bloemendal *et al.*, 1992 and Kruiver and Passier, 2001) would represent magnetite only and that lower values would indicate the presence of hematite.

Magnetite fully saturates in a 300 mT field and hematite is (much) harder, yielding lower S-ratios. Up to now, the ratio has been used as a qualitative indicator only. The interpretation of the  $S_{300}$  in terms magnetite and hematite has been criticized by Kruiver and Passier (2001) who modelled that for oxidized magnetite the forward  $S_{300}$  would yield values lower than one and that when more than two magnetic minerals are present the S-ratio can be seriously flawed. So, the meaning of lower S-ratios needs to be assessed on a case-by-case basis.

Another way to quantify mixed magnetic mineralogy is the socalled IRM component analysis, the decomposition of a measured IRM acquisition curve into several components with the use of model functions. Initially, cumulative log-Gaussian curves were used based on the experimental observation by Robertson and France (1994) that such curves closely conform to measured IRM acquisition curves. Kruiver *et al.* (2001) proposed the use of the *F*-test (and *t*-test where appropriate) to judge upon the number of coercivity fractions required for an optimal fit from a statistical viewpoint. The cumulative

**Figure M54** Magnetic fingerprint diagram of MDF<sub>ARM</sub> vs  $k_{ARM}$ /IRM (after Egli, 2004). Summary of the magnetic properties of ARM (300 mT peak AF, 0.1 mT bias field) and IRM (300 mT acquisition field to avoid magnetization that cannot be AF demagnetized) for all iron spinel components identified by Egli (2004). The magnetic components group into different clusters, indicated by gray ellipses and rectangles. White letters classify all components into low-coercivity magnetosomes (biogenic soft, BS: dots), high-coercivity magnetosomes (biogenic hard, BH: squares), ultrafine extracellular magnetite (EX: circles), pedogenic magnetite (PD: diamonds), detrital particles transported in water systems (D: diamonds), windblown particles (eolian dust, ED: open squares), atmospheric particulate matter produced by urban pollution (UP: crosses), and a maghemite component in loess (L: open triangles). Other components, as BM (dots) and BI (half-filled squares), have been measured in a few samples only and are not labeled. The open rectangle indicates the range of values measured in samples of cultured magnetotectic bacteria (triangles). GS15 labels the measurement of extracellular magnetite particles produced by a cultured dissimilatory iron-reducing microorganism. Its properties are influenced by the strong magnetostatic interactions within clumps of these particles which form spontaneously during the sample preparation. Smaller values of MDF<sub>ARM</sub> and larger values of  $k_{ARM}$ /IRM are expected for these particles when they are dispersed in natural sediments: in this case, GS15 would probably fall into the cluster labeled with PD+EX. Arrows indicate the decrease of  $k_{ARM}/IRM$  observed during anoxic conditions in lake sediments.

log-Gaussian model function would be valid in the absence of magnetic interaction. Egli (2003) extended the use of the model functions to a set of skewed generalized Gaussian functions where skewness and kurtosis are additional free parameters. He showed that many natural samples would require skewed model functions for optimal fits (kurtosis appeared to be not significant). Heslop et al. (2004) utilized Preisach modeling to document that thermal relaxation and magnetic interaction would yield negatively skewed distributions already for low levels of interaction and thermal relaxation supporting the observations of Egli (2003, 2004). In Figure M54, the summary diagram of Egli (2004) is reproduced. He processed a series of lake sediments, marine sediments, soils, loesses, polluted samples, and magnetotactic and extracellular bacteria with the procedure described by Egli (2003). He concluded that a plot of the median destructive field (MDF, the peak alternating field strength at which 50% of a remanent magnetization is demagnetized) of the ARM vs the ARM susceptibility divided by the IRM discriminates the grouping most instructively. In many natural samples combinations of these groups are present and observed variability could be described meaningfully by these "endmember groups." It should be kept in mind that the low IRM peak acquisition field (300 mT) used in the approach excludes hematite, goethite, and other antiferromagnets from the analysis.

A nice way to illustrate the occurrence of magnetic interaction is by the so-called first-order reversal curve (FORC) plots (Figure M55), an approach introduced into environmental magnetism by Pike *et al.* (1999) and Roberts *et al.* (2000). On the abscissa coercivity is plotted, whereas on the ordinate magnetic interaction is expressed. Zero magnetic interaction occurs when  $\mu_0 H_u$  equals zero, most contour density in this area in the samples before sequential extraction implies minor interaction which was taken by Van Oorschot *et al.* (2002) that IRM component analysis was warranted. The plots are normalized.

#### Proxy for anthropogenic pollution

A number of studies have produced reasonable correlations between magnetic proxy parameters, in particular low-field susceptibility, and a series of contaminants, either of organic or of inorganic chemical origin. The underlying reason for the magnetic methods to yield fairly consistent results under certain conditions is the sorption capacity of fine-grained iron oxides and sulfides. For airborne particulate matter-for example from industrial fly ash, general industrial activity, or urban traffic-magnetic parameters may provide an estimate of the pollution load (e.g., Dekkers and Pietersen, 1992; Morris et al., 1995; Matzka and Maher, 1999; Xie et al., 2001; Muxworthy et al., 2002). The suitability of magnetic parameters for monitoring of pollution loads in some central European countries has been investigated by the MAGPROX team. In a number of settings magnetic susceptibility is a good indicator of atmospherically derived particulate matter. A recent example of the magnetic expression of the dust load in tree leaves includes the work by Hanesch et al. (2003), the impact of an industrial zone could be evaluated straightforwardly. In the same area, a province in Austria, heavy metal concentrations in soils could be traced magnetically by low-field susceptibility patterns (Hanesch and Scholger, 2002).

#### Summary

Subtle changes in magnetic properties reflect changes in magnetic mineralogy, grain size, oxidation degree, stoichiometry, strain state, etc. These can be understood and explained in terms of changing provenance areas, climatic conditions, diagenetic regimes, and—under certain conditions—anthropogenic pollution. Therefore, combined with analytical assets: sensitivity, rapidity, nondestructiveness, and comparative ease of sample preparation, they are an attractive set of proxy parameters. The interpretive value can be enhanced by utilizing several magnetic proxies together with a few geochemical proxies, for example, elemental analysis. Increased use of magnetic proxies is foreseen as a consequence of methodological advances in unraveling mixed magnetic mineralogy and further establishment of more quantitatively based parameters.

#### MAGNETIC REMANENCE, ANISOTROPY

It has been known since the early 1950s that rocks and sediments display a magnetic anisotropy when constituent mineral grains have a preferred orientation (Graham, 1954; Hargraves, 1959). Magnetic fabric is usually described by the anisotropy of magnetic susceptibility (AMS), measured in weak applied fields. With this method all minerals in a rock or sediment contribute to the susceptibility. Therefore, the observed anisotropy is the sum of the individual mineral components, their specific susc/eptibility anisotropy and their preferred alignment. Since nonferromagnetic matrix minerals often make up the bulk composition of a rock or sediments, the low-field susceptibility of these minerals can dominate the measured signal. The anisotropy of magnetic remanence (AMR) is only dependent on the ferromagnetic grains (s.l.) in a rock. Since the number of different ferromagnetic phases is more limited, the source of the AMR is easier to distinguish, and the degree of anisotropy is less sensitive to mineral variation (Jackson, 1991).

In early studies several authors noted that certain rocks that display AMS also have natural remanent magnetizations (NRMs) that are shallowly inclined toward the plane of high susceptibility (Howell *et al.*, 1958; Hargraves, 1959; Fuller, 1960). This observation promoted the first studies examining the anisotropy of remanent magnetization. Since then numerous investigations have used the anisotropy of remanent magnetization to determine if the ferromagnetic minerals are preferentially aligned, which may in turn affect the characteristic remanent magnetization (ChRM) of a rock.

#### Theoretical background

The physical theory of magnetization and the magnetic behavior of minerals is given elsewhere in this volume. Detailed coverage on the theory of AMS and AMR is available in several textbooks and review papers (Jackson, 1991; Rochette *et al.*, 1992; Tarling and Hrouda, 1993; Borradaile and Henry, 1997; Tauxe, 2002). A cursory description necessary to understand the basis of anisotropy of remanent magnetization follows.

The magnetization **M** of a material is a vector sum of two components: the induced magnetization  $\mathbf{M}_{i}$  and remanent magnetization  $\mathbf{M}_{r}$ ,

$$\mathbf{M} = \mathbf{M}_{i} + \mathbf{M}_{r}$$

The induced magnetization can be expressed as

 $\mathbf{M}_{i} = \chi \mathbf{H},$ 

where  $\chi$  is the susceptibility, a material constant that can be described by a tensor of second order, and **H** is the inducing field. The remanent magnetization is the magnetization that remains after the material is removed from an applied magnetic field and is carried by ferrimagnetic minerals.

A mathematical description of a weak-field magnetic remanence is analogous to AMS. This has been described in Stacey and Banerjee (1974) as

 $\mathbf{M}_{\mathrm{r}} = k_{\mathrm{r}} \mathbf{H},$ 

where  $k_r$  is the remanent susceptibility, which is also a material constant that can be described by a tensor of second order for linearly anisotropic magnetizations.

$$k_{\rm r} = \begin{bmatrix} k_{\rm r11} & k_{\rm r12} & k_{\rm r13} \\ k_{\rm r21} & k_{\rm r22} & k_{\rm r23} \\ k_{\rm r31} & k_{\rm r32} & k_{\rm r33} \end{bmatrix}$$

It can be represented geometrically by an ellipsoid with principal axes parallel to the eigenvectors of  $k_r$  and lengths equal to the corresponding eigenvalues, where  $k_{r1} \ge k_{r2} \ge k_{r2}$ . It must be noted that  $\mathbf{M}_r$  should be both linearly dependent on the intensity of the inducing field and reversible.

In a rock or sediments, we are interested in the total contribution of all ferrimagnetic minerals to the observed signal. If a material is isotropic, i.e., the minerals show no preferred orientation, then M<sub>i</sub> will be along the direction of the applied field and Mr will be in the direction of the field that produced the remanence. If, however, the minerals in a rock or sediment have a preferred orientation then the acquired magnetization will lie between the applied field direction and the direction of the easy axis of magnetization. The easy axis of magnetization may be related to the shape of the grain, as is the case for ferrimagnetic spinel. Minerals that display shape anisotropy have a high spontaneous magnetization and a slight departure from equidimensional habit leads to the magnetization being preferentially aligned along the long axis of a grain. Crystallography may also control the direction of magnetization, due to the geometric distribution of atoms within the crystallographic lattice. The ferrimagnetic minerals, hematite and pyrrhotite, are controlled by magnetocrystalline anisotropy. Compared to the value along the c-axis, the susceptibility in the basal plane is two orders of magnitude higher in hematite and three orders of magnitude higher in pyrrhotite. Stress within a mineral may also lead to an anisotropic acquisition of magnetization, known as magnetostriction. It arises from the strain dependence of the anisotropy constants and has been observed in titanomagnetite.

#### Types of remanent magnetization

A rock or sediment can acquire different types of remanent magnetizations. Some types of remanence are acquired by natural processes, whereas other types are imparted under laboratory conditions. When rocks form from molten lava or sediments are deposited, the magnetic moments of ferromagnetic minerals align statistically with the prevailing Earth's magnetic field and receive a remanent magnetization, known as the NRM.

The NRM that is found in rocks that are formed from molten lava is called a thermal remanent magnetization (TRM). When individual ferrimagnetic minerals cool through their Curie temperature or Néel temperature, the ferrimagnetic grains take on the magnetization of the ambient magnetic field. TRM is very stable over time. Sediments acquire their remanent magnetization as they are deposited. The ferrimagnetic grains align statistically in the ambient field as they settle and the acquired magnetization is called a detrital remanent magnetization (DRM). As the grains are cemented in the matrix of the sediment, the resulting magnetization is a postdetrital remanent magnetization (pDRM).

It is also possible to give a material a TRM in the laboratory by heating the material above the Curie or Néel temperature of the constituent ferrimagnetic phases and cooling it in a field of known direction and intensity. Other laboratory-acquired remanent magnetizations include anhysteretic remanent magnetization (ARM) and isothermal remanent magnetization (IRM). An ARM is acquired when an alternating field ( $H_{AC}$ ) is superimposed on a weak DC bias field, which serves to impart a magnetization in a known direction. All ferrimagnetic minerals with a coercivity less than or equal to  $H_{AC}$  will be remagnetized. Anhysteretic remanence shows grain-size dependence in magnetite (Figure M56a), such that single-domain grains (0.03–0.05 µm) have a higher remanence than larger multidomain grains. Grains of superparamagnetic size effectively carry no remanent magnetization at temperatures where they are superparamagnetic.

An IRM is acquired in a strong DC field ( $H_{IRM}$ , generally >10 mT) of known intensity and direction. All ferrimagnetic grains with a coercivity less than or equal to  $H_{IRM}$  will be remagnetized. Since IRM is a strong-field remanence the imparted magnetization is not linearly related to  $H_{IRM}$ . If the applied field is below saturation and if only

**Figure M56** (a) Variation in the intensity of anhysteretic remanent susceptibility ( $k_a$ , intensity of ARM normalized for the applied DC field) as a function of grain size in magnetite. (b) Variation in intensity of saturation IRM in different magnetic minerals as a function of grain size (after Jackson, 1991).

the first-order terms are considered, a symmetric matrix can be assumed for constant  $H_{\rm IRM}$  (Cox and Doell, 1967; Stephenson *et al.*, 1986; Jackson, 1991). Saturation IRM also shows a grain-size dependence for (titano-)magnetite, hematite, and pyrrhotite (Figure M56b).

#### Measurement of the anisotropy of magnetic remanence

All methods that measure the AMR require a laboratory magnetization to be imparted along a set of known directions. The most commonly applied laboratory magnetization is an ARM, although several studies have used other types of magnetization, such as IRM and TRM. Since the remanent anisotropy is a symmetric tensor of second rank, at least six independent measurements must be made to define the tensor. Many measurement schemes for the AMS have been proposed over the years (see Borradaile and Henry, 1997), based on early suggestions of Nye (1957), who suggested 13 positions (Figure M57, excluding position 5 and 9), and Girdler (1961), who suggested nine positions (positions 1-4, 6-8, 10, 11). Cox and Doell (1967) first described a method to measure the anisotropy of IRM (AIRM), using 15 independent positions (1-11, with positions 1, 3, 5, and 7 measured twice). McCabe et al. (1985) proposed using ARM to define the remanent anisotropy; they used the same positions as used by Girdler (1961) to measure AMS

Independent of the type of remanence that is applied and the number of positions that are used, a general procedure is followed. First a sample is demagnetized and its remanent magnetization is measured as a basis for the "demagnetized" or natural remanent state. A laboratory magnetization is then applied along the first axis, the imparted remanent magnetization is measured, and the component due to the imparted magnetization is found by vector subtraction of the natural remanence. The sample is again demagnetized to remove the imparted

**Figure M57** Lower hemisphere, equal area plot that shows the directions of magnetic field used to investigate the acquisition of anisotropic remanent magnetization.

magnetization and the demagnetized state is measured as a control. This procedure is repeated along all the selected field positions, and the measurements are used to define the matrix  $k_r$ . Differences between the best-fit ellipsoid and the individual measurements give the residuals, and these can be minimized by using a least-squares computation. Jackson (1991) proposed that a goodness-of-fit (GoF) can be determined from

$$GoF = RMS/(k_{r1} - k_{r3}) \times 100\%$$

where RMS is the root mean squared residuals normalized to  $k_{\text{mean}}$ . The expression is an estimate of how well the anisotropy ellipsoid is resolved. The ellipsoid can be considered well resolved for GoF values under 10%; typically values are on the order of a few percent.

Stephenson *et al.* (1986) suggested an alternative method to obtain the ellipsoid of anisotropy of remanence. They measured the individual diagonal and off-diagonal matrix elements directly. Here a laboratory remanent magnetization is applied along the sample *x*-axis and the three components of the magnetization are measured. The sample is demagnetized and the same field is next applied along the sample *y*-axis and all the three components of the magnetization are measured. After demagnetization the field is now applied along the sample *z*-axis and the magnetization is measured. This yields nine values that overdefine the tensor and yield a measure of the precision of fit. This method is probably reliable for IRM, since the imparted remanence is relatively large, allowing for accurate determination of the magnetization components oriented normal to the applied field direction. It is less reliable for ARM and TRM where imparted remanences are relatively weak.

## Anisotropy of anhysteretic remanent magnetization (AARM)

The anisotropy of ARM has also been called the anisotropy of anhysteretic susceptibility (AAS), since normalizing the magnetization by the field strength converts it to a pseudosusceptibility. An ARM is acquired from the DC bias field, often on the order of 0.05–0.1 mT, superimposed on the AC field. The strength of the bias field is on the order of one to two times that of the Earth's magnetic field. The intensity of the AC field can be chosen as desired, but is generally less than 300 mT, due to limits of commercially available AF demagnetizing units. This limitation means that an ARM can only be imparted to minerals with low coercivity, such as (titano-)magnetite or pyrrhotite. A detailed description of the measurement procedure is outlined above and has been given in McCabe *et al.* (1985).

Since the coercivity of ferromagnetic minerals, particularly magnetite and titanomagnetite, is dependent on grain size, it is possible to impart an ARM to a particular grain-size fraction during demagnetization in the DC bias field. This is accomplished by switching on the DC bias field in a specific AC field range or coercivity window during demagnetization. The imparted magnetization is known as a partial ARM (pARM). Jackson *et al.* (1988) demonstrated that the method can be used to distinguish if a specific grain-size fraction is responsible for the observed AARM. For example, a high coercivity window (e.g., 80-150 mT) will only magnetize single-domain magnetite, whereas a low coercivity window (e.g., 0-30 mT) would magnetize larger multidomain grains (see "Geological Applications" sections for a practical example).

## Anisotropy of isothermal remanent magnetization (AIRM)

The advantage of AIRM is that a relatively strong DC field is applied to the sample, such that higher coercivity phases may also be magnetized. As stated above, IRM is not linearly related to the applied field; however, a symmetric matrix can be assumed if only the first-order terms are considered. Jelinek (1996) proposed a nonlinear AIRM model that more precisely describes the magnetization phenomena, in which the anisotropy is also described by a symmetric second-order tensor. The typical strength of the applied field is between 5 and 60 mT (Tarling and Hrouda, 1993). Cox and Doell (1967), who proposed the method originally, used an applied field of 700 mT, which is above the saturation of the ferromagnetic phases. The measurement procedure is the same as outlined above. The main difficulty with their method is the complete demagnetization between each imparted magnetization step. If lower fields are used, it should be possible to demagnetize with alternating field (AF) demagnetization. Cox and Doell (1967) rotated their samples in the 700 mT field of an electromagnet to randomize the magnetization, since complete randomization of magnetic domains is reversible.

As with AARM, Cox and Doell (1967) suggested that it is possible to examine a partial IRM. In their case, they proceeded as follows. After measuring the sample magnetized in a 700 mT field, the sample can be subjected to AF demagnetization in a significantly smaller field, e.g., 100 mT. The remaining magnetization is then remeasured. The sample can then be further demagnetized in a stronger field, e.g., 200 mT, and then remeasured. In this manner a set of deviation vectors is produced,

$$D = J_{\rm r} - J_{\rm m}H/H$$

where  $J_r$  is the measured remanent magnetization, which is produced in the field *H*, and  $J_m$  is the mean amplitude of a set of  $J_r$  vectors averaged over all the results from the different directions of the applied field. This gives a set of D(H') for each value of the alternating field demagnetization (*H'*).

Several cautionary notes should be made concerning the method and the magnetization process in AIRM. The first caution is with regard to the accuracy with which a field strength can be applied. A field strength between 5 and 60 mT is in a range where the magnetization of a sample is quickly acquired for (titano-)magnetite and iron sulfides (Figure M58). Slight variations in field strength may lead to apparent anisotropy that is not related to the preferred orientation of ferromagnetic grains. Figure M58 shows a typical IRM acquisition curve for a pelagic limestone. In this example a variation in

**Figure M58** Example of an IRM acquisition curve for a magnetitebearing, pelagic limestone.

IRM intensity on the order of 2%, comparable to the required resolution in the study of AMR, would occur if the field strength varied by only  $\pm 2$  mT.

Caution must also be exercised when measuring the AIRM in pyrrhotite-bearing rocks. A study by de Wall and Worm (1993) demonstrated that the shape of the ellipsoid and degree of anisotropy are dependent on the applied field in rocks containing pyrrhotite. Although the orientations of the principal axes are not affected, they showed that the degree of anisotropy in a sample of isometric pyrrhotite ore varied between 3.8 and 1.05 for applied field strengths between 1.5 and 100 mT, respectively. The authors attributed this effect to the control of the observed anisotropy by magnetocrystalline anisotropy in low applied fields, and by magnetostatic anisotropy, which arises from the cylindrical sample shape, in strong fields. Jackson and Borradaile (1991) reported a similar dependence of AIRM and field strength in hematite-bearing slates, but attributed the effect to different coercivity fractions in the rocks.

It has been noted by Tauxe *et al.* (1990) that following repeated application of an IRM, the coercivity of the specimen increased after exposure to the first high field, so that in spite of demagnetization to remove the previous magnetization, some grains affected by the first field application were no longer affected by subsequent field applications. The authors attributed this effect to hematite grains with metastable domains, which change domain state during the AIRM experiment.

#### Anisotropy of thermal remanent magnetization (ATRM)

Heating a sample above the Curie or Néel temperature of its ferromagnetic phases and cooling it in an applied field will produce a TRM. As outlined in the general procedure, the sample must be first demagnetized. This can be achieved either with AF demagnetization or by heating the rock above its Curie temperature  $(T_{\rm C})$  or Néel temperature  $(T_{\rm N})$ , and cooling in zero field. The rock is then magnetized in the first field direction by reheating above  $T_{\rm C}$  or  $T_{\rm N}$  and cooling in a field of fixed intensity and rate of cooling. It is important that the field intensity and rate of cooling is the same in all heating runs. After measurement of the imparted TRM, the sample is again demagnetized. At least six independent heating steps are necessary to define the tensor, 12 if the sample cannot be demagnetized in alternating fields and must be reheated above the blocking temperature. It is important to control that no chemical alteration has occurred, which could produce new ferromagnetic minerals and affect the acquired TRM. Often a thermomagnetic curve is made on a small piece of the sample to check that the ferromagnetic mineralogy is thermally stable.

As for a pARM, a partial TRM (pTRM) can be acquired if the field applied during cooling is turned on only when cooling through a particular temperature range. This requires accurate monitoring of the temperature during cooling.

#### **Geological applications**

Several examples are presented below to illustrate how AMR can differ from AMS and the type of geologic information that can be obtained from remanent fabrics. The most common method used in examining AMR is AARM. The experimental method is relatively simple and this magnetization method avoids many problems that have been found in applying IRM or TRM. The method is suitable for magnetite- and possibly pyrrhotite-bearing rocks, but not for high coercivity phases, such as hematite. In this case, AIRM and ATRM are more suitable methods. An example is given for AMR in hematite-bearing rocks. In the examples below, the magnitudes of the principal axes of the anisotropy ellipsoids are defined as  $k_1 \ge k_2 \ge k_3$ .

#### AMS and AARM

If the same processes leading to grain orientation affect the ferromagnetic and paramagnetic minerals in a rock, one would expect that the magnetic fabric of both components should be similar. The orientation of the AARM ellipsoid is close to the AMS ellipsoid, and the main difference between the two fabrics is found in terms of the degree of anisotropy, lineation, and foliation. If the two mineral components formed at separate times in the history of the rock or if deformation mechanisms acting on the different mineral components varied, then it is possible that the susceptibility and remanence magnetic fabrics could be different.

The first example illustrates how rock rheology can lead to two different magnetic fabrics. The Lower Paleozoic stratigraphic sequence from the Central Appalachian Fold and Thrust Belt includes the Lower Ordovician Coburn limestone, which is overlain by the Reedsville/ Martinsburg shale in central Pennsylvania, USA. Both lithologies underwent the same deformation during the Alleghenian orogeny. The AMS was measured with an Agico KLY-2 susceptibility bridge, and the susceptibility fabric in the limestones can be characterized by a prolate ellipsoid with  $k_1$  subparallel to pencil structure in the overlying shales, which is also the structural trend of the major fold structures, and  $k_2$  and  $k_3$  distributed in a girdle normal to the  $k_1$  axes (Figure M59). The prolate fabric is the result of a horizontal tectonic compaction superimposed on the vertical bedding compaction. The shales, on the other hand, have oblate AMS ellipsoids with  $k_3$  subparallel to the pole to bedding and  $k_1$  aligned within the bedding plane, subparallel to the pencil structure or fold axis. The bedding compaction controls the susceptibility fabric in the shales.

Magnetite is the major ferromagnetic phase in both lithologies. Anisotropy of ARM was investigated using a 0.1 mT DC bias field with a 150 mT alternating field, and the measurement procedure of McCabe et al. (1985). The AARM of the limestones is similar to the AMS fabric both in the orientation of the principal axes and the shape of the ellipsoid (Figure M59). This suggests that the susceptibility and remanent fabrics in the limestone are both controlled by magnetite. The AARM in the shales, however, is characterized by prolate ellipsoids, in which  $k_1$  is well-grouped and subparallel to the pencil directions and  $k_2$  and  $k_3$  are distributed in a girdle in a plane with  $k_1$  as its pole (Figure M59). This remanent fabric shows that the magnetite grains have been more strongly affected by the horizontal compaction. The difference between the AMS and AARM fabrics can be explained by the fact that paramagnetic clays and phyllosilicates dominate the AMS fabric, which is largely controlled by bedding compaction. The magnetite grains acted as rigid particles in a passive matrix during deformation, and were therefore quicker to respond to the horizontal compression.

In the second example the AARM was determined in the Ordovician Martinsburg Formation from Lehigh Gap in eastern Pennsylvania

**Figure M59** Lower hemisphere, equal area plot showing the orientation of the principal axes of the AMS (upper plots) and AARM (lower plots) for the Coburn limestone (*left*) and Reedsville/Martinsburg shale (*right*). The principal axes  $k_1$  are squares,  $k_2$  are triangles, and  $k_3$  are circles in this and subsequent figures. Bedding plane in shales is shown with the dashed line.

**Figure M60** Lower hemisphere, equal area plots of the AARM for (a) low-coercivity range (0.035 mT bias field, 0–30 mT AF), and (b) high-coercivity range (0.1 mT bias field, 60–100 mT AF). The bedding plane is shown with the dotted line and the cleavage plane with the dashed line.

using ARMs applied in two different coercivity ranges. Samples were taken from the part of the outcrop in which pencil structures are well developed and a bedding and incipient cleavage can be identified. Magnetite and pyrrhotite are the main ferromagnetic phases in the rocks, as determined from IRM acquisition and thermal demagnetization of a multiple component IRM. The AARM was first determined using a 0.035 mT DC bias field with an alternating field of 30 mT, and then using a 0.1 mT DC bias field was turned on between 60 and 100 mT, in which the DC bias field was turned on between 60 and 100 mT. The first application would only affect coarser ferromagnetic grains, whereas the higher coercivity range would selectively magnetize finer grain sizes (Figure M56a). Figure M60a shows that the low

coercivity AARM fabric is not well defined, but the anisotropy is loosely related to tectonic compaction. This suggests that the coarser grain were less efficient in orienting in the strain field. The high coercivity fabric is well-defined and characterized by a triaxial ellipsoid, in which the  $k_3$  axes are subparallel to the pole to cleavage, and  $k_1$  axes mirror the pencil lineation.

#### AIRM

Tan and Kodama (2002) investigated paleomagnetic directions in the Mississippian Mauch Chunk Formation in eastern Pennsylvania. They found that the inclination of the ChRM was shallower than the

**Figure M61** Lower hemisphere, equal area plots of the AIRM for undemagnetized samples (upper left) and thermally demagnetized samples (upper right) from red beds of the Mauch Chunk Formation. expected direction and used AMR to see if the ferromagnetic grains showed preferential flattening in the bedding plane. Hematite is the sole ferromagnetic carrier in the red beds, and the ChRM was isolated in thermal demagnetization above 670°C. IRM acquisition curves indicate that 85%-90% of the saturation IRM is activated in an applied field of 1.2 T. The AMS in the rocks has a degree of foliation on the order of 1.01 to 1.04, which would not result in a significant inclination flattening. An IRM was applied along nine directions following the method of McCabe et al. (1985) using a 1.2 T impulse field, and the tensor solution was found using a method outlined in Tauxe (2002). Samples were heated to 670°C and cooled in zero field, so that only the ChRM-bearing hematite retains an IRM. In this manner the magnetic fabric due to the grains that are responsible for the ChRM can be isolated. The AIRM shows that the  $k_3$  axes are well-grouped along the pole to bedding in both the undemagnetized and thermally demagnetized samples (Figure M61). The  $k_1$  and  $k_2$  axes lie in the bedding plane and are slightly better grouped in the undemagnetized samples. Both sets of data show the same degree of lineation, but the demagnetized samples show a slightly higher degree of foliation (Figure M61). In both AIRM cases the degree of flattening is almost an order of magnitude higher than in the AMS. Tan and Kodama (2002) used the AIRM and AMS data to obtain an individual particle anisotropy factor, which was then used to correct the paleomagnetic inclination. They could show that, after correction, the expected inclination was in good agreement with a European igneous paleopole of the same age.

#### AMS, AARM, and ATRM

Selkin et al. (2000) made a combined study of AMS, ATRM, and AARM in an anorthositic layer from the Upper Banded Series of the Precambrian Stillwater complex. The susceptibility fabric, which was measured with a KLY-2 susceptibility bridge, is compatible with the preferred orientation of plagioclase crystals in the samples, where  $k_3$ is normal to the foliation plane of the rock and  $k_1$  is close to the *c*-axis orientation of plagioclase (Figure M62a). Thermal demagnetization data indicates that titanium-poor magnetite is the main ferromagnetic phase in the samples. The AARM was measured in a 0.05 mT DC bias field and 180 mT alternating field using six different positions. The ATRM was determined by heating the samples to 600°C and cooling in a 25  $\mu$ T field in air; six positions were used to define the tensor. The two different remanent fabrics are similar, but distinctly different from the susceptibility fabric (Figure M62b,c). The AARM and ATRM ellipsoids are prolate with  $k_1$  well-grouped, coinciding with the pole to the foliation plane defined by the plagioclase crystals and k<sub>3</sub> constrained in the direction of the plagioclase c-axes. The authors interpret these results as showing that single-domain magnetite grains are responsible for the remanent anisotropy. Needles of single-domain magnetite have been identified by TEM in plagioclase in various intrusions, including

**Figure M62** Lower hemisphere, equal area plot for the magnetic fabric of an anorthosite sample, measured by (a) AMS, (b) ATRM, and (c) AARM. Large black symbols show the principal axes of the plagioclase fabric, and small black symbols are the site mean averages of the individual sample measurements (open symbols). *P* is the degree of anisotropy  $(k_1/k_3)$ , *L* is the degree of lineation  $(k_1/k_2)$ , and *F* is the degree of foliation  $(k_2/k_3)$  (after Selkin *et al.*, 2000).

the Stillwater complex, and often the needles are perpendicular to the plagioclase *c*-axes. Further support for this interpretation was obtained from hysteresis loops made along the direction of the principal axes of the remanence ellipsoids. Single-domain magnetite could also be responsible for an inverted magnetic fabric in susceptibility anisotropy. However, the same fabric would be obtained if paramagnetic minerals are responsible for the AMS. The AMR was used to correct estimates of paleointensity, which were affected by the preferential alignment of the magnetite grains.

### MAGNETIC SHIELDING

There are numerous uses for magnetic shields in research and consumer electronics. In geophysical research, magnetic shields are used in paleomagnetic laboratories to protect samples and improve the performance of sample magnetometers. Research shields range in size from 10 cm to 15 m.

The irony in magnetic shielding theory is that a shield actually adds another magnetic field. This new field is specifically designed to be equal and opposite to the existing field, resulting in a nullification of, not a removal of the ambient magnetic fields. This is analogous to gravitational forces at Lagrangian points, or the balance of centripetal and gravitational forces on orbiting bodies, or noise cancellation by antiphase headphones.

#### Materials used

Diverse materials and techniques are used for magnetic shielding. The choice depends on the kind of fields to be opposed (e.g., AC vs DC) and the specific application. In general, shielding can be accomplished by using one of two physical phenomenon, either electrical conductivity or strong magnetic responses. Electrical conductors carry currents that produce a magnetic field perpendicular to the current direction. To generate these currents in a conductive sheet, there must be an original, varying magnetic field. Within the conductor, these currents produce a new magnetic field in the opposite direction to this exciting field (Lenz's law). By surrounding a site with a good conductor, the volume will be shielded from varying fields coming from all directions. The important parameters for efficient shielding by conductors are: conductivity and thickness of the shielding material, frequency of the magnetic field, and the completeness of enclosure. Of course, electrical wires can be powered externally to produce a magnetic field of almost any configuration, including the nullification case of shielding. This will be considered in detail later.

Materials with strong magnetic properties, usually metals containing Fe, Ni, or Co, can react to changing magnetic fields by generating an oppositely directed field (magnetic permeability) or can be tuned to oppose a steady field (magnetic remanence). Efficient shielding by magnetic materials depends on the material, its treatment history, as well as the ambient field characteristics of frequency, strength, gradient, and source direction.

#### Sources of magnetic fields

The goal of magnetic shielding can be either to nullify ambient magnetic fields (external source shielding, described in detail later) or to nullify local, instrument-generated magnetic fields (internal source shielding). Many consumer electronics and medical diagnostic instruments generate large local magnetic fields. Here the goal of shielding is to protect other circuits and conductors within the instruments from unwanted induced currents, and to allow the normal functioning of other, nearby electronic equipment. The larger the source field, the more important shielding becomes. Significant care and expense is taken to shield the immediate environment from monitors and TVs (cathode-ray tube types), and nuclear magnetic resonance (NMR) instruments. Since these internal sources generate rapidly varying magnetic fields, the shielding material must have either high magnetic permeability or high conductivity.

External source shielding has the challenge of encountering a different magnetic environment (differences in frequency, strength, and direction) in each location. In theory, the entire range of the electromagnetic spectrum could be shielded against, but an equally broad range of shielding materials would need to be used simultaneously. Great design simplifications can be realized by restricting the shielding to a specific frequency or a narrow range of frequencies.

#### Shielding in paleomagnetic research

Paleomagnetic research uses shields to protect samples during remanence measurements and during demagnetization experiments. In general, shielding design focuses on the reduction of DC fields (stable in the time domain). Most laboratory sites have large field gradients owing to the steel in pipes, ducts, building framework, furniture, and research equipment. Where space permits, some laboratories have fabricated specific, isolated buildings without steel components, to create a low-gradient environment. Isolation from varying field sources is another critical design feature. These sources can be: vehicles (moving or parked), elevators (especially piston types), steel doors, steel containers, mass spectrometers, magnetic mineral separators, circuit panel boxes, and electric-powered mass transit.

Three different shielding techniques are used in paleomagnetic laboratories: coils, high-permeability magnetic sheets, and remanent magnetic sheets. Current flow in coils of wire can be adjusted to produce any magnetic field desired, including a field that matches, but is in the opposite direction to, a component of the ambient field. Sets of coils can be configured to control a component of the field over a specified volume, e.g., a pair of coils, spaced apart a distance equal to their radius (the Helmholtz arrangement). For a review of other multicoil arrangements see Kirschvink (1992). The advantages of coil systems are: relatively low cost, open arrangement, flexible positioning, and adjustable field strength (net fields other than zero). Disadvantages are: small-shielded volume relative to apparatus size (shielded volume to coil volume about 1:100), the need for a large DC power supply, continuous cost for electrical power, and difficult access to the shielded center of a three-component set.

High-permeability magnetic materials are extensively used for research shielding. Nickel-rich metals are common, along with newly developed materials such as glass and amorphous metals. Rolled into cylinders, these shields can be arranged concentrically to provide excellent shielding. Design considerations for these cylindrical shields are: orientation (optimum direction of cylinder axis is perpendicular to the field), open or closed ends (open-ended cylinders have higher fields at least 2 diameters inside), and treatment history (both metallurgical and magnetic degaussing). Small room-sized shields have been made from high-permeability sheet material (Patton and Fitch, 1962). There are hybrid designs for these larger shields that utilize low-cost remanent materials for the bulk of the shielding. The high-permeability magnetic materials are used only as an inner shield, taking advantage of their ability to react to (shield against) weak and variable magnetic fields. The advantages of high-permeability magnetic materials are: effective shielding over a wide range of frequency and field strengths, including DC fields. Disadvantages are: cost, annealing and processing restrictions on size and shape, and permeability reduction if deformed.

Remanent magnetic materials have been extensively used (since 1980) for large volume, room-sized shields (Scott and Frohlich, 1985). Originally developed for the transformer industry, silicon steel alloys are used as magnetostatic shields in many paleomagnetic laboratories. Magnetostatic or DC shielding incorporates a series of design simplifications that allow the fabrication of large (15 m) and user-friendly enclosures (open doorways and windows). Therefore, an entire paleomagnetic laboratory along with thousands of specimens can be contained inside a shielded enclosure. Remanent shielding materials must be magnetically tuned (using anhysteretic remanence) to generate the balanced opposing (or shielding) field. The advantages of remanent magnetic materials are: low cost, wide range of size, and high magnetic field strength. Disadvantages are: postfabrication tuning (remagnetization) is required, and ineffective shielding against variable magnetic fields.

One distinguishing feature of shields that use magnetic materials is the concentric layers of shielding material, referred to as shielding stages. While the typical two-stage shield provides a sufficient field reduction for many applications, shields with up to six stages have been fabricated for specific research applications. Each shielding stage can only respond to the magnetic field where it is located, so that interior stage shields respond to much smaller fields than the initial (outermost) shield. Therefore, interior shields are less effective in both absolute strength and percent reduction in residual fields. This is caused by the reduced magnetic alignment in weaker magnetic fields, called the Langevin alignment function. This applies to both high-permeability materials (permeability is much smaller in lower fields) and in remanence shields (the smaller biasing field lowers the strength of anhysteretic remanence). Using a three-stage shield as an example, we start with the outer stage in the Earth's field (50000 nT), which can reduce the interior field by 95% (down to 2500 nT). The middle stage is in the 2500 nT field, and can reduce the interior field by 90% (down to 250 nT). The inner stage is in the 250 nT field, and can reduce the interior field by 80% (down to 50 nT). Most shields are assembled starting with the outer shield, progressively adding stages to the interior. The residual interior field provided by a magnetic shield is proportional to both the initial strength of the ambient magnetic field, and to the magnitude of pre-existing field gradients.

The spacing between shielding stages is approximately 10% of the shield diameter. Why so far apart? And why not fill the interval between the stages with shielding material? Wills (1899) examined these questions in detail for both the two- and three-stage cases. Counterintuitively, his numerical (2D) models showed that for two-stage shields the residual field was five times higher if the area between the shielding stages was solid. Theoretically, this decreased shielding with increased mass is analogous to the decreased field from a single-domain particle as it increases in volume to a multidomain state. Thick magnetic material will magnetically interact with itself, in a process of self-cancellation that produces a small external field. Likewise, the spacing between stages allows each stage to be magnetically independent, instead of being linked by dipolar interaction into a lower energy state. Wide spacing between stages is also an important design feature when large field gradients are present.

If the goal is to shield against high-frequency fields (>100 Hz), then thick electrically conductive sheets are used. Thickness is an advantage in this case, where the conductivity phenomenon of skin-depth is important. Induced electric currents should be able to flow uninterrupted in any direction, thus generating the opposing magnetic field. With conductive materials, multiple shielding stages are not as useful as concentrating the material in a single, thick layer. At low frequencies (<100 Hz), the rate of change of the magnetic field will not be able to generate sufficient current flow to create the opposing magnetic field. In the case of biological research, the shielding must respond to a wide range of frequencies, therefore dual material shields are usually fabricated. One of the design challenges is that these two materials react orthogonally. Conductive material react to magnetic fields that arrive perpendicular to the sheet, as compared to magnetic material that react to magnetic fields that arrive parallel to the sheet.

#### MAGNETIC SURVEYS, MARINE

#### Definition

A marine magnetic survey is the measurement of Earth's magnetic field intensity or its components (such as vertical component) along a series of profiles over an area of interest with the objective of measuring the magnetism of the ocean floor. The seafloor is known to be highly magnetized in a pattern of magnetic stripes that record the history of Earth's magnetic field behavior, which in turn, allows marine scientists to determine the age and history of seafloor spreading in the ocean basins (see Vine-Matthews-Morley hypothesis). Magnetic surveys are also used to locate a concentration or absence of magnetic minerals in the search for economic ore deposits (Sheriff, 1981). Variations in the observed magnetic field from the predicted regional field are called magnetic anomalies and are attributed to variations in the distribution of materials having different magnetic polarity, remanent magnetization, and/or susceptibility. The SI units of measurement for Earth's magnetic field intensity are nanoteslas (nT) or in the older cgs system gammas, where 1 gamma is equal to 1 nT. Earth's magnetic field intensity varies between 30000 and 60000 nT and magnetic anomalies measured at sea are typically in the range of 1-1000 nT.

#### History of marine magnetic surveying

Magnetic field measurements have been made at sea since the early days of marine exploration, although these consisted primarily of directional measurements for declination and inclination (see History of geomagnetism, Voyages making geomagnetic measurements, Halley, Carnegie Institute of Terrestrial Magnetism). One of the first observations that magnetic fields at sea may be caused by seafloor geologic sources was made by Cole (1908) who compiled a declination chart of the western Atlantic Ocean around Bermuda in which "sources of considerable disturbance" could be discerned. The research vessel (R/V) Carnegie (see Carnegie research vessel) carried out the first global marine magnetic surveys for the purpose of mapping Earth's magnetic field. During World War II, the rise of submarine warfare precipitated the development of magnetic airborne detectors (MAD); a self-orienting fluxgate magnetometer flown by an aircraft above the ocean to detect submerged submarines (Rumbaugh and Alldredge, 1949). This development allowed for continuous magnetic field intensity measurements to be made at sea. After the war, one of these magnetometers was modified into a towed marine magnetometer (Heezen *et al.*, 1953) and in 1948 the first shipboard magnetic anomaly profile was collected across the Atlantic Ocean from Dakar to Barbados with R/V Atlantis. The profile crossed the then unknown Mid-Atlantic Ridge and recorded a strong anomaly over the rift valley that is now known to be the Brunhes central anomaly that marks the locus of the active mid-ocean ridge spreading center where new crust is being created at the seafloor. Strong magnetic lows were also found over the flanks of the ridge, which are now known to be the reversed crust of the Matuyama Chron and again part of the seafloor spreading magnetic stripes (see *Vine-Matthews-Morley hypothesis*).

In 1954, Arthur Raff at Scripps Institution of Oceanography began using a fluxgate magnetometer based on the Lamont design. Raff worked with Russell Varian and Martin Packard to calibrate the ship-towed magnetometer against their newly developed proton precession magnetometer that provided an absolute value of Earth's magnetic field intensity (Glen, 1982). Proton precession magnetometers do not suffer from drift problems or require calibration like the fluxgate sensors and is the standard tool of today's magnetic surveying practice. These early surveys proved successful and Arthur Raff teamed up with geophysicist Ronald Mason visiting from Imperial College in London to tow their magnetometer as part of a large bathymetric survey off the west coast of North America using the US Coast and Geodetic Survey (USCGS) ship Pioneer. This survey was published by Raff and Mason (1961) and became one of the key data sets leading to the acceptance of the ideas about how the marine magnetic stripe pattern was recorded by the ocean crust and subsequently preserved by the seafloor spreading process (Dietz, 1961; Hess, 1962).

Today, modern marine magnetometers have a precision of between 1 and 0.1 nT using proton precession sensors, optically pumped cesium magnetometers or more recently, the Overhauser nuclear precession magnetometer (see Observatory instrumentation). While magnetometers are still towed behind ships for conventional surveys, magnetic measurements are also made from a variety of seagoing platforms including deep-diving submersibles (Macdonald et al., 1983), deep-towed sleds (Macdonald, 1977), remotely operated vehicles (ROVs) (Johnson et al., 2002), and autonomous underwater vehicles (AUVs) (Tivey et al., 1997). Airborne magnetic surveys are also an important method of surveying particularly over the sediment-dominated continental shelf areas in the hunt for natural resources of economic value such as oil and gas. The US Naval Oceanographic Office also ran an airborne magnetic survey program called Project MAGNET for many years with the aim of mapping Earth's magnetic field intensity on a global scale (see Project MAGNET).

#### Methodology, analysis, and processing

Sea surface marine magnetic surveys are typically obtained by towing a magnetometer sensor behind a ship. The sensor is towed at the end of a cable with electrical conductors that enable the sensor to be powered and communicated to from the ship (Figure M63). The sensor is towed between 3 and 6 ship lengths behind the ship in order to reduce the magnetic effects of the ship on the measurement. The optimal lateral line spacing for a survey is directly related to the water depth because this is the filtering distance over which the magnetic field has propagated. The typical depth of the ocean ranges between 2 and 6 km so that a line spacing of 2 to 10 km is usually sufficient for most surveys (Figure M64). Magnetic surveying is often done in conjunction with other geophysical techniques such as swath bathymetric surveying, gravity and seismic profiling, any of which may determine the ultimate line spacing required. The best approach to magnetic surveying is to collect profiles perpendicular to the magnetic "grain" or striping that characterizes the ocean basins.

The first step in processing is the removal of noise spikes that may have been produced from external sources, such as motors and generators. At equatorial latitudes it is also usually necessary to remove the diurnal variation in Earth's magnetic field due to the combined effects

of the equatorial electrojet and the weak equatorial geomagnetic field. Diurnal records can be obtained from nearby geomagnetic observatories on land or with a temporarily installed base station on the seafloor. The next step is to merge the magnetic time series data with the ship's position. In the modern era this is easily accomplished with Global Positioning Satellite (GPS) data, but in the past this was perhaps the largest source of error, especially in remote areas of the ocean. Once the position of the magnetic field measurement is known the regional magnetic field is removed to reveal the residual "magnetic anomaly" field. Typically, the predicted regional field is obtained from the global International Geomagnetic Reference Field (see *IGRF*, *DGRF*) spherical harmonic model for the appropriate date and geographical location of the survey. The suitably processed data can then be plotted as wiggle plots (Figure M65) or depending on the data density gridded into a contour map (Figure M66).

Magnetic anomaly highs represent places where the local magnetic field exceeds the regional field and magnetic lows are where the local magnetic field is less than the regional field. For marine magnetic surveys these high- and low-magnetic anomalies correspond to magnetized zones of normal and reverse polarity ocean crust, respectively. The source of marine magnetic anomalies is primarily the volcanic rocks that comprise ocean crust and typically not the overlying

**Figure M65** Map showing the magnetic anomaly wiggles along the tracklines of a marine magnetic survey on the western flank of the Mid–Atlantic Ridge near 26°N. sediments. The magnetic anomalies can be correlated and identified with the predicted anomalies from the geomagnetic polarity timescale (GPTS) and thereby allow for an isochron map of the ocean crust to be generated (Figure M67). This allows for a history of seafloor spreading to be documented (see Figure M68) and for spreading rates to be calculated.

Magnetic anomalies vary in their morphology according to their latitude of formation. Magnetic anomalies arise not only from the magnitude of the magnetization but also the direction of the magnetization. Unlike gravity, which is directed toward Earth's center, magnetic field lines originate on south poles and end on north poles. Thus, magnetic anomalies are centered over the magnetized body at the poles, but offset and phase-shifted at midlatitudes with magnetic lows and highs marking the north and south ends of a normal polarity magnetized body. At the equator a normal polarized body produces a magnetic low. These phase shifts can be compensated for by either reducing the anomaly to the pole (see *Reduction to pole*) or by computing the crustal magnetization (Figure M67).

Magnetic surveys are also collected with deep-towed sensors or other moving platforms such as submersibles or AUVs (see for example Tivey *et al.*, 1997, 2003). Such surveys are usually detailed studies encompassing small areas of the seafloor (<10 km). Additional

processing steps are required in the analysis of these kinds of data. The depth and height above the seafloor of the vehicle or platform must be known with some precision. Various algorithms exist to continue the data from an uneven observation surface onto a level observation

plane above the topography (see Tivey *et al.*, 2003). If the type of magnetic sensor used in the survey is a vector magnetometer rather than an absolute sensor then the orientation of the vehicle (i.e., its attitude) must also be known. Finally, navigation requires specialized acoustic

ranging to determine the vehicle's position underwater. Once these steps have been completed then the data can be treated like sea surface data by removing the regional field to obtain an anomaly and then calculating a source crustal magnetization.

### MAGNETIC SUSCEPTIBILITY, ANISOTROPY

#### Introduction

The preferred orientation of minerals is typical of almost all rock types. In some rocks, for example, metamorphic mica-schist, it is very strong and visible to the naked eye, while in others, like basalt and massive granite, it is very weak and detectable only by sensitive instruments. It develops during various geological processes, such as by water flow in sediments, by lava or magma flow in volcanic and plutonic rocks, or by ductile deformation in metamorphic rocks, and in turn, these processes can be assessed from it. The preferred orientation of rock-forming minerals has been measured in thin sections using microscope and universal stage analysis since the beginning of the 20th century, while today, more sophisticated techniques have been developed (e.g., X-ray pole figure goniometry, neutron pole figure goniometry, and electron backscatter diffractography).

Magnetic minerals, mostly occurring in rocks in accessory amounts, show preferred orientation. This orientation, called magnetic fabric, can be advantageously investigated by means of magnetic anisotropy, a technique based on the directional variability in magnetic properties. For example, the magnetic susceptibility of hematite or pyrrhotite crystal is an order of magnitude higher within the basal plane than along the c-axis, thus constituting the magnetocrystalline anisotropy. In magnetite grains, the susceptibility is the highest along the longest dimension of the grain, and lowest along the shortest dimension regardless of the orientation of crystal lattice. This anisotropy is called shape anisotropy. If the magnetic grains are oriented preferentially in a rock, the rock shows magnetic anisotropy. Modern instruments are sensitive enough to be able to measure anisotropy in almost all rock types with sufficient accuracy. In addition, this technique is so sensitive that in rocks with a very weak-preferred orientation of minerals (e.g., some volcanic rocks), it is the only method that gives reasonable results. This technique is also extremely fast, an order of magnitude faster than classical methods of structural analysis. For these reasons, anisotropy has experienced broad use in many branches of geology and geophysics and has become one of the most important techniques of modern structural geology.

#### Principles of anisotropy of magnetic susceptibility

The magnetization (M) of a magnetically isotropic substance is dependent on the intensity of the magnetizing field (H) as follows:

$$M = kH$$

where k is the magnetic susceptibility, independent of the field in paramagnetic and diamagnetic substances and being a complex function of the field in ferromagnetic *sensu lato* (in a broad sense) substances. In weak fields, in which the so-called initial susceptibility is measured, the susceptibility is also constant in ferromagnetic *sensu lato* substances.

If in magnetically anisotropic rocks, the magnetization is no longer parallel to the magnetizing field, then, the relationship between the magnetization and the intensity of the weak field is described in a more complex way by a set of three equations:

$$M_1 = k_{11}H_1 + k_{12}H_2 + k_{13}H_3$$
$$M_2 = k_{21}H_1 + k_{22}H_2 + k_{23}H_3$$
$$M_3 = k_{31}H_1 + k_{32}H_2 + k_{33}H_3$$

where  $M_i$  (i = 1, 2, 3) are the components of the magnetization vector,  $H_j$  (j = 1, 2, 3) are the components of the vector of the intensity of magnetic field, and  $k_{ij}$  ( $k_{ij} = k_{ji}$ ) are the components of the symmetric second-rank susceptibility tensor that reflects the directional variation of susceptibility in its shape. The susceptibility is the highest in one direction and the lowest in a perpendicular direction. In these two

directions and in a direction perpendicular to them, the magnetization is parallel to the field. In the Cartesian coordinate system defined by these directions, the above equations simplify to:

$$M_1 = k_{11}H_1$$
$$M_2 = k_{22}H_2$$
$$M_3 = k_{33}H_3$$

The components  $k_{11} \ge k_{22} \ge k_{33}$ , often denoted as  $k_1 \ge k_2 \ge k_3$ , or  $k_{\text{max}} \ge k_{\text{int}} \ge k_{\text{min}}$ , are called the principal susceptibilities (the maximum, intermediate, and minimum susceptibilities) and their directions are the principal directions. The susceptibility tensor, even though mathematically rigorous, is simple and elegant and is nonillustrative from a geological point of view. Fortunately, it can be geometrically represented by the susceptibility ellipsoid or AMS ellipsoid (for details see Nye, 1957) that are quite illustrative and frequently used in geological interpretations of AMS; their definitions are clear from Figure M69. The axes of the AMS ellipsoid are parallel to the principal directions and the semiaxes lengths equal the principal susceptibilities.

AMS can be measured with various instruments (e.g., low-field torque meter, AC induction bridge, anisotropy spinner magnetometer), their principles being described in another entry of this volume. Nevertheless, the principle of the AMS determination lies in measuring the susceptibility of a specimen in at least six independent directions, and subsequently fitting the susceptibility tensor to these data using the least-squares method (Figure M70). Measuring susceptibility in more than six directions enables the error in fitting the tensor as well as the errors in determining the principal susceptibilities and principal directions to be evaluated.

**Figure M69** Definition of the susceptibility ellipsoid and AMS ellipsoid. Legend: OH, direction of external magnetic field  $H_{ex}$ ; OM, anisotropic magnetization induced by  $H_{ex}$ ; OC, component of magnetization parallel to  $H_{ex}$  or the quantity measured by usual methods. If \vert  $H_{ex}$  \vert = 1, OC is the susceptibility parallel to  $H_{ex}$  (directional susceptibility). Loci of H, where  $OH = 1/\sqrt{OC}$ , represents the susceptibility ellipsoid (heavy line) and the loci of M (thin line) is the AMS ellipsoid. The dashed line represents the directional behavior of the directional susceptibility; note that it is not represented by an ellipsoid. (Adapted from Nagata, 1961.)

For each principal direction, two error angles are determined that delimit a region within which the true principal direction lies with a probability of 95% (Figure M71; for details see Jelínek, 1977).

The theory of AMS in rocks works with field-independent susceptibility that results from the linear relationship between magnetization and the magnetizing field. This is valid in diamagnetic and

**Figure M70** Rotatable design (independent of the coordinate system) of measuring directions used in the Jelínek (1977) method for the AMS determination. Besides, some instruments measure a slowly rotating specimen; consequently, a much larger set of directional data is obtained. (After Jelínek, 1977.)

paramagnetic minerals by definition, as well as in ferromagnetic minerals *sensu lato*, provided that the fields used in common AMS meters are weak enough so that the initial susceptibility is measured. Recently it has been shown that this is true for magnetite, while the susceptibility of pyrrhotite, hematite, and titanomagnetite may be field-dependent. This may theoretically result in the invalidity of the AMS theory in rocks whose AMS is carried by these minerals. Fortunately, the recent investigations have also shown that this effect does not manifest in the orientations of the principal susceptibilities and the AMS ellipsoid shapes. It affects only the degree of AMS, that can be corrected by relatively simple means (de Wall, 2000; Hrouda, 2002). Consequently, the simple and elegant linear AMS theory may be still in use.

The causes of the magnetic anisotropy of rocks are usually summarized as follows: (1) the alignment of nonequidimensional grains, (2) the lattice alignment of crystals with magnetocrystalline anisotropy, (3) the alignment of magnetic domains, (4) the stringing together of magnetic grains (this is special case of (1)), (5) stress-induced anisotropy, and (6) exchange anisotropy (Banerjee and Stacey, 1967). Extensive investigations of magnetic anisotropy have shown that the dominant factors are (1) and (2) (Tarling and Hrouda, 1993).

The eccentricity and shape of the AMS ellipsoid can be characterized by parameters derived from the relationship between the principal susceptibilities. More than 30 such parameters have been introduced (see Tarling and Hrouda, 1993), despite two are sufficient to do so. The most commonly used are:

- $P = k_1/k_3$ —degree of AMS
- $P_j = \exp\{\{2[(\eta_1 \eta)^2 + (\eta_2 \eta)^2 + (\eta_3 \eta)^2]\}$ —corrected degree of AMS
- $L = k_1/k_2$ —magnetic lineation
- $F = k_2/k_3$ —magnetic foliation
- $T = (2\eta_2 \eta_1 \eta_3)/(\eta_1 \eta_3)$ —shape parameter
- $q = (k_1 k_2)/[(k_1 + k_2)/2 k_3]$ —shape parameter

where  $\eta_1 = \ln k_1$ ,  $\eta_2 = \ln k_2$ ,  $\eta_3 = \ln k_3$ ,  $\eta = (\eta_1 + \eta_2 + \eta_3)/3$ . The parameters *P* and *P<sub>j</sub>*, being interrelated as  $P_j = P^a (a = \sqrt{T^2/3})$ , indicate the intensity of the preferred orientation of the magnetic minerals in a rock. The parameters *L* and *F* characterize the intensity of the linearparallel and planar-parallel orientations, respectively. The direction of magnetic lineation is parallel to the maximum susceptibility, while the magnetic foliation pole is parallel to the minimum susceptibility (Figure M72). The parameters *T* and *q* characterize the shape of the AMS ellipsoid. If 0 < T < +1 or 0 < q < 0.7 the AMS ellipsoid is oblate (the magnetic fabric is planar); T = +1 or q = 0 means that the AMS ellipsoid is rotationally oblate. If -1 < T < 0 or 0.7 < q < 2 the AMS ellipsoid is prolate (the magnetic fabric is

**Figure M72** Definition of magnetic foliation and magnetic lineation with respect to the AMS ellipsoid. (Adapted from Siegesmund *et al.*, 1995.)

linear); T = -1 or q = 2 means that the AMS ellipsoid is rotationally prolate.

The eccentricity and shape of the AMS ellipsoid can be represented graphically using two types of AMS plots (Figure M73a,b). In the first type (Figure M73a), the magnetic foliation (F) is plotted on the abscissa and the magnetic lineation (L) on the ordinate, analogous to the Flinn plot used by structural geologists. In the second type of plot (Figure M73b), the degree of AMS (P or  $P_j$ ) is as abscissa and the T parameter is the ordinate. The first plot type is convenient for the AMS of deformed rocks because it formally resembles the deformation plot used by structural geologists. The second plot type is convenient in cases when the degree of AMS is of primary interest.

The orientations of the directions of the principal susceptibilities are usually presented on the lower hemisphere of an equal-area projection. The general convention is to use square symbols for  $k_1$ , triangles for  $k_2$ , and circles for  $k_3$ .

#### AMS of minerals

Whereas in paleomagnetism only ferromagnetic minerals *sensu lato* are important, most frequently represented by magnetite, hematite, and pyrrhotite, since they carry a remanent magnetization, in the AMS are important not only these minerals, but also some paramagnetic ferromagnesian silicates, as for example olivine, pyroxene, augite, hornblende, mica, and diamagnetic calcite. The AMS of these minerals are presented in Table M5, in terms of the degree of AMS, the shape parameter, and the AMS type. The AMS of hematite and pyrrhotite is magnetocrystalline in origin and extremely strong. In ferromagnesian silicates and in calcite, the AMS is also magnetocrystalline but much weaker.

**Figure M74** Relation between the degree of grain AMS ( $P_g$ ) and the dimension ratio a/b of prolate spheroid (titano-)magnetite grains for various values of intrinsic susceptibility (SI). (Adapted from Hrouda and Tarling, 1993.)

Magnetite displays shape anisotropy depending on the eccentricities of the grains and on the intrinsic susceptibility of the mineral. The degree of grain AMS is then (Uyeda *et al.*, 1963)

$$P = (1 + \kappa N_{\rm c})/(1 + \kappa N_{\rm a}),$$

where  $\kappa$  is the intrinsic susceptibility, which is isotropic and dependent only on the chemical composition of the mineral, and  $N_a$  and  $N_c$  which are the demagnetizing factors along the longest and shortest grain axes, respectively, solely depending on the grain shape. The quantitative relationship, though straightforward, is relatively complex, described by formulas containing elliptic integrals. Figure M74 shows this relationship quantitatively. It is obvious that grains with a lower intrinsic susceptibility show a lower degree of AMS than the grains with a higher intrinsic susceptibility having exactly the same shapes. Consequently, the AMS data for magnetite presented in Table M5 are only informative.

Rock susceptibility, in general, is controlled by all minerals present in a rock. Figure M75 shows model contributions of individual mineral groups. In strongly magnetic rocks, with a bulk susceptibility higher than  $5 \times 10^{-3}$  (SI units), the effect of mafic silicates is negligible and the rock susceptibility is effectively controlled by magnetite only. In weakly magnetic rocks, with bulk susceptibility less than  $5 \times 10^{-4}$ (SI units), the content of ferromagnetic minerals is often so low that the susceptibility is effectively controlled by mafic silicates. In rocks with a bulk susceptibility between  $5 \times 10^{-4}$  and  $5 \times 10^{-3}$  (SI units), the AMS, in general, is controlled by both ferromagnetic and paramagnetic minerals. If the bulk susceptibility is less than  $5 \times 10^{-5}$  (SI units), neither the effect of diamagnetic fraction (the calcite in marble) is negligible.

## Quantitative relationship between AMS and mineral preferred orientation

The AMS of rocks is controlled not only by the intensity of the preferred orientation of magnetic minerals, but also by their grain AMS. The effect of these factors is obvious from a simple model in which the degree of AMS of the rock ( $P_s$ ) is plotted against the degree of AMS of the magnetic grains ( $P_g$ ) for different intensities of the preferred orientation of the principal axes (characterized by parameter *C* in Figure M76). If the grain anisotropy is small (similar to that of magnetite and phyllosilicates), the rock AMS is controlled by both the grain AMS and the intensity of the preferred orientation. If the grain AMS is high (as in hematite and pyrrhotite), the rock AMS is controlled solely by the intensity of the preferred orientation of the magnetic axes.

The preferred orientation of minerals in rocks is traditionally represented by density diagrams presented on equal-area projections. The density that maps the preferred orientation of a specific crystal axis can be described mathematically by the orientation tensor, defined as:

$$\mathbf{E} = \frac{1}{N} \begin{vmatrix} \boldsymbol{\Sigma}l_i^2 & \boldsymbol{\Sigma}l_i \boldsymbol{m}_i & \boldsymbol{\Sigma}l_i \boldsymbol{n}_i \\ \boldsymbol{\Sigma}\boldsymbol{m}_i \boldsymbol{l}_i & \boldsymbol{\Sigma}\boldsymbol{m}_i^2 & \boldsymbol{\Sigma}\boldsymbol{m}_i \boldsymbol{n}_i \\ \boldsymbol{\Sigma}\boldsymbol{n}_i \boldsymbol{l}_i & \boldsymbol{\Sigma}\boldsymbol{m}_i \boldsymbol{n}_i & \boldsymbol{\Sigma}\boldsymbol{n}_i^2 \end{vmatrix}$$

where  $l_i$ ,  $m_i$ ,  $n_i$  are the direction cosines of the *i*th linear element represented by unit vector and N is the number of the linear elements considered (Scheidegger, 1965). The principal values of this tensor ( $E_1 \ge E_2 \ge E_3$ ) have the following property:

$$E_1 + E_2 + E_3 = 1.$$

Consequently,  $E_1 > E_2 = E_3$  represents a cluster type of distribution, whereas  $E_1 = E_2 > E_3$  corresponds to a girdle-type pattern (Figure M77). In a perfect cluster, in which all linear elements are parallel,  $E_1 = 1$ ,  $E_2 = 0$ ,  $E_3 = 0$ . In a perfect girdle,  $E_1 = 0.5$ ,  $E_2 = 0.5$ ,  $E_3 = 0$ .

A straightforward relationship exists between the orientation tensor and the susceptibility tensor (for a summary see Ježek and Hrouda, 2000). For a rock, whose AMS is carried by a single magnetic mineral, the relationship is:

$$\mathbf{k} = K\mathbf{I} + \Delta \mathbf{E}$$

where **k** is the rock susceptibility tensor, **I** is the identity matrix. For magnetically rotational oblate grains,  $K = K_2 = K_3$ ,  $\Delta = K_1-K$  ( $K_1$ ,  $K_2$ ,  $K_3$  are the grain principal susceptibilities) and **E** is the orientation tensor of the grain minimum susceptibility axes. For magnetically rotational oblate grains,  $K = K_1 = K_2$ ,  $\Delta = K-K_3$ , and **E** is the orientation tensor of the grain maximum susceptibility axes. For the grains displaying so-called perfectly triaxial AMS ( $K_1-K_2 = K_2-K_3$ ),  $K = K_2$ ,  $\Delta = K_1-K_2 = K_2-K_3$  and  $\mathbf{E} = \mathbf{E}_x-\mathbf{E}_z$  is the Lisle orientation tensor, where  $\mathbf{E}_x$  and  $\mathbf{E}_z$  are the Scheidegger orientation tensors of the maximum and minimum axes, respectively.

Since the rock susceptibility is affected by all minerals present in the rock, the theoretical rock susceptibility can be calculated if the susceptibility tensors of all minerals and their relative contributions are known. Unfortunately, this is never known in practice and studies of the quantitative relationship between the AMS and preferred orientation are made only in such rocks in which the contribution of one mineral to the rock susceptibility is dominant. In this case, the model rock susceptibility is:

**Figure M75** Mineral contribution to the susceptibility of a rock. Note that 1% of magnetite contributes more than 100% of phyllosilicates. (Adapted from Hrouda and Kahan, 1991.)

**Figure M76** The dependence of the degree of AMS of a model rock ( $P_s$ ) on the grain degree of AMS ( $P_g$ ) and on the parameter *C* characterizing the intensity of the preferred orientation of the axes of magnetically uniaxial grains. (Adapted from Hrouda, 1980.)

#### $\mathbf{k} = p\Sigma \mathbf{K} = p\Sigma (\mathbf{O}\mathbf{K}_{\mathrm{d}}\mathbf{O}'),$

where  $\mathbf{k}$  is the rock susceptibility tensor,  $\mathbf{K}$  is the magnetic grain susceptibility tensor,  $\mathbf{K}_d$  the diagonal from the grain susceptibility tensor,  $\mathbf{O}$  the matrix specifying the mineral orientation ( $\mathbf{O}'$  is the transposed matrix of  $\mathbf{O}$ ), and *p* the percentage of a magnetic mineral in a rock.

The orientation of magnetic minerals can be investigated either through direct measurement of individual grains (microscope and universal stage methods), through determining the orientation tensor using X-ray pole figure goniometry, or electron backscatter diffraction with orientation contrast. Studies of this type were made for hematite (deformed hematite ore, Minas Gerais, Brazil, Hrouda et al., 1985), biotite (Bíteš orthogneiss, Hrouda and Schulmann, 1990), chlorites (Lüneburg et al., 1999; Chadima et al., 2004), and calcite (Carrara marble, Owens and Rutter, 1978). Results from these studies show that the principal susceptibilities of the whole rock measured are oriented in the same way as those calculated from the crystallographic axis pattern. The degree of AMS and the shape parameter are not always in agreement with that calculated from the crystallographic axis pattern. The differences may reflect the situation that the AMS and X-ray measurements are often not executed on exactly the same specimens, and the respective specimen volumes differ substantially (1 cm<sup>3</sup> vs thin section). In addition, minor effect of other magnetic minerals cannot be excluded. Nevertheless, the agreement between the theoretical and measured AMS can be considered to be satisfactory. Some of these results are illustrated in Figure M78.

# Resolution of AMS into paramagnetic and ferromagnetic components

In rocks with the bulk susceptibility between  $5 \times 10^{-4}$  and  $5 \times 10^{-3}$ , the AMS is, in general, controlled by both ferromagnetic and paramagnetic minerals. As these mineral groups may behave differently in various geological situations, it is desirable to resolve the rock AMS into its ferromagnetic and paramagnetic components. This resolution is usually made through measuring the AMS in various strong magnetic fields of the order of tesla in which the ferromagnetic and paramagnetic minerals behave in a different way (described in an another part

**Figure M77** Relationship between preferred orientation of a linear element and principal values of the orientation tensor. (Adapted from Woodcock, 1977.)

**Figure M79** Susceptibility vs temperature relationship in the temperature interval between room temperature and 200°C for biotite (a) and magnetite (b).

of this volume) or at variable temperatures in which the ferromagnetic and paramagnetic minerals also behave differently.

Variation of the susceptibility of paramagnetic minerals with temperature is represented by a hyperbola, while in ferromagnetic minerals it is a complex curve in case of magnetite characterized by acute susceptibility decreases at about  $-155^{\circ}$ C, the Verwey transition, and at about 580°C, the Curie temperature. Fortunately, in some temperature intervals, typically between room temperature and 200°C, the ferromagnetic susceptibility is either constant or follows only a mildly sloped straight line (Figure M79).

The susceptibility vs temperature curve of a rock containing both ferromagnetic and paramagnetic minerals for the case in which the ferromagnetic susceptibility is constant within the considered temperature interval, is:

 $k = p_{\rm p}C/T + p_{\rm f}k_{\rm f},$ 

and for the case in which the ferromagnetic susceptibility is represented by only a mildly sloped straight line, it is:

$$k = p_{\rm p}C/T + p_{\rm f}(bT + a),$$

where k is the rock susceptibility,  $k_{\rm f}$  the ferromagnetic susceptibility,  $p_{\rm p}$  and  $p_{\rm f}$  the percentages of paramagnetic and ferromagnetic fractions, respectively, C the paramagnetic constant and T the absolute temperature, a and b are constants.

The first equation is that of a hyperbola offset along the susceptibility axis, and the second is a combination of a hyperbola and a straight line. By fitting the hyperbola and straight line either horizontal (first equation), or sloped (second equation) to k vs T curve using the least-squares method, one obtains the paramagnetic susceptibility contribution ( $p_pC/T$ ) and the ferromagnetic susceptibility contribution ( $p_f$  $k_f$  or  $p_f(bT + a)$ ). These methods were developed by Hrouda (1994) and Hrouda *et al.* (1997), respectively, and are broadly used in resolving the mean bulk susceptibility measured on powder specimens into paramagnetic and ferromagnetic components.

Richter and van der Pluijm (1994) developed a technique for the AMS resolution into the paramagnetic and ferromagnetic components based on susceptibility measurements at low temperatures (between the temperature of liquid nitrogen and room temperature). At these temperatures, the contribution of paramagnetic fraction to the rock susceptibility is amplified because of the hyperbolic course. By plotting the reciprocal susceptibility against temperature one can easily visualize the linear paramagnetic susceptibility contribution and separate it from the ferromagnetic contribution. If this measurement is made in six directions, one can obtains six directional paramagnetic and ferromagnetic susceptibility tensor can be calculated in a standard way (Figure M80).

#### Thermal enhancement of the magnetic fabric

The AMS is often measured using the instrumentation of a paleomagnetic laboratory. Paleomagnetic techniques, such as AF demagnetization and thermal demagnetization, have then been logically tested as to whether they are also applicable to the AMS (Urrutia-Fucugauchi, 1981). It has been shown that the AF demagnetization has only weak effect on the AMS and its use ceased. On the other hand, the effect of thermal demagnetization on the AMS can be strong. However, thermal demagnetization mechanisms are different in AMS than in remanent magnetization. Thermal demagnetization affects the induced magnetization very weakly, probably negligibly, but may induce the creation of new magnetic phases or even new minerals. If this creation is made in a zero magnetic field, it would have virtually no effect on the remanent magnetization, but would have a very strong effect on the AMS. Often, the newly created phases are more magnetic than the original phases and may be coaxial to the old phases. Thermal demagnetization, in fact, enhances the original magnetic fabric. Newly created phases can also be noncoaxial, and their creation may obscure the original magnetic fabric. If the new creation is confined to a phase of different origin than the original phase, thermal treatment may "visualize" the cryptic fabric (Henry et al., 2003). Even though positive results may be obtained in this way in some cases, this technique cannot be recommended to be used in a routine way because the process of the creation of new magnetic phases due to specimen heating is very complex, and our knowledge about this is far from complete.

## Statistical evaluation of the AMS data

The AMS technique is so fast that several specimens are usually measured in a site. The site data or the data from geological bodies should be evaluated statistically. The simplest approach is to consider the individual principal directions as vectors and to process them using a vector statistics, for example the Fisher statistics. Unfortunately, the principal directions do not have a Fisherian distribution, being orthogonal and bipolar, so various modifications of the Fisher statistics have been proposed (Ellwood and Whitney, 1980; Park *et al.*, 1988).

To avoid these problems Jelínek (1978) has developed a statistical method that is based on averaging out the individual components of the susceptibility tensors in one coordinate system (e.g., geographical) after they have been normalized against their mean susceptibility. In this way the mean tensor (and the orientations of its principal directions) as well as the elliptical confidence regions (in terms of confidence angles) about each principal direction are computed from the

**Figure M80** Principle of the resolution of AMS into paramagnetic and ferromagnetic components using measurement of low-temperature susceptibility. (a) Six orientations of a specimen used to construct the susceptibility tensor, (b) the relative amount of paramagnetic and ferromagnetic susceptibilities is determined in six orientations from heating curves, the upper curve being the original heating curve and the lower curve being the paramagnetic remnant, and (c) the resolved paramagnetic and ferromagnetic subtensors. variance-covariance matrix (Figure M81). This technique seems to be the most frequently used at present.

In data sets with widely scattered principal directions, neither analytical method provides an adequate visual representation of the observed data. To overcome these disadvantages, Constable and Tauxe (1990) developed a bootstrap method which delineates the confidence regions using Monte Carlo probability modeling.

Statistical evaluation of the AMS data is a complex problem and further investigations are required to evaluate the effectiveness of the individual methods (for discussion see Ernst and Pearce, 1989; Tarling and Hrouda, 1993; Borradaile, 2001).

## Geological applications of AMS

## Magnetic fabric in sedimentary rocks

The AMS in sedimentary rocks provides information on the deposition and compaction processes (for a summary, see Hamilton and Rees, 1970; Rees and Woodall, 1975; Rees, 1983; Taira, 1989; Tarling and Hrouda, 1993; Hrouda and Ježek, 1999). In natural sedimentary rocks unaffected by later deformation, the relationship that is primarily investigated is the agreement between the magnetic foliation and lineation and the sedimentary external structures (sole markings, flute casts, groove casts) and internal structures (cross-bedding, current-ripple lamination, symmetric and asymmetric ripples). It has been found that the magnetic foliation is always oriented near the bedding/compaction plane, while the magnetic lineation is mostly roughly parallel to the near-bottom water current directions determined using sedimentological techniques (see Figure M82). Less frequently, the magnetic lineation may be perpendicular to the current direction, which is typical of the flysch sediments of the lowermost A member of the Bouma sequence. The degree of AMS is relatively low and the AMS ellipsoid is, in general, oblate.

In artificial sediments deposited through grain by grain (or from thin suspension) deposition from still or running water onto a flat or sloping bottom under controlled conditions in tanks and flumes in laboratories, the AMS ellipsoid is clearly oblate; the magnetic foliation dips less than  $15^{\circ}$  from the bedding toward the origin of flow and the magnetic lineation is parallel to the direction of flow, slightly plunging toward the origin of flow.

During deposition from medium-concentrated suspensions, the AMS ellipsoids can be clearly triaxial to slightly prolate, in which the

**Figure M82** Magnetic and sedimentary fabrics in sediments of the Rosario Formation, La Jolla, California (crosses, magnetic foliation poles; open circles, magnetic lineation). Equal-area projection on lower hemisphere (projection plane = bedding plane). (Adapted from von Rad, 1971.)

magnetic foliation dips less than  $15^{\circ}$  toward the origin of flow, and the magnetic lineation is perpendicular to the direction of flow and to the dip of magnetic foliation. During deposition from very concentrated grain dispersions onto a sloping bottom, the AMS ellipsoids are triaxial. The magnetic foliation dips  $25^{\circ}-30^{\circ}$  toward the origin of the flow and the magnetic lineation is parallel both to the flow and to the dip of magnetic foliation, and plunges slightly toward the origin of flow.

During the process of diagenesis, the originally sedimentary magnetic fabric may be slightly modified due to ductile deformation accompanying this process. If the ductile deformation is represented by vertical shortening due to the loading by the weight of the overlying strata, the degree of AMS and the oblateness of the AMS ellipsoid increase, whereas the magnetic foliation and lineation retain their orientations (e.g., Lowrie and Hirt, 1987). If the ductile deformation is represented by the bedding parallel shortening or by the bedding parallel simple shears or by both, the degree of AMS initially decreases and only later increases when the deformation is strong enough to overcome the initial compaction. The magnetic fabric initially becomes more planar, and only later it does become more triaxial or even linear. The magnetic lineation deviates gradually from the direction of flow toward that of maximum strain, often creating a bimodal pattern. The magnetic foliation remains initially near the bedding. After a stronger strain, it deviates from it, creating a girdle in the magnetic foliation poles that are perpendicular to the magnetic lineation.

#### Magnetic fabric in volcanic rocks

The AMS of volcanic rocks is, in general, very weak, reflecting a very poor dimensional orientation of the magnetic minerals (mostly titanomagnetites) in these rocks. In spite of this, their AMS can, in general, be measured precisely because the volcanic rocks are often strongly magnetic, and the AMS seems to be the quickest method to be able to reliably investigate the weakly preferred orientation of the minerals.

Since the first investigations of the AMS of volcanic rocks it has been clear that it reflects the dimensional orientation of magnetic minerals created during a lava flow. The magnetic foliation is often found to be near or even parallel to the flow plane in lava flows, sills, and dikes (Ernst and Baragar, 1992; Cañon-Tapia *et al.*, 1994; Raposo and Ernesto, 1995; Hrouda *et al.*, 2002a). The magnetic lineation is mostly parallel to the lava flow directions (Figure M83), even though perpendicular or oblique relationships can also be rarely found.

AMS enables not only the lava flow process to be investigated, but also the rheomorphic flow in ignimbrites and the motions of tuffs and tuffites (MacDonald and Palmer, 1990).

## Magnetic fabric in plutonic rocks

In plutonic rocks, the AMS is one of the most powerful tools of structural analysis, because it can efficiently measure the magnetic fabric even in massive granites that are isotropic at the first sight. The AMS of plutonic rocks varies from very weak (typical of volcanic rocks) to extraordinarily strong (typical of metamorphic and/or strongly deformed rocks).

Granites, the most important representatives of plutonic rocks, usually display a bimodal distribution of their magnetic susceptibility. One mode corresponds to susceptibilities in the order of  $10^{-5}$  to  $10^{-4}$  SI units and are due to weakly magnetic (Dortman, 1984) or paramagnetic (Bouchez, 2000) granites. These are equated with the S (sedimental) type granites, such as the ilmenite-bearing granites. The other mode has susceptibilities in the order of  $10^{-3}-10^{-2}$  SI units, and this is due to magnetic or ferromagnetic granites. These are equated with the I (igneous) type granites such as magnetite-bearing granites. In magnetic granites, the AMS investigates the preferred orientation of magnetite by grain shape. In weakly magnetic granites, the AMS reflects the preferred orientation of mafic silicates (mainly biotite, and less frequently amphibole) by crystal lattice.

The plutonic rocks that have suffered no postintrusive deformation show the magnetic fabric created during the process of magma emplacement. The characteristic features of this magnetic fabric are as follows: the degree of AMS is relatively low, indicating only weak preferred orientation of magnetic minerals created during the liquid flow of magma; the magnetic fabric ranges from oblate to prolate according to the local character of the magma flow; the magnetic foliation is parallel to the flow plane and the magnetic lineation is parallel to the flow direction; the magnetic foliations are steep in stocks and upright sheetlike bodies in which the magma flowed vertically (Figure M84). On the other hand, it is oblique or horizontal in the bodies where the magma could not ascend vertically and moved in a more complex way. The magnetic lineation can be vertical, horizontal, or oblique according to the local direction of the magma flow. The magnetic fabric elements usually show a close relationship to the shapes of magmatic bodies and to magmatic structural elements, if observable. Many examples are shown in the book by Bouchez et al. (1997).

Some plutonic rocks exhibit a very high degree of AMS and a very high mean magnetic susceptibility. The magnetic fabric in these rocks usually indicates a preferred orientation of magnetite by grain shape that is younger than the fabric of the surrounding silicates and takes its shape from highly anisometric intergranular (interfoliation) spaces. This magnetic fabric is usually termed as the mimetic magnetic fabric (e.g., Hrouda *et al.*, 1971).

Some granites have suffered tectonic ductile deformation after their emplacement. In this process, the originally intrusive magnetic fabric is overprinted or even obliterated by the deformational magnetic fabric. The degree of AMS of such rocks is often much higher, because the ductile deformation is a relatively efficient mechanism for the reorientation of magnetic minerals. The magnetic foliations and lineations deviate from the directions of the intrusive fabric elements toward the directions of the principal strains. A good example includes granites of the West Carpathians whose magnetic fabrics are coaxial with those of surrounding metamorphic rocks and covering sedimentary rocks as result of ductile deformation associated with retrogressive deformation acting during creation and motion of the West Carpathian nappes (Hrouda *et al.*, 2002b).

## AMS of metamorphic and deformed rocks

The AMS of metamorphic rocks in general and even of low-grade metamorphic rocks is considerably higher than the AMS in undeformed sedimentary and volcanic rocks. Hence, the mechanism orienting magnetic grains during low-grade metamorphism is very effective. It probably involves ductile deformation or recrystallization in an anisotropic stress field operating during metamorphism. The AMS therefore enables these processes to be studied.

AMS is an extremely powerful tool in investigating the progressive modification of the sedimentary magnetic fabric by ductile deformation that takes place in accretionary prisms (Figure M85). After sediment deposition, the AMS ellipsoid is usually oblate with the magnetic foliation near the bedding, and if a magnetic lineation is present, it is near the current direction. In initial stages of deformation, represented by

shortening along the bedding, the AMS ellipsoid changes from oblate to triaxial; the degree of AMS may slightly decrease, the magnetic foliation remains parallel to bedding, but the magnetic lineation reorients perpendicular to the shortening direction. In progressing deformation, spaced cleavage develops and the magnetic lineation becomes parallel to the bedding/cleavage intersection line. The AMS ellipsoid becomes prolate. If the deformation continues, giving rise to the development of slaty cleavage, the AMS ellipsoid becomes oblate again, the degree of AMS considerably increases, the magnetic foliation pole reorientates parallel to the cleavage and the magnetic lineation remains parallel to the bedding/cleavage intersection line. If the deformation is very strong, the magnetic lineation may be dip-parallel in the cleavage plane.

AMS can be used in revealing the origin of folds (Hrouda, 1978; Hrouda *et al.*, 2000). Various types of folds differing in terms of the

Figure M84 Magnetic fabric in the Flamanville granite, Normandy, France. Note steep magnetic foliations conforming the magmatic body shape. (Adapted from Cogné and Perroud, 1988.)

relation of the magnetic fabric to the fold curve were found, and simple techniques for the recognition of unfoldable and homogeneous folds were elaborated.

AMS can also be used in deciphering the sense of a shear movement (sinistral or dextral) (Rathore and Becke, 1980). This method is based on the assumption that the minimum susceptibility direction rotates during a simple shear movement in a manner similar to that of the minimum strain direction.

AMS can also be used as a strain indicator of deformed igneous rocks. During the process of deformation, the degree of AMS, in general, increases and the principal directions reorientate into the directions parallel to the strain directions. Studies of this type were made in dikes, volcanic bodies, and granitic rocks (e.g., Henry, 1977).

Strain analysis is one of the most laborious techniques of structural analysis and it is confined to rocks containing convenient strain indicators (oolites, concretions, reduction spots, lapilli, fossils). For this reason, many attempts have been made to use the AMS as a strain indicator. After revealing a close correlation between the directions of principal susceptibilities and principal strains (for examples, see Tarling and Hrouda, 1993), the quantitative relationship between the AMS and strain has been investigated theoretically through mathematical modeling (for review, see Hrouda, 1993), empirically through examining natural rocks with known strain (for review, see Borradaile, 1991), and experimentally through deforming rocks and rock analogs in the laboratory (for review, see Borradaile and Henry, 1997). The first set of formulae describing a quantitative relationship between the AMS and strain was obtained through empirical studies of the AMS and strain (determined through investigation of natural strain markers—reduction spots) in Welsh slates (Figure M86) (Kneen, 1976; Wood *et al.*, 1976):

$$L = (k_1/k_2) = (s_1/s_2)^a$$
  

$$F = (k_2/k_3) = (s_2/s_3)^i$$
  

$$P = (k_1/k_3) = (s_1/s_3)^i$$

or in terms of natural strain:

$$\ln L = a(e_1 - e_2)$$
$$\ln F = a(e_2 - e_3)$$
$$\ln P = a(e_1 - e_3)$$

where  $k_1 \ge k_2 \ge k_3$  are the principal susceptibilities,  $s_1 \ge s_2 \ge s_3$ are the principal strains, and  $\varepsilon_1 = \ln s_1$ ,  $\varepsilon_2 = \ln s_2$ ,  $\varepsilon_3 = \ln s_3$ , are the principal natural strains. In later empirical studies, several other formulae were suggested, but as shown by Hrouda (1982), all of them can be converted, within an error of a few percent, into the above formulae.

In theoretical studies pioneered by Owens (1974), no simple formula for the AMS-to-strain relationship has been found. However, the curves

Figure M85 Scheme of the AMS development in progressively deformed accretionary prisms sediments. (Adapted from Pares *et al.*, 1999.)

representing the ln*P* vs ( $\varepsilon_1$ – $\varepsilon_3$ ) relationship (for summary, see Hrouda, 1993), considering various AMS carriers (magnetite, hematite, pyrrhotite, and paramagnetic mafic silicates), are represented by monotonously rising and only gently curved lines (Figure M87). In small strain ranges, mainly in their initial parts, the lines do not differ very much from straight lines. Consequently, using a reasonable simplification, the theoretical AMS-to-strain relationship can be described in the same way as the empirical AMS-to-strain relationship.

In experimental studies, the AMS of rock analogs deformed in laboratory was investigated (Borradaile and Alford, 1987, 1988). The rock analogs were relatively strongly magnetically anisotropic before deformation, and to describe the AMS to strain relationship the following formula respecting the predeformational AMS was used:

$$P'-P'_0=B(\varepsilon_1-\varepsilon_3),$$

where  $P'_0$  and P' are the corrected degrees of AMS before and after deformation, respectively, and *B* is a constant. Analysis by Hrouda (1991) shows that this relationship can also be converted into the relationship presented for empirical data.

It is obvious from the above analysis that the AMS-to-strain relationship obtained through empirical, theoretical, and experimental studies

Figure M86 AMS to strain relationship in Welsh slates. (Adapted from Kneen, 1976.)

Figure M87 An example of theoretical AMS to strain relationship. Pure shear strain, March model, prolate ellipsoids magnetite grains with variable aspect ratios (a/c). (Adapted from Hrouda, 1993.)

can, with a reasonable simplification, be represented by the formulae first derived for the empirical relationship. Unfortunately, the above studies have also shown that the *a* values are not the same for all rock types, but vary according to the mineral carrying the AMS (Tarling and Hrouda, 1993) and also probably by the lithology of the rock investigated.

Even though a great majority of the empirical studies had revealed a relatively close correlation between AMS and strain, some studies had obtained results suggesting no correlation or even inverse correlation between the AMS and strain (Borradaile and Mothersill, 1984;

Borradaile and Tarling, 1984). This implies that some rocks may have had complex deformation histories in which various rock components responded in different ways to overall strain and such rocks should not be used in the strain determination via AMS. Nevertheless, it is believed that in homogeneously deformed rocks, the AMS can serve as a quantitative strain indicator, which is evident from the great majority of empirical and experimental studies.

Study of the anisotropic properties of magnetic susceptibility and remanent magnetizations is an active field of research in paleomagnetism. These studies have important applications in petrofabrics, structural geology, metamorphism, rock magnetism, volcanology, and tectonics. Here we concentrate on the anisotropy of magnetic susceptibility (AMS) of rocks measured at low magnetic fields, and in particular, on the effects of laboratory heating on the AMS of rocks. Mineralogical changes resulting from heating samples in the laboratory have long been recognized and studied (see Table M6). The potential use of temperature-induced effects to investigate composite magnetic fabrics needs further development.

#### Introduction

The magnetic susceptibility of rocks given by the ratio between magnetization (M) and applied magnetic field (H) exhibits anisotropic properties. These properties have been used to investigate the characteristics of rock fabric (Tarling and Hrouda, 1993).

$$M_i = k_{i,j}H_j$$

The susceptibility  $k_{i,j}$  of anisotropic samples is a second-order tensor (Nye, 1957), which is usually represented in terms of the principal susceptibility axes (maximum  $k_1$ , intermediate  $k_2$ , and minimum  $k_3$ ). The

*Note:* The actual temperatures are strongly dependent on grain size and shape, redox conditions, rate of heating, etc., and are only preliminary and indicative. Similarly, the magnetic product resulting from heating is dependent on the specific redox conditions at that temperature and it is likely that many of these reactions take place slowly at lower temperatures under natural conditions—for example, goethite may change to magnetite at 100°C-120°C under low oxidation conditions (after Tarling, 1983; Tarling and Hrouda, 1993).

AMS is generally measured at low magnetic fields, and several instrumental systems have been developed and commercially produced in the last decades (e.g., Kappabridge, Saphire, Bartington, Digico, Molspin, and PAR-SM2). AMS is also determined from measurements in cryogenic magnetometers.

AMS is usually analyzed in terms of the orientation of the principal susceptibility axes and the AMS parameters. The parameters based on the magnitudes of principal susceptibilities have been proposed to quantify the anisotropy degree, lineation, foliation, and shape of susceptibility ellipsoid (Tarling and Hrouda, 1993). The magnitude and shape of susceptibility ellipsoid have been determined from various plots, which include the Flinn diagram of lineation as a function of foliation and the plot of shape parameter as a function of anisotropy degree (Jelinek, 1981). They permit distinction of susceptibility ellipsoid, with prolate, oblate, and triaxial (neutral) ellipsoids.

In paleomagnetic and rock magnetic studies, several methods have been developed to investigate the temperature dependence of magnetic properties and remanent magnetizations (Tarling, 1983; Dunlop and Özdemir, 1997). These studies use laboratory heating or thermal treatment on samples under controlled conditions (e.g., thermal demagnetization, thermomagnetic measurements, temperature-dependent susceptibility, and paleointensity experiments). Understanding the effects of heating on the magnetic properties and magnetic mineralogy is then an active research field. This note is concerned with the effects of laboratory heating on the AMS of rocks. Thermal treatment has been proposed to enhance AMS in rocks, and used to investigate on temperature-induced fabric changes.

The low-field magnetic susceptibility changes as a result of growth/ destruction/transformation of iron oxides, sulfides and carbonates, and hydroxides. Oxidation and reduction processes occur at different temperature ranges during thermal treatment. Magnetic oxides can result from transformation of iron sulfides (pyrite, pyrrhotite). Several methods have been implemented to study mineral alteration during laboratory heating (e.g., Dekkers, 1990; Van Velzen and Zijderveld, 1992), and to promote, reduce, or avoid oxidation/reduction of magnetic minerals (for instance, use of inert or reducing atmospheres in heating/ cooling chambers of ovens).

Susceptibility is a bulk property, resulting from relative contributions of the diamagnetic, paramagnetic, and ferromagnetic minerals. It depends on its mineralogy, grain size and shape, mineral distribution, crystallographic preferred orientation, layering, etc. Interpretation of AMS in terms of rock fabric can often be complex, particularly for composite or multicomponent fabrics. Thermal treatment has been proposed to enhance and quantify given components of AMS fabric (Urrutia-Fucugauchi, 1979, 1981), where heating produces new magnetic minerals from the phyllosilicates and ferromagnetic minerals, which mimic the crystallographic structure in micas and clays.

#### **Temperature-dependent mineral transformations**

Mineralogical changes resulting from heating samples in the laboratory have long been identified and studied (e.g., Abouzakhm and Tarling, 1975; Urrutia-Fucugauchi, 1979, 1981). Susceptibility increases and decreases during heating results mainly from formation of iron-titanium oxides (titanomagnetites and magnetite) and transformation of oxides (hematization of magnetite), respectively. Magnetic oxides can be produced from a range of minerals and processes, such as iron sulfides, carbonates and silicate minerals, hydroxides, and other iron oxides (e.g., Tarling, 1983; Borradaile *et al.*, 1991; Tarling and Hrouda, 1993; Henry *et al.*, 2003). Lithologies in which iron oxides are not present, other minerals play an important role and constitute special cases that require further investigation.

Pyrrhotite-bearing rocks can display changes due to transformation of antiferromagnetic hexagonal pyrrhotite to ferrimagnetic monoclinic pyrrhotite (Bina *et al.*, 1991). Most often, complex series of mineralogical changes occur at different temperature ranges. Oxidation of pyrrhotite at high temperature results in further susceptibility increase (Dekkers, 1990). Magnetite formation between 500 and 725 °C result in susceptibility increase, which can be followed by decrease at higher temperature as a result of hematization (biotite granites; Trinidade *et al.*, 2001). Mineral transformations depend not only on mineral type, but also on grain size, mineral impurities, time, atmosphere conditions (inert, oxidizing, or reducing conditions), and water content. Temperature-induced changes in the bulk susceptibility and AMS have often been related to the formation of magnetite. Perarnau and Tarling (1985) proposed magnetite formation from vermiculite at 450 °C and from illite at >850 °C.

## Thermal enhancement of AMS

Early studies of AMS thermal enhancement used samples from Late Precambrian tillites, Late Jurassic red beds, and Late Tertiary volcanics (Urrutia-Fucugauchi, 1981). Thermal treatment resulted in enhancing given components of the AMS fabric in the first two cases, and no significant changes in the AMS axis pattern for the volcanic rocks. Thermal enhancement was proposed as a method to study composite fabrics (Urrutia-Fucugauchi, 1979). Subsequent studies applying thermal treatment to glacial deposits, slates, sandstones, and red beds supported that heating enhanced the primary AMS fabric and pointed out the complexity of heating-induced effects on magnetic mineralogy (e.g., Urrutia-Fucugauchi and Tarling, 1983; Perarnau and Tarling, 1985; Borradaile *et al.*, 1991; Borradaile and Lagroix, 2000).

An example of simple thermal enhancement of AMS is illustrated in Figure M88. Samples studied are Cretaceous sandstones sampled near a fault system in Venezuela (Perarnau and Tarling, 1985). The initial fabric is poorly defined with mixed maximum, intermediate, and maximum axes (Figure M88a). Maximum and minimum axes are oriented normal to bedding, and maximum, intermediate, and minimum axes conform a girdle distribution on the bedding plane. After heating to 350°C, the AMS axes pattern changes, resulting in minimum axes preferentially aligned normal to bedding, and maximum axes on the bedding plane and oriented to the north (Figure M88b). The thermal enhanced fabric is interpreted as a depositional sedimentary fabric, resulting from new magnetic minerals that mimic the crystallographic structure and shape of micas and clays. Samples from sites closer to the fault show a fault-parallel oblateness effect (Perarnau and Tarling, 1985).

Composite AMS fabrics are in general difficult to interpret, and several methods have been proposed in an attempt to separate the different mineral contributions (e.g., Hrouda and Jelinek, 1990). Other methods using measurements at high and low fields, low-temperature observations, etc. have also been used contributions (e.g., Rochette and Fillion, 1988; Pares and Van der Pluijm, 2002).

An example of magnetic fabric enhancement of a given component of a composite fabric in glacial sediments induced by laboratory heating is summarized in Figures M89 and M90. Samples used come from a Late Precambrian Port Askaig Formation from southwestern Scotland (Urrutia-Fucugauchi, 1981; Urrutia-Fucugauchi and Tarling, 1983). The mean susceptibility showed little change up to 300-400°C and increased markedly after heating at 400 and 500°C (Figure M90). The orientation of principal susceptibility axes before thermal treatment shows a pattern with vertical minimum axes and maximum axes on the bedding plane (with some scatter; Figure M89a). This pattern conforms that expected for a depositional sedimentary fabric in sediments deposited under the influence of dominant currents (indicated by the lineation). With thermal treatment up to 500°C, there are marked changes in bulk susceptibility and AMS axes pattern (Figure M89b). The maximum axes are grouped close to paleovertical and minimum axes lie in the paleohorizontal plane. Thus, heating-induced changes result in an inverse fabric. The scatter in AMS axes is reduced, which gives a well-defined NW-SE lineation (Figure M89a,b). This new fabric was interpreted in terms of compressional stresses acting parallel to bedding on strata free to extend in directions normal to bedding and compression. Deformation results on lineation increase eventually exceeding foliation, with predominantly prolate-shaped ellipsoids.

Figure M88 Example of thermal enhancement of AMS (for explanation see text).

Figure M89 Example of magnetic fabric enhancement induced by laboratory heating. Orientation of principal susceptibility axes before and after thermal treatment (for explanation see text).

The initial fabric can be totally obliterated, resulting in oblate ellipsoids but with different orientation to bedding. Maximum axes align normal to bedding and minimum axes parallel to compression (Graham, 1966). The AMS after heating to 500 °C then suggests a magnetic fabric that is strain-controlled with compressional stresses locally NW-SE oriented, in agreement with geologic and petrofabric studies which indicate strong deformation of this region during the Caledonian orogeny (Borradaile, 1979). AF and thermal demagnetization of remanence suggests that magnetic carriers are slightly oxidized titanomagnetites. Thermal demagnetization to  $300^{\circ}C-400^{\circ}C$  produces further oxidation with some hematization accompanied by increase of coercive force and Curie temperature. Heating to higher temperatures results in the formation of new magnetite from paramagnetic minerals, which accounts for the marked increase of mean susceptibility (Figure M90). Formation of new magnetic minerals occurs preferentially controlled by existing tectonic fabrics.

Borradaile and Lagroix (2000) presented data for high-grade gneisses from the Kapuskasing granulite zone. They used measurements of AMS

Figure M90 Example of magnetic fabric enhancement induced by laboratory heating: mean susceptibility (for explanation see text).

and anisotropy of anhysteretic remanent magnetization (AARM) to define the magnetic fabric. AMS was mainly due to the contributions of magnetite and silicate minerals. Thermal treatment does not result in increase of mean susceptibility, but definition of AMS and AARM axial orientation is improved. Heating results in enhancement of the magnetite subfabric, which can then be quantified. This magnetite subfabric reveled by the thermal treatment is also shown in the heated AARM fabric, which is also preferentially enhanced by the laboratory heating.

Other examples of successful thermal enhancement of component of composite fabrics have been observed in granites, particularly in S-type granites in which fabrics arise from biotite and tourmaline minerals (Trinidade *et al.*, 2001; Mintsa *et al.*, 2002). The AMS of paramagnetic phyllosilicates in granites generally correlate well with the crystallographic fabric (e.g., Borradaile and Werner, 1994). Mintsa *et al.* (2002) presented results for the Carnmenellis granite, where thermal treatment above 500 °C results in enhancement of the biotite fabric overcoming the tourmaline contribution. Secondary magnetic produced by laboratory heating within biotite crystals mimics the phyllosilicate cleavage, which in turn corresponds to magmatic (linear) flow structures in the granitic body. Comparison of the AMS fabric lineations before and after the laboratory thermal treatment shows clear differences between the composite initial fabric produced by the biotite fabric and the (inverse) tourmaline fabric (Mintsa *et al.*, 2002).

## Discussion

Measurement of magnetic susceptibility has long been used to monitor changes in magnetic minerals produced by heating of rocks in the laboratory. The effects of heating on the AMS and the enhancement of components of AMS fabric open new exciting possibilities in petrofabric studies. In the simple case, heating produces new magnetic minerals, which mimic the crystallographic structure in micas and clays (Urrutia-Fucugauchi, 1979, 1981). The initial studies showed, however, that heating-induced changes in AMS are more complex than simple enhancement of the magnetic fabric. Recent studies investigating different lithologies (e.g., granites, gabbros, diorites, ignimbrites, volcanoclastic sediments, loess, and limestones) confirm that heating does not always result in simple AMS fabric enhancement (Henry *et al.*, 2003). Henry *et al.* (2003) distinguish three different cases when comparing the heating-induced fabric with the preexisting fabric. First case is simple enhancement of preexisting fabric or masked poorly defined initial fabric. Second case corresponds to formation of an inverse fabric. Third case is the formation of a different fabric, which shows principal susceptibility axes related to petrostructural elements, but differing from the initial fabric.

In the cases where thermal treatment results in increasing the bulk susceptibility and anisotropy degree, heating-induced changes facilitate the measurement of the susceptibility tensor and principal susceptibility axes. Susceptibility increase during heating mainly results from the formation of iron-titanium oxides, principally titanomagnetites and magnetite. Susceptibility decrease results from transformation of oxides, like hematization of magnetite. Iron-titanium oxides could be produced from a range of minerals and processes; most often including iron sulfides, iron carbonates, iron silicate minerals, hydroxides, and other iron oxides do not play a dominant role present special cases that are still not fully investigated for magnetic properties.

Study of AMS changes induced by progressive thermal treatment appears as a useful method to investigate the fabric of rocks. Laboratory stepwise heating has potential for enhancement of AMS and revealing masked or cryptic fabrics. Further investigation of heatinginduced effects in mineralogy, grain size, and textural changes, applied systematically to different lithologies, is clearly required. The methodology permits studying composite fabrics and may give further insight on the relationship of AMS to the different petrofabrics arising from stratification, depositional conditions, current-induced features, strain effects, cleavage, microfracturing, etc.

# MAGNETIC SUSCEPTIBILITY, ANISOTROPY, ROCK FABRIC

Although the anisotropy of magnetic susceptibility (AMS) of rocks first called the attention of scientists because of its possible influence on the direction of the remanent magnetization, it was relatively soon realized that the AMS of a rock is in general too weak to exert a noticeable influence in the paleomagnetic record (e.g., Uyeda *et al.*, 1963). On the other hand, due to the close relationship that exists between the crystalline structure of minerals and their AMS (Nye, 1960), it was well established that the AMS should bear a very close relationship with the mineral fabric of the rock. It is therefore not surprising that the modern interest in the study of the AMS of rocks resides mainly in its value as a petrofabric indicator rather than as a paleomagnetic tool.

There are several sources for the AMS of rock. The most common of these sources is the anisotropy arising from the crystalline structure of the minerals (Nye, 1960). Almost all minerals will have an AMS that is controlled by these sources, although their bulk susceptibility will be generally small. A second source of AMS is found only in some minerals with a strong permeability. These minerals will show an anisotropy that arises from the overall shape of the grain rather than from its crystalline structure. For this reason, this source of AMS is called shape anisotropy. Finally, when two or more ferromagnetic minerals are in close proximity to each other, they can interact magnetically and such interaction becomes the source of a magnetic anisotropy. If the distance between the grains is too small (<2 grain radius) the interactive effects can be so strong that they will overcome the shape anisotropy of individual minerals (Cañón-Tapia, 1995). All of these sources of anisotropy contribute in different amounts to the total AMS measured in the laboratory. In general, the contributions are not simple to express because they depend on the relative proportion of minerals with a given value of bulk susceptibility and degree of anisotropy (Cañón-Tapia, 2001). Traditionally, the presence of a mineral phase with a high value of bulk susceptibility has been assumed to indicate an AMS dominated by such phase, but recent evidence suggests that the main source of anisotropy will reside in the most anisotropic phase even if such phase has a lower value of bulk susceptibility (Borradaile and Gauthier, 2003). Therefore, some attention has to be given to the mineral composition of the rock type under examination to assess the probable sources of its AMS, and hence to make a meaningful interpretation.

The variables responsible for the acquisition of a rock fabric also depend on the type of rock that is considered. Although a mineral fabric is acquired as a response to deformation forces, the total amount of deformation differs greatly from rock to rock, as do the actual mechanism of deformation experienced by the rock. Consequently, the AMS of a rock specimen needs to be examined to the light of the lithology under consideration to reach a meaningful interpretation. Notably, this lithological dependence of the AMS has been disregarded through most of the history of the AMS method probably because advances in the identification of the forces responsible for fabric acquisition of different lithologies have been uneven in time.

Undoubtedly, the study of fabric structures in sedimentary and deformed rocks has a longer history. Therefore it is not surprising that the earlier works establishing a link between sedimentary features (bedding) and AMS were made on these lithologies (Ising, 1942; Granar, 1957). Among the first attempts to explain theoretically the magnetic fabric acquisition of sedimentary rocks is the work by Rees (1961), followed by experiments in which different sedimentation conditions were explored (Rees, 1966, 1968; Hamilton et al., 1968). These works showed that the influence of the magnetic moment induced in a ferromagnetic particle that is about to be deposited will only become important for very small particles, because the magnetic moment induced in the particle is proportional to the cube of the particle dimension whereas the influence of either gravitational or hydrodynamic forces is proportional to its fourth power. Also, the formation of ripples and cross-lamination in sediments deposited under relatively strong currents was shown to affect the measured AMS because each sample might contain different sets of cross-laminations each with a different orientation. Nevertheless, it was concluded that in general the AMS measurements of sediments reflects the gravitational and hydrodynamic forces acting during deposition, and therefore this method yields results equivalent to those concerning the preferred orientation of particles as obtained from optical observation.

Departures from the AMS obtained under experimental conditions (or so-called "primary fabrics") were considered to be "anomalous" by Hamilton and Rees (1970). The causes of the anomalous fabrics were associated with deformation (whether penecontemporaneous with sediment deposition as for example by gravitational slump or by tectonic-related deformation), mineral alteration, or with the activity of plants and burrowing animals. In all of these cases, the magnetic fabric was predicted to yield a larger site-scatter of directions of the principal susceptibilities of individual specimens than it would be found if the sediments in the site had formed by normal depositional processes. Consequently, the scatter of AMS axes became to be synonymous of fabric alteration processes.

In contrast to sediments, prior to the 1970s the interest in the fabric of igneous rocks was almost null (Smith, 2002). Therefore, it is not surprising that most assumptions concerning the interpretation of AMS in sediments were adopted indiscriminately when the first studies of the AMS of igneous rocks were made. In particular, the idea of a mineral fabric as the result of the preferred orientation of minerals already present during viscous flow of melted rock became easily adopted as equivalent to the processes of fabric acquisition studied in sediments (Khan, 1962). As time passed, however, it was realized that the AMS of igneous rocks presents much more variability than the AMS of sediments, leading to a series of confusions and contradictions concerning the utility of AMS in this type of rocks (for a recent historical recount focusing on this type of rocks see Cañón-Tapia, 2004). Although some discrepancies can exists concerning the exact mechanism responsible for the fabric acquisition of a particular rock, most workers will nowadays acknowledge that the mechanisms of deformation of igneous rocks are varied and complex, and have a different character than the (deformation) mechanisms responsible for the acquisition of a mineral fabric in sedimentary rocks. Consequently, different assumptions should be made when interpreting AMS measurements in either rock type.

Another consequence of the advances made in the understanding of emplacement mechanisms of igneous rocks and magmatic deformation, is that the AMS of this type of rocks is not unique and it does not remain constant in the same unit, as previously assumed. These characteristics of the AMS are common to all mineral fabrics that are

acquired during magmatic deformation, provided the density of suspended minerals is not very large. In these cases, the movement of the particles of almost any shape can be approximated by the equations of movement of ellipsoidal particles derived by Jeffery (1922). The movement of these particles will be periodic, and therefore a cyclic behavior of the mineral fabric (passing from well-defined mineral orientations to random distributions of mineral grains) will be found as a function of total shear. Consequently, systematic variations of AMS are predicted as the result of the velocity gradients commonly found in igneous rocks, and therefore, a nonunique AMS signal is to be expected. Nevertheless, as the variations of the fabric are directly related to the magmatic deformation, it is possible to devise sampling strategies (e.g., Cañón-Tapia and Chávez-Álvarez, 2004) that provide enough evidence allowing us to extract useful information concerning the late aspects of the emplacement of these type of rocks (including but not limited to) the local flow direction.

Although the same basic equations could be used in principle to model the mineral fabric of a sedimentary rock, it should be noted that in these cases, other factors like the rolling-over effect of elongated grains over the deposition bed or the mechanical interaction of a much larger population of grains, will result in conditions that differ from those found in igneous rocks. Consequently, the AMS of both rock types might reflect completely different processes.

In summary, although the AMS of all rock types bears a close relation to their mineral fabric, the basic assumptions required for the correct interpretation of this type of results are lithology-dependent. Nevertheless, the AMS method remains a very useful petrofabric tool, provided that the interpretation of results is made with a clear understanding of the physical conditions relevant for each particular case.

# MAGNETIC SUSCEPTIBILITY (MS), LOW-FIELD

All mineral grains are "susceptible" to become magnetized in the presence of a magnetic field, and MS is an indicator of the strength of this transient magnetism within a material sample. MS is very different from remanent magnetism (RM), the magnetization that accounts for the magnetic polarity of materials. MS in sediments is generally considered to be an indicator of iron, ferromagnesian or clay mineral concentration, and can be quickly and easily measured on small samples. In the very-low-inducing magnetic fields that are generally applied, MS is largely a function of the composition, concentration, grain size, and morphology of the magnetizable material in a sample. It is also somewhat variable in direction (MS has anisotropy) according to magnetocrystalline anisotropy, mineral distributions, and grain morphology. MS has the advantage of being quickly and easily measured on small, friable, unoriented samples using commercially available devices such as balanced coil induction systems (susceptibility bridges). Most of these instruments generate alternating magnetic fields at from 500 Hz to 5 kHz. Sensitivity is better at higher frequencies so most of the commercially available bridges operate at around 5 kHz.

Magnetizable materials in sediments include not only the *ferrimagnetic* and *antiferromagnetic* minerals, such as the iron oxide minerals magnetite and maghemite, and iron sulfide and sulfate minerals, including pyrrhotite and greigite, that may acquire an RM (required for reversal magnetostratigraphy), but also any other less magnetic compounds, *paramagnetic* compounds. The important paramagnetic minerals in sediments include the clays, particularly chlorite, smectite, and illite, ferromagnesian silicates such as biotite, pyroxene, and amphiboles, iron sulfides including pyrite and marcasite, iron carbonates such as siderite and ankerite, and other iron- and magnesiumbearing minerals.

In addition to the ferrimagnetic and paramagnetic grains in sediments, calcite and/or quartz may also be abundant, as are organic compounds. These compounds typically acquire a very weak negative MS when placed in inducing magnetic fields, that is, their acquired MS is opposed to the low magnetic field that is applied. The presence of these *diamagnetic* minerals reduces the MS in a sample. Therefore factors such as changes in biological productivity or organic carbon accumulation rates may cause some variability in MS values.

Low-field MS, as used in most reported studies, is defined as the ratio of the induced moment ( $\mathbf{M}_i$  or  $\mathbf{J}_i$ ) to the strength of an applied, very low-intensity magnetic field ( $\mathbf{H}_i$ ), where

$$\mathbf{J}_{i} = \chi_{ii} \mathbf{H}_{i} \text{ (density-specific)}$$
(Eq. 1)

or

$$\mathbf{M}_{i} = k_{ij}\mathbf{H}_{j} \text{ (volume-specific)}$$
(Eq. 2)

In these expressions, MS in SI units is parameterized as k, indicating that the measurement is relative to a 1 m<sup>3</sup> volume and therefore is dimensionless; MS parameterized as  $\chi$  indicates measurement relative to a mass of 1 kg, and is given in units of m<sup>3</sup> kg<sup>-1</sup>. Both k and  $\chi$  have anisotropy.

Bulk (initial) measurements of MS are often performed without consideration of the anisotropy of samples, and for most samples the bulk MS error that is due to this anisotropy is usually small. The anisotropy effect is further reduced when samples are crushed before the MS is measured. Unlike the remanence of a sample, MS is much less susceptible to remagnetization than is the remanent magnetization in rocks. MS can be measured on small, irregular lithic fragments, and on the highly friable material that is difficult to sample for RM measurement.

## Applications and interpretations of bulk (initial) low-field magnetic susceptibility

MS variability from sample to sample results primarily from changes in the amount of its iron, clay, and ferromagnesian constituents. This variability in sedimentary sequences is primary, produced during deposition, and secondary, resulting from alteration of the deposited sequence. The primary factors include weathering, erosion and deposition rates, and biological productivity. These factors are tied to climate, tectonic and volcanic processes, availability of nutrients, and local (relative) or global sea-level changes. Secondary processes include pedogenesis, diagenesis, and within-sediment redox effects driven by sulfate-reducing bacteria.

## Studies of marine sedimentary sequences

Marine sediments are composed of terrigenous, detrital and eolian components, and a biogenic component of the carbonate and/or siliceous tests of marine organisms. There is also a component of sediment derived from marine weathering processes, but this is generally minor. The MS signature mainly represents contributions from the terrigenous and biogenic components. Because the biogenic component is only weakly diamagnetic, in general, the terrigenous component dominates the MS. Therefore, the processes controlling the influx into the marine environment of terrigenous components will usually account for the MS variations observed. Thus, climate cycles that cause erosion and transport of terrigenous material will result in a cyclic signal in the MS recorded in the deposited sediments. There are many factors that can modify this signature, but while the expected variations may be reduced in magnitude, usually the character of the cycles will remain and can be extracted. Superimposed on these cyclic variations are contributions from unique events, such as volcanic eruptions or meteorite impacts, which may be of local, regional, or global significance.

# Continuous and discrete measurements on unlithified sedimentary cores; marine and lacustrine

Routine MS measurements were not possible on sediments until the 1960s when published instructions for building instruments became available and when the first commercially produced instruments entered the market. Early work on sediments was difficult because of the low sensitivity of these instruments. Besides instrumental problems, there were ambiguities in units reported, making interpretations difficult. In the 1970s, publications of MS of discrete samples from marine piston cores began to appear in the literature. In the 1980s, better instrumental sensitivity made it possible to build instruments for continuous MS measurement on cores and these were applied to marine and lacustrine sequences. Much of this work was directed toward correlating cores. In unlithified sediments an inverse correlation between percent carbonate and MS variability, observed as early as the middle 1970s, was interpreted to result from variations in marine organic carbonate productivity (Ellwood and Ledbetter, 1977). More recent work looking at the spectral character of these MS variations has shown that the cycles observed are correlated to climate cyclicities.

Ultimately, the MS in most marine and lacustrine sediments can be used as a proxy for physical processes responsible for delivering the detrital and eolian components to the system. These processes are both regional and global and include climate, volcanism and tectonic processes. In marine sediments they also include relative sea-level changes and eustacy. (See Evans and Heller (2003) for a general discussion of unlithified marine and lacustrine sediments.)

# Surface sediment measurements from pilot and trigger core-top samples

MS has proved useful in some cases. For example, the MS has been measured on a large number of cores from throughout the Argentine Basin in the South Atlantic Ocean and the variability is characterized (Sachs and Ellwood, 1988). They showed that the detrital components responsible for the MS originated from two primary sources. These components are brought into and along the western margin of the basin from Antarctica by Antarctic Bottom Water (AABW), and into the basin from rivers along the eastern margin of South America. Both sources exhibit relatively high MS values at their sources. These values exhibit a rapid down-current MS reduction away from the source. AABW and other bottom currents then disperse detrital components throughout the basin, so that the majority of MS values from the basin show similar values.

# Results from lithified marine sedimentary rock sequences

During diagenesis the MS of marine sediment decreases. This occurs because ferrimagnetic grains that dominate in unlithified sediments are generally converted to paramagnetic phases during burial and diagenesis, mainly by the action of sulfate-reducing bacterial organisms. This process transforms much of the iron to paramagnetic phases such as iron sulfide and carbonate minerals. In general, however, this process does not remove the iron from the system, so that total iron content is conserved. These new phases then contribute, along with the other paramagnetic detrital components present, such as clays, and the remaining authigenic ferrimagnetic constituents, to the MS in lithified sediments. Measured MS values for most marine limestones, marls, shales, siltstones, and sandstones range from 1  $\times$  10<sup>-9</sup> to 1  $\times$  10<sup>-7</sup> m<sup>3</sup> kg<sup>-</sup> Shales and some marls have the greatest anisotropy, but for most of these samples it is less than 2%. Limestones, marls, siltstones, and sandstones are usually less than 1%. Shale and marl samples are friable and measurement is done generally on small broken fragments, further reducing the anisotropy effect. Therefore, the error introduced by the anisotropy of MS is minimal. A test of the MS variability in single limestone beds has demonstrated the nonvarying nature of the MS over distances up to 25 km (Ellwood et al., 1999). Diagenesis also modifies some of the paramagnetic constituents that make up the terrigenous component of marine sediments. In many cases clavs dominate much of the detrital/eolian component, and these are generally not destroyed but may be altered. The iron is still conserved in the secondary clays, as is the paramagnetic behavior of these materials. Other common detrital components observed in marine rocks are the ferromagnesian minerals including biotite, tourmaline, and other compounds (see Ellwood *et al.*, 2000 for discussion).

Ultimately, following diagenesis, the MS observed for most marine sedimentary rocks can be used as a proxy for physical processes responsible for delivering the detrital/eolian component of these sediments into sedimentary basins. As observed for unlithified sediments, these processes in lithified sediments are both regional and global and include climate, volcanism, tectonic processes, relative sea-level changes, and eustacy.

## Presentation of MS data from lithified sequences

For presentation purposes and inter data set comparisons, the bar log format, similar to that previously established for magnetic polarity data presentations, is recommended. These bar logs should be accompanied by both raw and smoothed MS data sets. Here, raw MS data (dashed line in Figure M91) are smoothed using splines (solid line with circles indicating data point locations shown in Figure M91). The following bar log plotting convention is used; if the MS cyclic trends increase or decrease by a factor of two or more, and if the change is represented by two or more data points, then this change is assumed to be significant and the highs and lows associated with these cycles are differentiated by filled (high MS values) or open (low MS values) bar logs (Figure M91). This method is best employed when high-resolution data sets are being analyzed (large numbers of closely spaced samples) and helps resolve variations associated with anomalous samples. Such variations may be due to weathering effects, secondary alteration and metamorphism, longer term trends due to factors such as plate-driven eustacy, as opposed to shorter term climate cycles, or event sequences such as impacts (Ellwood et al., 2003), and to other factors. In addition, variations in detrital input between localities, or a change in detrital sediment source is resolved by developing and comparing bar logs between different localities. It is also recommended that MS data be represented in log plots due to the range of MS values often encountered. However, MS data variations in log plots for some ranges  $(1-3 \times 10^{-x} \text{ vs } 4-9 \times 10^{-x})$  may appear to exhibit large variations that are artifacts of the presentation style. Therefore, bar logs help to reduce these ambiguities.

## Climate cycles and other MS variations

MS results for almost all studies of marine sedimentary rocks show many levels of cycles. Some of these cycles are very long-term and are interpreted as resulting from transgressive-regressive variations (T-R cycles) due to sea-level rise and fall associated with eustacy. Other cycles are much shorter and are interpreted to result from climatically driven processes (Ellwood *et al.*, 2001a,b). Figure M91 is an example of cyclic MS data from limestone—marl couplets from immediately below the Danian-Selandian (Paleocene) stage boundary at Zumaia, Spain. These couplets have been interpreted to result from climate variability, shown to represent climate precession (19–23 ka; Dinares-Turell *et al.*, 2003).

In addition to these cycles, there are distinct MS peaks that are correlated to maximum flooding surfaces (MFS; see discussion in section "Climate Cycles and Other MS Variations"), and to sudden influxes of detrital material into sedimentary basins by turbidity currents or other sediment suspensions. There are also large, relatively sudden shifts or offsets in MS magnitudes within sequences. The Danian-Selandian boundary illustrated in Figure M91 may be such a case. If "knife edge" in character, these shifts have been interpreted as possible unconformities; several tests have demonstrated such an effect. However, not all such abrupt changes will be "unconformities," but may instead be "pseudounconformities" representing missing core sections, unrecognized faults, or other problems. Work by da Silva and Boulvain (2002) for Upper Devonian rocks in Belgium has shown a direct, high

**Figure M91** (a) Uppermost Danian limestone (resistant)—marl couplets at Zumaia, Spain. (b) MS for the interval shown. High MS values are associated with the marls. Note the character change in the basal Selandian shales (Ellwood *et al.*, in preparation).

correlation between both third and fourth order T-R cycles and MS variations determined for those rocks.

Large magnitude and rapid shifts in MS (represented by multiple data points) are interpreted to result from geological processes that reflect fundamental changes in the sediments being delivered to marine basins. For example, the sharp change from low MS in the Permian to high MS in the Triassic (Hanson *et al.*, 1999) is argued to result from a sudden dramatic influx into ocean basins of detrital material that helped to cause the mass extinctions in the marine fauna at this time (Thoa *et al.*, 2004). A similar pulse in MS is associated with the K-T boundary and is attributed to erosion following the meteorite impact at that time (Ellwood *et al.*, 2003).

## Correlations

MS studies of Phanerozoic marine rock sequences have concentrated on the geological boundaries known as Global Boundary Stratotype Sections and Points (GSSPs) that are currently being defined by the International Geological Congress's (IGC) Sub-commission on Stratigraphy. A GSSP represents a "point" or level in a stratigraphic sequence that defines the beginning of a new geological stage in chronostratigraphic time. GSSPs are becoming the basis for the modern Geological Timescale. Today, about half of the more than 90 GSSPs for the Phanerozoic have been formally defined. IGC intends to have all GSSPs formally defined by the year 2008. All of these boundaries are well studied and much of the biostratigraphy has been published. Most stage boundaries are defined based on the first occurrence of a new fossil species, while a few use other criteria. For example, the Paleocene-Eocene GSSP in Upper Egypt near Luxor is defined by a negative carbon isotope shift in the sequence exposed there and in most other Paleocene-Eocene sequences. The biostratigraphy for this section is also well known and the MS signature is distinctive (Figure M92).

The MS of several of these GSSPs has been studied and a number of results have been published (for examples see Hanson *et al.*, 1998 and Thoa *et al.*, 2004 for MS results from the Permian-Triassic boundary, and Crick *et al.*, 2001 for the MS of the Silurian-Devonian boundary. The Silurian-Devonian boundary represents the first GSSP, established in 1972). The purpose of this work has been to use MS as a viable tool for correlating geological sequences, especially for the Paleozoic where polarities are not well defined and where remagnetization is a significant problem. Published and unpublished work on GSSPs and well-studied associated sections has demonstrated that MS variations can be correlated between sections (Crick *et al.*, 1997).

It has been argued that MS tracks processes that control the influx of detrital and eolian grains into the marine environment. For example, sequence stratigraphic studies have demonstrated that at times when sea level is at a maximum, producing an MFS, at the end of a transgressive cycle there is a large influx of detrital material into the marine environment. There is a corresponding MS high associated with these MFSs. However, as a general rule, during transgressive cycles, especially in distal marine sequences, MS is observed to decrease. This happens because detrital sediments are usually trapped near shore during transgressions. During regressions, when base level is lowered due to falling sea level, erosion flushes detrital sediment into ocean basins and MS increases in basinal sediments during these times. Thus T-R cycles play an important role in creating some cyclic MS variations.

Results of the MS work in these rocks have shown that the MS is mineral-dependent but may be independent of the macrolithology. Reworking of sediments by ocean currents, and the variable deposition of clays may produce large MS changes in both limestones and shales, even though in general the lithology may appear to be relatively nonvarying. In addition, while local subsidence may cause a lithologic change from shale to limestone or limestone to shale, the MS may remain relatively constant (Figure M93).

Studies of sedimentary sequences exposed during archeological excavations within limestone caves and deep rock shelters

Archaeological artifacts found during excavation are usually encased in sediments. In most cases, the microenvironment within caves and deep rock shelters protects deposited sediments from the large-scale alteration effects produced by pedogenesis. Artifacts, lithic fragments, and other materials are generally interpreted to have been deposited as part of a stratigraphic sequence and are isochronous with the encasing sediments. Careful microstratigraphic excavations expose stratigraphic sequences that can be sampled for many purposes, including the study of faunal and floral materials, geochemical studies, dating, and characterization of MS variability. For this purpose, sediment is usually collected as a set of continuous samples that allows evaluation of a reasonably complete archaeological sequence. Such a sequence is illustrated in Figure M94a.

The source of these sediments can be fairly complex. In most cases, pedogenesis of the limestone-surrounding caves is the source of eroded soil that can be blown, washed, or tracked in from outside the cave. Sediments may be deposited from streams flowing through or within caves or derived as residues from dissolution of the containing limestones. Because the sedimentary sequences in caves have been shown to accumulate relatively rapidly, limestone residues are considered to be only a minor source of the observed sediments, leaving fluvial and soil materials as the dominant sedimentary sources. Some of the material transported into caves is loess and the MS usually reflects the glacial-interglacial variations observed in these loess sequences (loess MS studies are discussed below.)

The MS of accumulating sediments derived from limestone pedogenesis in archaeological stratigraphic sequences varies with changing climate. In general, periods of warm climate exhibit increases in pedogenesis that produce extremely fine-grained ferrimagnetic iron oxide minerals, primarily magnetite and maghemite. During cold periods, pedogenic activity is reduced, thus reducing the production of ferrimagnetic components. As surface soils are blown, tracked or washed into caves and rock shelters, the MS reflects the climate at the time

**Figure M94** (a) Interior excavations in Scladina Cave, Belgium. (b) MS of Scladina Cave sediments. The data points correspond to samples from several overlapping sections within the cave that were correlated with the archaeological levels shown on the left. MS measurements have then been used to construct the MS bar log which in turn is compared with the marine oxygen isotope results for the last ~130 ka (Imbrie *et al.*, 1984; Martinson *et al.*, 1987). For comparison with the MS results, the  $\delta^{18}$ O, as a function of time, equivalent to a bar log that represents the times of relatively warm (hatched) and relatively cool (white) climates. The  $\delta^{18}$ O isotope stage number assignments are based on the dates obtained by Otte *et al.* (1993, 1998). The ages for the samples from the cave, in thousands of years, and their locations within the sequence are indicated, as are the lower Mousterian level (lithic artifacts produced by Neanderthals) and the location of Neanderthal skeletal remains. The assigned ages for the top and the bottom of the MS warm zones have been based on the assumption that the top and bottom of each level are equivalent in age to the  $\delta^{18}$ O ages of the isotope substages (from Ellwood *et al.*, 2004).

the material is accumulating. This has been tested in a number of cases against faunal, floral, and lithic data sets, by relating MS data to dated chronologies, and by studies of the concentration and character of the dominant magnetic components in these sediments. All are consistent in most cases with the climate interpretation given here.

Fluvial sediments within caves are usually deposited as quickly accumulating, thinly laminated sequences of clays, silts, and sands, and thus easily identified as fluvial. In MS studies these sequences usually do not show much variation. Areas of sedimentary mixing or disturbance are also distinctive because the mixing process radically reduces the MS variability. In addition, in some archaeological contexts there are alteration effects that produce distinctive, much reduced MS magnitudes that are essentially nonvarying through sequences that are expected to show climate variations. In many cases the sediments from the top-down to midlevel in a sequence show good cyclicity, whereas below that is observed a distinctive offset to much lower MS values. Rock magnetic analyses of these materials show that the primary magnetite or maghemite has been altered and either replaced by paramagnetic iron oxyhydroxides like goethite, or removed by dissolution effects.

#### Correlations

Excellent correlations have been shown among archaeological sites in Europe using MS (Ellwood *et al.*, 2001b). These sites range in age from  $\sim$ 3000 B.P. to  $\sim$ 50000 B.P. and are based on a modified version of the graphic correlation method (Shaw, 1964) and available <sup>14</sup>C dates from each site for which data are reported. MS high (warm) and low

570

(cool) values from individual sequences are differentiated diagrammatically by developing bar logs (an example is given in Figure M94b). To these bar log diagrams are added archaeological industries, levels, and available dates. The archaeological lithic industries and dates constrain the MS bar logs to a chronology that allows comparison to a previously developed (and continuously evolving) standard sequence (composite standard, CS). The boundaries between warm and cool MS climate proxies are assigned ages by comparison to the CS making it possible to compare these boundaries to other cave sequences.

## Climate cycles

Results from MS data show cycles, which correlate with climate cycles. Both short- and long-term cycles have been resolved from cave sequences. Neoglacial cycles, with a  $\sim 2500$  year cyclicity, well known from Quaternary climate studies and also reported from work on the Greenland GISP2 Ice Core, have been observed in a number of caves in Europe (Ellwood *et al.*, 1996). Longer term cyclicities (Figure M94b, from Ellwood *et al.*, 2004) have been correlated to  $\sim 20$  ka fluctuations observed in the marine oxygen isotopic record (Imbrie *et al.*, 1984).

## Relative dating

Relative dating can be accomplished by comparing known dates with MS bar log age assignments, either by using dates assigned by comparison with the MS standard sequence (CS) or with the marine isotope curve. Results from this method have been used to date Neanderthal remains in Scladina Cave in Belgium (Ellwood *et al.*, 2004). This result was further tested using high-precision radiometric dating and found to be consistent within the errors assigned by these methods.

### Studies of loess

MS work on Chinese loess sequences in the early 1980s showed a strong correlation with the marine oxygen isotopic record and MS variability. Much of this work has been summarized by Evans and Heller (2003). It was observed that during interglacial periods MS values were high, while during glacial times MS values were low. This was attributed to differences in pedogenic rates, with the production of more ferrimagnetic minerals during interglacial times. In the main, at least for the Chinese sequences, the MS variations in loess appear to provide a proxy for climate fluctuations. However, there are a number of problems with such a simple interpretation. The original protolith from which the loess was derived has an important effect on final MS variability, and in some cases has been shown to produce an inverse MS relative to the Chinese loess sequences, with interglacials showing lower MS values than during glacial times. This is due to erosion of coarse magnetite from an original, high-magnetite-content protolith, and this magnetite is accumulated in loess sequences during glacial times. However, pedogenesis during interglacial times oxidizes the original magnetite, producing a suite of magnetic minerals with a significantly weaker MS. In addition, during interglacials, deep pedogenesis can affect underlying loess sequences, causing ambiguities in the observed MS results.

# Grain size estimates based on frequency dependence of MS

There is a grain-size dependence to MS that results from measurement at varying frequencies. This effect has been loosely employed in some rock magnetic studies using balanced coil instruments that can measure MS at varying frequencies. There is only one such instrument currently commercially available and it allows measurements at two frequencies,  $\sim$ 500 Hz and  $\sim$ 5 kHz. Measurements of the same sample at both frequencies have been compared and results interpreted to represent grain size differences between samples. There are at least three significant problems with this method.

- An instrument that only operates at two frequencies is not capable of measurement at intermediate frequencies where responses in varying size ranges may be important.
- 2. In general, it is assumed that while coarse, multidomain ferrimagnetic grains respond quickly to inducing magnetic fields at both low and high frequencies, the more stable, single-domain or pseudosingle-domain grains do not respond as quickly to high-frequency-inducing fields. This results in a lag in higher frequency fields that is reflected in lower MS values for samples containing these grains. However, there is a third size range of ferrimagnetic particles, the ultrafine-grained superparamagnetic grains produced during pedogenesis. While these are generally unimportant in remanence studies, due to Brownian motion effects, they respond rapidly to both low- and high-frequency-inducing magnetic fields, in much the same way as do multidomain grains, and thus are not distinguishable from larger grains.
- 3. MS originates mainly from a large range of paramagnetic and ferrimagnetic grain compositions and grain sizes. Because only two frequencies are used in frequency-dependence studies, the true behavior of grains at higher, intermediate, and lower frequencies is poorly known or unknown in most cases. Clearly, much more work needs to be done before reliable interpretations of MS data from variable frequency measurements are useful.

## MAGNETIZATION, ANHYSTERETIC REMANENT

Anhysteretic remanent magnetization (ARM) is a magnetization an assemblage of magnetic particles acquires when it is subjected to an alternating field (AF) of gradually decreasing amplitude  $(H_{AF})$  with a constant decrement ( $\Delta H_{AF}$ /cycle) simultaneously with a steady, unidirectional DC field ( $H_{DC}$ ). The ARM is measured when both AF and DC fields are zero. Typically, the DC field is maintained while the AF is slowly ramped down to zero, and then reduced to zero. For isotropic samples, the direction of the ARM is parallel to  $H_{\rm DC}$  but the intensity will depend on the amplitudes and relative orientations of the AF and DC fields. The maximum ARM intensity occurs when  $H_{AF}$  and  $H_{DC}$ are parallel. For a standard laboratory experiment,  $H_{\rm DC} \ll H_{\rm AF}$  with  $H_{\rm AF} = 100-200$  mT and  $H_{\rm DC} = 0.05-0.1$  mT.  $H_{\rm DC}$  is also referred to as a bias field because it produces a statistical preference or biases the direction of ARM along  $H_{DC}$ . A special case of ARM is a partial ARM (pARM) produced by a DC field applied only for a limited time between two AF field values ( $0 \le H_1, H_2 \le H_{max}$ ). A related parameter is the ARM susceptibility,  $\chi_{arm} = dM_{arm}/dH_{DC} \ (H_{DC} \rightarrow 0)$  where  $M_{arm}$ is the ARM intensity. Typically,  $\chi_{arm}$  is determined from a single measurement using one DC field value,  $\chi_{arm} = M_{arm}/H_{DC}$ . For massnormalized ARM (in A m<sup>2</sup> kg<sup>-1</sup>) per unit DC field (in A m<sup>-1</sup>), the SI unit for ARM susceptibility is kg m<sup>-3</sup>. For volume-normalized ARM (in A m<sup>-1</sup>), the SI unit for ARM susceptibility is dimensionless.

With the possible exception of lightning-induced remanence (see *Magnetization, isothermal remanent (IRM)*), ARM is not a naturally occurring remanence like TRM, DRM, or CRM. However, laboratory-produced ARM is used in a variety of applications in paleomagnetism. For example, ARM-based methods have been developed to (1) estimate absolute paleointensity from igneous rocks and relative paleointensity from lake and marine sediments; (2) characterize magnetic carriers and determine domain state and grain size; (3) detect magnetic fabrics in rocks and sediments; and (4) study the fundamental aspects of magnetism. Anhysteretic magnetization also forms the basis for AC-bias magnetic recording.

The combined action of an AF and DC field ( $H_{\rm AF} \gg H_{\rm DC}$ ) is much more efficient in producing a remanence that is more resistant to demagnetization than an isothermal remanent magnetization (IRM), which results from the application of a DC field alone. Two fundamental characteristics of ARM distinguish it from an IRM given in the same DC field: (1)  $M_{\rm arm} \gg M_{\rm irm}$ , and (2) in order to demagnetize the ARM, AF fields approximately equal to the coercivity ( $H_c \gg H_{DC}$ ) must be applied, whereas AF or DC fields equal to  $H_{DC}$  are needed to demagnetize the IRM. In a classic study, Rimbert (1959) was the first to demonstrate analogous properties between ARM and TRM (see Magnetization, thermoremanent (TRM)). Therefore, ARM could be used as a surrogate for TRM in laboratory experiments (Rimbert, 1959; Gillingham and Stacey, 1971; Levi and Merrill, 1976; Dunlop and Argyle, 1997), thus avoiding the need to heat the sample to high temperatures and the possibility of mineralogical alteration. The AF field for ARM acquisition acts as the randomizing agent in analogous fashion as temperature for TRM acquisition. Consider a single-domain (SD) grain with uniaxial anisotropy and coercivity,  $h_c$ . The following illustration is applicable whether we are dealing with moment rotation between easy axes in SD particles or wall displacement in multidomain particles. In this case, the magnetic moment is pinned in the positive direction along the anisotropy axis and will undergo an irreversible rotation into the opposite orientation when a field greater than  $h_{\rm c}$  is applied along the negative direction. Starting from a large AF field such that  $H_{AF}$  is greater than  $h_c$ , the AF field overcomes the anisotropy barrier and the magnetization will follow the oscillating field, i.e., the large AF field initially saturates the sample during each cycle. However, once  $H_{AF} < h_c$ , the particle moment is blocked into a stable position along the anisotropy axis closest to the DC field direction. As  $H_{\rm AF}$  is reduced to zero, little or no change in magnetization occurs. For an ensemble of SD particles with randomly oriented anisotropy

axes, a statistical bias is produced resulting in a net remanence along  $H_{\rm DC}$ . If  $H_{\rm DC} = 0$  during the application of the AF field, the net remanence will be zero and the process is simply AF demagnetization (see *Demagnetization*).

ARM can be an unwanted spurious magnetization produced during AF demagnetization of natural remanent magnetization (NRM). This type of ARM can be generated by (1) insufficient magnetic shielding of external DC fields or (2) distorted or asymmetric AF waveforms that produce higher-order even harmonics from the fundamental AF drive frequency (Collinson, 1983). In either case, a small net DC bias is present during the AF demagnetization process that can produce an ARM of similar or even greater magnitude, than the initial or partially demagnetized NRM signal. Therefore, it is important to provide adequate shielding around the AF coils to attenuate external DC fields, such as the Earth's magnetic field or laboratory fields. This is usually achieved with multilayer, mu-metal shielding. Asymmetries in the AF waveform can be attenuated by tuning the AF coil to the fundamental

frequency. Spurious ARM can also be significantly reduced by doing a double-demagnetization at each demagnetization step. In this technique, the sample is (1) demagnetized along three orthogonal axes (+x, +y, +z), (2) NRM measured, (3) demagnetized along -x, -y, and -z, (4) NRM remeasured, and (5) the vector sum of steps (2) and (4) is determined. Collinson (1983) provides detailed reviews of AF and ARM instrumentation.

## Experimental properties of ARM

The grain size dependences for weak-field ARM ( $H_{\rm DC} < 0.2$  mT) and its median destructive field (MDF) in magnetite from various sources are shown in Figure M95. The intensity of ARM peaks within the single-domain size range ( $d < 0.1 \mu$ m) and then drops off approximately as  $d^{-n}$  (n = 0.5-1) for pseudosingle-domain (PSD) and multidomain grain sizes. Below 0.05 µm, ARM intensity also falls with decreasing grain size as particles become superparamagnetic and their

ability to acquire remanence is lost. This grain size trend is similar in form to other grain size-dependent trends in magnetic properties (e.g., TRM, SIRM,  $H_c$ ) and is a hallmark of the change in micromagnetic states from superparamagnetic to stable single- to multidomain configurations with increasing grain size. For single-domain particles, ARM and TRM have many similar experimental characteristics (Dunlop and Özdemir, 1997) including: (1) comparable resistance to AF demagnetization (Levi and Merrill, 1976), (2) linear dependence on  $H_{DC}$  for weak fields,  $H_{\rm DC}$  < 0.2 mT (Dunlop and Argyle, 1997), and (3) pARMs that obey laws analogous to the three Thellier laws for partial TRM: additivity, reciprocity, and independence (Yu et al., 2002a,b, 2003; see Magnetization, thermoremanent (TRM)). These experimental observations form the basis for ARM methods of paleointensity determinations (e.g., Shaw, 1974; Kono, 1978; Tauxe et al., 1995), which avoid multiple heating to high temperatures that are necessary for the conventional Thellier-Thellier method for paleointensity (Dunlop and Özdemir, 1997).

Whereas qualitative similarities exist between ARM and TRM as exemplified by properties (1)–(3) in the previous paragraph, TRM is still a more efficient remanence acquisition process than ARM for a given DC field. This is demonstrated by the grain size dependence of the ratio of intensities for weak-field TRM and ARM in magnetite (Figure M96), which show TRM/ARM ratios greater than 1 for all grain sizes (Levi and Merrill, 1976; Dunlop and Argyle, 1997). While the TRM/ARM ratio is between 1 and 2 and practically independent of grain size above 1  $\mu$ m, ratios exceeding 10 occur within a narrow size range between 0.1 and 0.5  $\mu$ m. This contrast in behavior for grain sizes above and below  $d = 1 \mu$ m is possibly related to different micromagnetic remanent states produced by field-cooling from above the Curie temperature for TRM (remanence acquired at elevated temperature) or field-cycling at room temperature for ARM (remanence acquired at room temperature). For instance, micromagnetic models suggest that for the 0.1–0.5  $\mu$ m size range, high-moment metastable single- or two-domain states are blocked in during TRM acquisition, but only low-moment vortex ground states result from the AF cycling during ARM acquisition (Dunlop and Argyle, 1997). In contrast, for  $d > 1 \mu$ m magnetites, TRM/ARM ratios between 1 and 2 suggest that similar micromagnetic states, probably with many domains, are produced during either field-cooling or field-cycling.

## ARM theories in single- and multidomain particles

For an assembly of noninteracting SD particles undergoing only fieldassisted switching (i.e., no thermal fluctuations or time-dependent switching), the intensity of ARM is theoretically independent of  $H_{\rm DC}$ (and will equal the saturation remanence) and the initial ARM susceptibility is infinite (Wohlfarth, 1964). However, these theoretical predictions are not observed in synthetic or natural materials. For instance, Figure M97 clearly demonstrates that the shape of the ARM acquisition curve is strongly affected by particle concentration, where high concentrations of particles result in stronger dipolar (magnetostatic) interactions between magnetic particles. The effect of increasing interactions is to lower the efficiency of ARM acquisition. Dunlop and West (1969) used the Néel-Preisach model for interactions to explain weak-field ARM and TRM behavior in several synthetic and natural samples containing

**Figure M97** ARM acquisition curves for samples containing dispersed grains of magnetite in different concentrations. The curves are normalized by saturation remanence and the magnetic field is the DC bias field applied during AF demagnetization. The magnetite sample contains a mixture of SD and PSD grains. (Redrawn from Sugiura, 1979).

SD particles of iron oxides. In the Néel-Preisach model, interactions are accounted for in particle assemblies by assuming each particle has an asymmetric rectangular hysteresis loop, with the amount of asymmetry being proportional to the strength of the interaction field. A distribution of interaction fields, determined by separate experiments, is then used to model the ARM acquisition curves. A shortcoming to this type of model is that moment switching occurs instantaneously, while it is known that time-dependent switching via thermal fluctuations is important in SD and small PSD particles according to the Néel theory of thermally activated magnetization (Dunlop and Özdemir, 1997). ARM theories for SD particles incorporating interparticle, dipolar interactions, and thermal fluctuations have been proposed by Jeap (1971), Walton (1990), and Egli and Lowrie (2002). The following equation was derived by Jeap (1971) for ARM for interacting SD grains:

$$p_{\rm arm} = \tanh(\mu_0 V M_{\rm s}/kT (BH_0 - \lambda p_{\rm arm}))$$
$$B \approx (M_{\rm sb}/M_{\rm s0}) (T_0/T_{\rm b})^{1/2}$$

where  $p_{\rm arm} = M_{\rm arm}/M_{\rm rs}$ ,  $M_{\rm s}$  is the saturation magnetization,  $M_{\rm rs}$  is the saturation remanence, k is Boltzmann's constant, V is grain volume, T is absolute temperature,  $\lambda$  is the mean interaction field, and the subscripts 0 and b refer to room temperature ( $T_0$ ) and the blocking temperature ( $T_b$ ). A field-blocking condition, derived from Néel's relaxation theory, is assumed whereby the alternating field necessary to reverse the magnetization in a given time interval corresponds to a relaxation time that makes  $\ln(f_0t) = 25$ , where  $f_0$  is the frequency factor usually taken as  $10^9$  Hz. Note, that when B = 1, the equation reduces to the SD equation for TRM with interactions.

In the most recent theoretical work, Egli and Lowrie (2002) show that even in noninteracting systems, ARM can be described solely by thermal fluctuation effects. Therefore, in dilute systems, such as in many rocks and sediments containing low concentrations of magnetic carriers, ARM properties are controlled by intrinsic parameters (coercivity and grain volume) rather than by interactions. The SD ARM equation derived by Egli and Lowrie (2002) is

$$p_{\rm arm} = \tanh(\chi_{\rm arm} H_{\rm DC}/M_{\rm rs})$$
  
$$\chi_{\rm arm} = 1.797 \mu_0 M_{\rm rs} \left(\frac{VM_{\rm s}}{kT\sqrt{\mu_0 H_{\rm K}}}\right)^{3/2}$$
  
$$\ln^{1/3} \left[\frac{0.35F_0}{f_{\rm ac}\Delta H_{\rm AF}\sqrt{\mu_0 H_{\rm K}}} \left(\frac{kT}{VM_{\rm s}}\right)^{3/2}\right]$$

where  $H_k$  is the anisotropy field,  $f_{ac}$  is the AF frequency, and  $\Delta H_{AF}$  is the decay rate of AF. This model predicts an increase in ARM intensity proportional to  $d^2$  within the SD size range (d < 60 nm). ARM intensity is also predicted to be weakly dependent on the characteristics of the AF. Experimental results on natural and synthetic samples gave results compatible with theoretical predictions.

For non-single-domain grains, Gillingham and Stacey (1971) proposed a multidomain theory of ARM incorporating domain wall translation under the influence of the self-demagnetizing field. The self-demagnetizing field itself can be thought of as an internal interaction field. Theory predicts that for DC fields in which domain wall translation occurs ( $H_{\rm DC} < H_{\rm c}$ ),  $M_{\rm arm} \propto H_{\rm DC}$ . Reasonable agreement has been obtained between theory and experiment for magnetite grains with  $d > 40 \,\mu\text{m}$ , which most likely contain true multidomain states. However, experimental ARM intensities were significantly larger than predicted for  $d < 40 \ \mu m$  or for particle sizes within the pseudosingledomain size range (Gillingham and Stacey, 1971). Dunlop and Argyle (1997) developed a PSD theory for ARM by combining theories incorporating a wall displacement term linearly dependent on  $H_{DC}$  (an MD process) and a wall moment term proportional to the hyperbolic tangent function (an SD process). Reasonable fits to experimental ARM acquisition data for magnetite particles in the 0.2-0.5 µm size range were obtained with this theory.

# Applications

#### Absolute paleointensity

Shaw (1974) proposed an alternative paleointensity method (now called the Shaw method) to the conventional Thellier-Thellier method, employing ARM and a single-step laboratory TRM heating. First, the NRM of the sample is stepwise AF demagnetized. Then an ARM (designated ARM1) is imparted and subsequently AF is demagnetized. Next, the sample is given a total TRM by heating the sample once above its Curie temperature and cooling in the same DC field as used in the ARM experiment. The TRM is then AF demagnetized using the same step as the one used for ARM. Finally, a second ARM (designated ARM2) is given and AF is demagnetized. If the sample does not experience any chemical alteration during the TRM step then a plot of ARM1 vs ARM2 using the peak AF as the common parameter should be linear with a slope of 1.0. In practice, a portion of the coercivity spectrum is selected that gives the best fit to a line of slope 1.0. Within this coercivity window it is assumed that the TRM is likewise unchanged and a plot of NRM vs TRM using the peak AF as the common parameter yields an estimate of the paleofield. Idealized Shaw diagrams are shown in Figure M98. This method is considerably quicker than the Thellier-Thellier method because less heating is required. Furthermore, samples are heated only once above the Curie temperature, which reduces the potential for chemical alteration that can occur during the multiple heatings used in the Thellier-Thellier method. Kono (1978) showed experimentally that the Shaw method could be as reliable as the Thellier-Thellier method for samples that undergo little or no chemical change during heating. However, a disadvantage of the Shaw method is that the entire experiment is unusable if alteration takes place during the single-step heating to the Curie temperature. Thermochemical alteration of the sample can lead to changes in its TRM capacity and produce erroneous paleointensity results. Modifications of the original Shaw method have been proposed to correct for limited amounts of thermochemical alteration

**Figure M98** Idealized Shaw diagrams for absolute paleointensity determination. (a) ARM1/ARM2 diagram is used to test samples for thermochemical alteration during heating. ARM1 (before heating) and ARM2 (after heating) are AF-demagnetized in identical steps (5, 10, 20,...,100 mT). The solid line represents the slope where ARM1/ARM2 = 1.0. Points that fall off the line (0, 5, 10 mT) may indicate part of the coercivity spectrum that was altered during heating. (b) NRM/TRM diagram is used to estimate the paleointensity. The line with slope = 1.0 from part (a) between 20 and 100 mT delimits the range of identical AF demagnetization characteristics of NRM and TRM within which the TRM and NRM may be compared with each other for estimating paleointensity.

during the TRM heating step (Kono, 1978; Rolph and Shaw, 1985). In these methods, a "slope correction" is (1) applied to the NRM/TRM slope using slopes of linear segments of the ARM1/ARM2 plot over "unaltered" coercivity windows or (2) applied individually to TRM data points using ARM1/ARM2 ratios measured at the same AF level as the corresponding TRM point.

Besides the Shaw method and its modified forms, several ARM techniques were developed earlier, which made use of the theoretical

(a) Normalized remanence curves for stepwise AF-demagnetization of NRM and the subsequent acquisition of partial ARM in the identical steps as the NRM demagnetization. (b) NRM/ARM plot (also called an Arai plot) for the data in (a). The Arai plot shows ARM gained during magnetization in specified AF fields vs NRM left after demagnetization in the same AF fields. relationships between the intensities of ARM and TRM (Banerjee and Mellama, 1974; Collinson, 1983). Here, the laboratory heating step was eliminated and replaced entirely by room-temperature ARM. However, the main shortcoming of such an approach was the difficulty in determining the correct calibration factor, R = ARM/TRM, for particular samples. Here *R* is known to be a function of grain size, interactions, and applied field (Figures M96 and M97) and would vary from sample to sample. These methods were used primarily to estimate paleointensities from lunar samples containing iron or ironnickel grains, which are highly susceptible to chemical alteration even when heated or slightly heated above room temperature (see review by Collinson, 1983).

#### Relative paleointensity

For marine and lacustrine sediments in which NRM is a detrital remanent magnetization (DRM), ARM is used as a normalizing parameter to remove the effects on the NRM intensity signal due to depth variations in concentration, grain size, and composition of the magnetic carriers of remanence (e.g., Tauxe, 1993; Valet, 2003 for comprehensive reviews). According to this hypothesis, down-core variations in NRM/ARM values should theoretically reflect relative variations in paleointensity of the Earth's field rather than variations in physical properties (grain size, concentration) of the magnetic particles in the sediment. The idea was originally proposed by Johnson et al. (1975a,b) and Levi and Banerjee (1976). These authors argued that the magnetic particles responsible for the stable portion of the NRM signal, namely, SD- and PSD-sized grains, will be the same grain size fraction that is most efficient in acquiring ARM (see Figure M95). King et al. (1983) propose three uniformity criteria for sediments under which NRM/ARM normalization provides a reliable measure of relative paleointensity: (1) magnetite is the predominate remanence carrier (uniformity in composition); (2) grain size varies between 1 and 15 µm (uniformity in grain size); and (3) variability in magnetite concentration is less than 20-30 times the minimum concentration (uniformity in concentration).

Another approach, which uses ARM to determine relative paleointensity in sediments, is the pseudo-Thellier method of Tauxe *et al.* (1995). In this procedure, NRM lost in successive AF demagnetization steps is compared to partial ARMs gained in matching AF steps, similar to the pNRM-pTRM steps in the Thellier-Thellier method. When NRM lost is plotted against the pARM gained for each matching AF step, the slope of the resulting line is proportional to the relative paleointensity (Figure M99). This method has two advantages over the conventional NRM/ARM normalization. (1) It allows identification of possible overprints due to viscous remanent magnetization (VRM), particularly at low AF demagnetization steps (<15 mT), which can bias the NRM/ARM estimate. (2) The pNRM-pARM data can be statistically analyzed in the same way as conventional Thellier-Thellier data and, most importantly, provide error estimates on the relative paleointensity determination.

## Magnetic granulometry

Magnetic granulometry is the determination of grain size of magnetic materials based on the discrimination between magnetic relaxation effects (superparamagnetic and SD particles) and domain processes (MD grains). An approximate method to distinguish fine grains ( $<20 \mu m$ ) from coarse grains ( $>20 \mu m$ ), known as the Lowrie-Fuller test and modified by Johnson et al. (1975a,b), compares the AF demagnetization spectra of a weak-field ARM and a strong-field SIRM. If the ARM is less stable or "softer" to AF demagnetization than the corresponding SIRM (where both parameters are normalized to their initial values before demagnetization) then the remanence is assumed to be carried by grains in multidomain states. If the opposite trend is observed, then the remanence must be carried by grains in SD or PSD states (e.g., Dunlop and Özdemir, 1997). Originally, this experimental method was developed as a simple way to screen samples to determine if the NRM in magnetite-bearing igneous or sedimentary rocks resided in SD or small PSD grains, which are likely to carry the stable, primary component of magnetization, or in MD grains, which are likely to be susceptible to secondary remagnetization. Subsequent experimental and theoretical modeling have shown that other factors such as particle volume and coercivity distributions and crystal defect density can complicate the original Lowrie-Fuller test by producing "false positives" (i.e., SD-type behavior for MD grains and vice versa). Dunlop and Özdemir (1997) provide a recent review of the theoretical and experimental work related to the Lowrie-Fuller test.

Banerjee *et al.* (1981) introduced a magnetic granulometry technique that uses the ratio of anhysteretic susceptibility ( $\chi_{arm}$ ) to initial magnetic susceptibility ( $\chi_0$ ). The method was designed as a rapid

way for determining the relative size variations of magnetite in marine and lake sediment cores and has found wide use as a grain size proxy in environmental magnetism studies because it can provide information about past variations in sediment source regions, transport paths, and postdepositional alteration. The basis of the method is that ARM is enhanced in the fine-grained SD fraction (less than 1.0 µm, see Figure M95), whereas  $\chi_0$  is relatively independent for the coarse-grained PSD and MD fraction. The ratio  $\chi_{arm}/\chi_0$ , therefore, should vary inversely with grain size, assuming that by taking the ratio, any effect due to variations in the concentration of magnetic carriers is removed (King et al., 1983). Data is presented either as bivariate plots of  $\chi_{arm}$  vs  $\chi_0$  or a plot of  $\chi_{arm}/\chi_0$  as a function of core depth. Figure M100 shows the experimental efficacy of the method using data from synthetic samples of magnetite with known grain sizes. However, it is important to note that the effects of particle interactions can significantly modify grain size estimates of natural magnetic mineral assemblages using such an approach. In addition, any ultrafine-grained (<0.05 µm), superparamagnetic particles present will contribute high susceptibility but very low ARM, yielding  $\chi_{arm}/\chi_0$  values that could be misinterpreted as a coarse-grained MD signal. Other authors have proposed variations of this method using  $\chi_{arm}$ /SIRM or  $\chi_{arm}/\chi_{FD}$  (where  $\chi_{FD}$  is the difference between  $\chi_0$  measured at low and high frequency) to discriminate SP from MD particle (Maher, 1988; Oldfield, 1994). An example of the  $\chi_{arm}\!/\chi_0$  method is shown in Figure M101 for lake sediments from Minnesota (USA) revealing relative changes in magnetic grain sizes due to paleoclimatic and anthropogenic events over the last 1000 years.

## Anisotropy of anhysteretic remanent magnetization

The directional dependence of ARM in a sample, commonly termed as the anisotropy of anhysteretic remanent magnetization (AARM), is used as a tool for quantitative analysis of petrofabrics in rocks and sediments and can provide information on depositional, emplacement,

**Figure M100** Model of ARM susceptibility vs low-field AC susceptibility for detecting magnetite grain size variations in natural samples. The model is based on data for sized magnetites. The slope of the line connecting the origin to the individual sample point can determine relative grain size variations of magnetite in natural samples. High slopes indicate finer grain sizes. Concentration of magnetite can be estimated from the distance from the origin to an individual data point. (Data taken from King *et al.*, 1983).

or tectonic histories of igneous, metamorphic, and sedimentary rocks (see review by Jackson, 1991). Similar to the traditional method of anisotropy of magnetic susceptibility (AMS, see *Magnetic susceptibility, anisotropy*), AARM is used to determine preferred orientations of magnetic mineral grains in a rock. However, because AARM fabrics reside exclusively in the ferrimagnetic, remanence-carrying fraction (e.g., magnetite, titanomagnetite, pyrrhotite), it may provide information about complementary or different geological events or processes from those responsible for AMS fabrics, which reflects an average of contributions from all nonmagnetic (paramagnetic and diamagnetic) and ferrimagnetic mineral phases present. The use of AARM in magnetic fabric studies was pioneered by the work of McCabe *et al.* (1985) and Jackson *et al.* (1988).

In the weak-field limit (H < 0.2 mT), where ARM acquisition is approximately linear in applied field, the ARM anisotropy can be described by a second-rank tensor and represented by an ellipsoid, mathematically equivalent to the AMS tensor. Mathematical and statistical treatment of AARM tensor data follows procedures developed for AMS data (e.g., Tauxe, 1998; Tarling and Hrouda, 1993). AARM is analyzed in terms of anisotropy of remanence tensor calculated by subjecting a sample to repeated ARMs along different orientations and measuring the intensity of ARM acquired along the applied field direction for each orientation. At least six independent orientations are needed to determine the tensor. Usually ARM is imparted along 9 to 15 different orientations and the tensor is determined by leastsquares analysis (McCabe *et al.*, 1985; Jackson, 1991). Jackson *et al.* (1988) developed a method employing pARMs over selective coercivity windows instead of total ARMs for AARM analysis. Unlike the

**Figure M102** Comparison of ARM anisotropy (AAS) and anisotropy of magnetic susceptibility (AMS) in the Trenton limestone. The directional data are plotted on equal area projections. The degree of ARM anisotropy is greater and its principal axes are more tightly grouped than the corresponding AMS data. (Reprinted from McCabe *et al.*, 1985, with kind permission of the authors.)

standard ARM method, the use of pARMs has the advantage of being able to isolate magnetic fabrics from discrete coercivity, or grain size, fractions. For instance, the different fabrics carried by SD and MD grain fractions can be distinguished from one another.

AARM and other remanence anisotropy methods (e.g., IRM) have several advantages over AMS; most notably, remanence-based methods (1) provide higher signal-to-noise ratios, particularly in weakly magnetic or weakly anisotropic rocks, and (2) can provide information related to the fidelity of the orientation of the NRM vector (i.e., whether NRM reflects magnetic alignment by the paleofield or alignment by a petrofabric) because both are carried by the same remanence-carrying phases. Figure M102 shows a comparison of AMS and AARM data for samples of the Trenton limestone (USA), taken from the work of McCabe et al. (1985). The AARM data shows a much more clearly defined west-southwesterly lineation with a higher degree of anisotropy than the companion AMS results. In this case, the lower degree of anisotropy determined from the AMS data resulted from a dilution effect on the susceptibility due to the diamagnetism  $(\chi < 0)$  of the calcite matrix and, therefore, was not as sensitive a measure as the AARM for detecting the petrofabrics. Other examples of fabrics determined by a combination of AMS- and AARM-derived data are given in a review by Jackson (1991).

Another example of the usefulness of AARM is its application in the field of sedimentary paleomagnetism. Jackson *et al.* (1991) developed a quantitative model for correcting inclination shallowing carried out by magnetite grains in sediments by measuring the ARM tensor, where ARM is assumed to activate the same coercivity spectrum responsible for DRM acquisition. The model assumes that whatever processes lead to inclination shallowing (e.g., compaction) result in a horizontally flattened distribution of long axis orientations of magnetic particles. In general terms, the **DRM** vector is related to the applied field vector (**H**) through the following equation:

$$\mathbf{DRM} = (k_{\mathrm{d}})\mathbf{H}$$

where  $k_d$  is the anisotropic detrital remanence tensor. According to the theory, the AARM tensor ( $k_a$ ) can be used as an approximation for  $k_d$  and the deposition field vector can be obtained from

$$\mathbf{H} = (k_d)^{-1} \mathbf{DRM} \cong (k_a)^{-1} \mathbf{DRM}$$

Figure M103 shows results from controlled deposition experiments using synthetic sediments composed of magnetite, silica, and kaolin (Jackson *et al.*, 1991). Both inclination error (Figure M103a) and ARM anisotropy (Figure M103b) are direct functions of kaolin concentration, presumably because of electrostatic interactions between clay and magnetite particles. Correcting the inclination values by multiplying the measured DRM vector by the inverse of  $k_a$  according to equation YY yields inclination values (Figure M103c) closer to the actual depositional field orientation and provides confirmation of the theoretical model proposed by Jackson *et al.* (1991). Therefore, this method can provide more accurate determinations of the direction of the ancient paleofield in magnetite-bearing sediments and sedimentary rocks.

# MAGNETIZATION, CHEMICAL REMANENT (CRM)

Chemical remanent magnetism (CRM) is imparted to ferro- and ferrimagnetic minerals by chemical processes, at temperatures below their Curie points, in the presence of an effective magnetic field. Here, chemical processes are considered broadly to include but not be limited to modifications in oxidation state, phase changes and crystal growth. The effective magnetic field is the resultant vector field acting on the chemically-altered material, including the external and various interaction fields.

Nearly a century and half ago, Beetz (1860) discovered CRM during laboratory electrolytic depositions of iron; these observations supported Weber's hypothesis that some atoms possess intrinsic magnetization. These results were confirmed by Maurain (1901 and 1902) with electrolytic depositions of iron and nickel in the presence of external fields. Koenigsberger (1938, part 1, p. 122 & part 2, p. 319) noted the presence of coherent remanence in some sedimentary rocks, which he called *crystallization remanence*, and he advanced the hypothesis that it was "impressed by the Earth's field at temperatures between about 100°C and 500°C during the time of lattice changes in magnetite which result very probably from unmixing of Fe<sub>2</sub>O<sub>3</sub>." With the rapid growth of paleomagnetism after World War II, it became apparent to many rock magnetists that the remanence of many sediments, especially red beds, was at least partly controlled by magnetic minerals chemically precipitated subsequent to deposition (e.g., Blackett, 1956).

In rocks, CRM is usually a secondary remanence; this is an important reason that in geophysics CRM studies lag behind investigations of TRM (Thermoremanent magnetization) and DRM (Depositional remanence), which are usually responsible for the primary remanence. In most paleomagnetic studies, it is advantageous to select samples that retain their primary TRM or DRM; secondary CRM is a nuisance to be avoided, if possible. However, in nature, CRM can rarely be entirely neglected. If a secondary CRM is superimposed on an extant primary TRM or DRM, one of the first objectives would be to remove (demagnetize) the CRM in order to expose the primary remanence. In many cases, especially for older, chemically-altered sediments, CRM is the dominant characteristic remanence, the primary DRM having been obliterated by processes similar to those that are responsible for the CRM.

## Theory for CRM

Many CRM properties can be explained with Néel's (1949, 1955) thermal fluctuations theory for super-paramagnetic (SP) particles, which has been highly successful at explaining TRM and many other properties of remanence. We consider the an assemblage of non-interacting, uniformly magnetized SP particles with identical volumes, v, which have uniaxial anisotropy and aligned easy axes. For thermal equilibrium and in the presence of an external magnetic field, H, applied parallel to the easy axes, the volume magnetization, M, is given by the equation

$$M = nM_{\rm S}(T) \tanh[M_{\rm S}(T)\nu H/kT]$$
(Eq. 1)

The argument  $[M_{\rm S}(T)vH/kT]$  is the alignment factor, which vanishes for H = 0.  $M_{\rm S}(T)$  is the spontaneous saturation magnetization of the grains at temperature *T*; *n* is the number of magnetic particles per unit volume; k is Boltzmann's constant; *T*, the absolute temperature (°K).

When the field is removed, M decays, seeking the new state of thermal equilibrium, M = 0, at a rate determined by the relaxation time,  $\tau$ . M is given by the equation

$$M = M_0 \exp[-t/\tau] \tag{Eq. 2}$$

where  $M_0$  represents the initial magnetization; t is the elapsed time since the field was removed. For the particle assemblage described above, Néel derived an equation for  $\tau$ , and in zero external magnetic field,

$$\tau = C^{-1} \exp[Kv/kT] \tag{Eq. 3}$$

where *K* is the uniaxial anisotropy energy per unit volume; *C* is the frequency factor whose value is on the order of  $10^9 \text{ s}^{-1}$ . *C* is a function of *T* and *T*-dependent material properties; however, *C*'s variation with temperature is significantly less than the exponential factor, and, in comparison, *C* is usually treated as constant. By contrast,  $\tau$ , which is also a measure of the remanence stability, varies orders of magnitude in response to modest changes of the argument (*Kv*/k*T*).

We now consider isothermal CRM production at temperature  $T_A$ , caused by crystal growth of magnetic particles. The precipitating ferroor ferrimagnetic particles grow from atomic/molecular paramagnetic nuclei to larger exchange-coupled SP grains with spontaneous magnetization,  $M_S$ . In an external field and thermal equilibrium, the particles are aligned according to Eq. (1). When the field is removed, and as long as the thermal fluctuations (kT) can easily overcome the anisotropy energy barriers (Kv),  $\tau \ll \tau_L$ , M decays quickly following Eq. (2), and there is no remanence. ( $\tau_L$  is a characteristic laboratory time on the order of minutes.) As the particle volumes increase, it becomes more difficult for thermal fluctuations to overcome the growing barriers to domain rotations. Because of the exponential dependence of  $\tau$  on  $\nu$  in Eq. (3), the magnetization changes to a stable CRM over a very narrow range of volumes,  $\Delta \nu$ . At volume  $\nu_{AB}$ ,  $\tau \gg \tau_L$ , and CRM is said to be blocked.  $\nu_{AB}$  is the critical blocking volume at  $T_A$ . That is, at temperature  $T_A$ , for  $\nu < \nu_{AB}$ , the particle assemblage is super-paramagnetic, while for  $\nu > \nu_{AB}$ , the magnetization is blocked as stable CRM in single domain (SD) particles. This is analogous to TRM production, where  $\nu$  is considered constant, and  $\tau$  increases as T cools below the Curie point,  $T_C$ . Above the blocking temperature,  $T_B$ , the SP magnetic moments are aligned according to Eq. (1) with  $\tau \ll \tau_L$ , so that when the external field is removed, the magnetization quickly decays following Eq. (2). At lower temperatures  $T < T_B$ ,  $\tau \gg \tau_L$ , and the magnetization is blocked as stable TRM.

CRM is usually difficult to distinguish from other remanences such as TRM and VRM (viscous remanence), because of overlapping stabilities and possible associations between CRM, partial-TRM (PTRM) and high-temperature VRM. For example, grain growth CRM at  $T_A > T_R$ , where  $T_R$  denotes room temperature, is in particles that have grown beyond the blocking volume,  $v_{AB}$ ; chemically precipitated particles with volumes  $v < v_{AB}$  do not contribute to the CRM. On cooling from  $T_A$  to  $T_R$ , a PTRM will be produced in particles with blocking temperatures  $T_A > T_B > T_R$ . Also, ubiquitous time effects might contribute significant VRM superimposed on the CRM. In addition, the resultant remanence is likely to grow on cooling from  $T_A$  to  $T_R$ , due to the increase in  $M_S$  on cooling for most magnetic minerals. Such complexities make it difficult to uniquely isolate CRM from other remanences, hence it is probable that CRM occurrences in the paleomagnetic record are more numerous than is usually recognized.

As long as the magnetic ensemble consists of non-interacting, homogeneously magnetized SD particles,  $\tau$  and the magnetic stability increase exponentially with particle volume. For multi-domain (MD) particles,  $\tau$  decreases with increasing volume, principally because it becomes progressively easier to alter the remanence by domain wall movements, as opposed to rotating the magnetic moments of SD particles. These considerations of remanence stability and relaxation times were demonstrated experimentally by coercivity measurements of dispersed fine particles of ferromagnetic metals (Fe, Ni, Co), as the grain sizes increased due to progressive heat treatments (e.g., Meiklejohn, 1953; Becker, 1957). Zero initial coercivity in the SP region is followed by increasing coercivity with particle sizes, presumably in the SD size range; the coercivity then decreases for larger presumably MD particles (Figure M104). Haigh (1958) first applied Néel's theory and the grain size dependence of the coercivity to rock magnetism to explain CRM properties in growing particles of magnetite obtained during laboratory reduction of hematite. Kobayashi (1959) also examined CRM in magnetite obtained from hematite reduction and showed that CRM stability with respect to both alternating fields and thermal demagnetization was much greater than for IRM (isothermal remanence) and very similar to the stability of TRM (Figure M105). Kobayashi (1961) produced CRM in cobalt grains precipitated from Cu-Co alloy and showed that the specific CRM intensity had a similar bell-shaped grain size dependence as the coercivity, increasing from zero for SP particles, attaining a maximum value and then decreasing for inhomogeneously magnetized MD particles (Figure M106). Grain growth CRM can explain many examples in paleomagnetism, where the natural remanence (NRM) is predominantly a secondary remanence in chemically-altered rock and where new particles of a chemicallynucleated magnetic phase have grown beyond the SP size range.

#### CRM in Igneous Rocks

### General Considerations

In igneous rocks, CRM can be produced by phase transformations or nucleation and growth of new magnetic minerals at temperatures

(b) Change in coercive force of Cu(98%)Co(2%) alloy as a function of annealing time (particle size) at 700°C, measured at 300 K (modified from Becker, 1957).

**Figure M105** (a) Thermal, (b) alternating fields (AF) demagnetization of remanence in magnetite. All remanence measurements were made at room temperature. CRM was produced at 340°C with external fields of (a) 0.3 mT, (b) 1 mT. Total TRM was produced in (a) 0.3 mT, (b) 0.05 mT. IRM( $T_0$ ) at room temperature was produced in fields of (a) 20 mT, (b) 3 mT. IRM(T) was produced at 340°C in fields of (a) 2 mT, (b) 1 mT. CRM (T = 340°C) and IRM (T = 340°C) were cooled to  $T_0$  in zero field prior to being demagnetized (modified from Kobayashi, 1959).

**Figure M106** Total, remanent, and reversible magnetization of Cu-Co alloy as a function of annealing time (particle size) at 750°C, measured at 750°C. The reversible magnetization is the difference between the total magnetization (in presence of an applied field) and the remanence (modified from Kobayashi, 1961).

below the Curie point of the new magnetic species. The effective magnetic field at the site of the new magnetic particles determines the direction and intensity of the CRM. In igneous rocks, magnetic interactions among multiple phases, such as during exsolution of the iron-titanium solid solution series, might significantly modify the external field through magnetostatic or exchange interactions with phase(s) having higher blocking temperatures. Occasionally, such interactions might produce CRM with oblique directions or opposite polarity to the external magnetic field and the existing magnetic phase (negative magnetic interactions), and in rare cases a self-reversal may result (Néel, 1955).

#### CRM Origin of Marine Magnetic Anomalies

The first remanence of freshly extruded submarine basalts is TRM in stoichiometric titanomagnetites,  $xFe_2TiO_4(1-x)Fe_3O_4$ , with  $x \sim 0.6 \pm 0.1$ , that is, about 60% molar ulvöspinel, with Curie points between  $100^{\circ}-150^{\circ}C$  (Readman and O'Reilly, 1972). The initial magnetic phase is transformed at the sea floor by topotactic low temperature oxidation to cation deficient titanomaghemites. The oxidation is thought to proceed by a net cation migration out of the crystal lattice to accommodate a higher Fe<sup>3+</sup>/Fe<sup>2+</sup> ratio and accompanying changing proportions of Fe:Ti. The resulting cation deficient phases retain the cubic crystal structure with smaller lattice dimensions, higher Curie points, approaching 500°C, and lower saturation magnetizations, responsible for the rapid diminution of the amplitudes of the marine magnetic anomalies away from spreading centers (e.g., Klitgord, 1976). Therefore, marine magnetic anomalies over the world's oceans can be considered to be preserved predominantly as CRM in oxidized Fe-Ti oxides.

The secondary CRM in submarine basalts usually retains the same polarity as the initial TRM recorded upon extrusion. This is indicated by the agreement, for overlapping time intervals, between the polarity time scales from marine magnetic anomalies, continental lavas and marine sediments, as well as the magnetic polarity of oriented dredged and drilled submarine basalts. The agreement of CRM and TRM directions is further supported by laboratory low temperature oxidation experiments of predominantly SD titanomagnetites (e.g., Marshall and Cox, 1971; Johnson and Merrill, 1974; Özdemir and Dunlop, 1985). The superexchange interactions vary with changes in cation distribution and lattice dimensions, as indicated by the reduced saturation magnetization and higher Curie points for the more oxidized titanomaghemites. However, it is possible that the orientations of the sub-lattice magnetic moments remain intact during low temperature oxidation of the titanomagnetite minerals, so that the ensuing CRM retains or inherits the original TRM direction.

Evidence from magnetic anomalies and magnetic properties of drilled oceanic basalts suggests an increase of the magnetization of extrusive submarine basalts of oceanic crust older than about 40 Ma (e.g., Johnson and Pariso, 1993). At present, the data are too sparse for one to be confident of the generality of this phenomenon or to select from several mechanisms that might be responsible.

#### CRM Influence on Paleointensity Studies

At present, only TRM can be used for obtaining absolute paleointensities of the Earth's magnetic field (see *Paleointensity from TRM*). Hence, all paleointensity methods require that the NRM be essentially pure TRM, or that the TRM can be readily isolated from the NRM. The paleointensity methods compare the NRM of each specimen to a new laboratory TRM produced in a known laboratory field,  $H_L$ . Because chemical and mineralogical alterations of specimens during laboratory heatings are common and often preclude reliable paleointensity determinations, the different paleointensity methods apply various pre- and post-heating tests to assess the extent of chemical changes on the remanence and paleointensity experiments. Several paleointensity methods use a single heating to above the specimen's highest Curie temperature to produce a total laboratory TRM. However, because reaction rates increase with temperature, such a procedure tends to maximize chemical alterations.

The Thelliers' double heating method (Thellier and Thellier, 1959) was developed to diminish this problem by gradually heating the samples in steps from room temperature,  $T_{\rm R}$ , to the highest blocking temperature. At each temperature step,  $T_{\rm I} > T_{\rm R}$ , the samples are heated twice; to determine both the thermally demagnetized partial-NRM (PNRM) and the acquired partial-TRM (PTRM) between  $T_{\rm I}$  and  $T_{\rm R}$ . The Thellier method depends on the additivity and independence of PTRMs acquired in different temperature intervals; that is, total-TRM =  $\Sigma$ PTRM. Also, it is assumed that the unknown paleointensity, H<sub>U</sub>, was constant throughout the remanence acquisition process and that H<sub>U</sub> and H<sub>L</sub> are sufficiently small that both TRMs are linearly proportional to the imposed field. When these conditions are satisfied and in the absence of chemical changes on heating, H<sub>U</sub> can be calculated from the ratio PNRM $(T_I, T_R)$ /PTRM $(T_I, T_R) = H_U/H_L$  and should be the same for each temperature interval. Every temperature step gives an independent paleointensity value. These consistency checks, provided by several independent paleointensity estimates at the different temperatures, are the primary asset of the Thellier method. The data can be displayed on a PNRM versus PTRM plot (an Arai diagram), with data corresponding to the different temperature steps (Figure M107). Ideal behavior in the Thellier sense implies linear data with a slope equal to  $-H_{II}/H_{I}$  (line A, Figure M107). The Thelliers' procedure is well suited to detect the onset of chemical alterations, which are more common at higher temperatures, and are often expressed as deviations from the ideal straight line. Another feature of the Thelliers' procedure is the PTRM check, where a PTRM is repeated at a lower temperature  $T_{\rm P} < T_{\rm I}$ . The PTRM check provides information about changes in the PTRM capacity of magnetic particles with  $T_{\rm B} \leq T_{\rm P}$ . For these reasons, the Thelliers' procedure is usually considered to be the most reliable paleointensity method

High-temperature chemical alterations during the Thelliers' paleointensity procedure is one of the more common causes for failed or abbreviated paleointensity experiments. If the CRM is expressed as a

**Figure M107** PNRM-PTRM diagrams for five hypothetical Thellier paleointensity experiments, A-E, discussed in the text. Like symbols indicate identical temperatures. Dashed lines 1, 2, and 3 indicate PTRM checks between the designated temperatures for experiments A, B, and D, respectively. Solid diamonds refer to unsuccessful PTRM checks.

greater PTRM capacity, which increases with temperature, the data will form a concave-up PNRM-PTRM plot (Figure M107, curve B). Provided the lower temperature data are linear and the PTRM checks show no evidence of alteration, then the lower temperature data can be used to calculate a paleointensity (Figure M107 curve B, points T1-T3). Recent studies suggest that at least 50% of the NRM should be used to obtain reliable results (e.g., Chauvin *et al.*, 2005).

CRM production that increases the PTRM capacity may result from precipitation of new magnetic particles or from unmixing of titanomagnetite grains to a more Fe-rich phase with higher saturation magnetization. Chemical modifications, which lead to higher PTRM, usually cause the PNRM-PTRM points to lie above the ideal line, and the calculated paleointensity will be lower than the actual paleofield. Alternatively, if the chemical alterations decrease the PTRM potential by destroying magnetic particles or by transforming them to a phase with lower intrinsic magnetic moments, then the PNRM-PTRM points will plot below the ideal line, with higher apparent paleointensities than the actual values (e.g., Figure M107, curve D and PTRM check 3). For a special case, where CRM acquisition grows linearly with temperature, the PNRM-PTRM plot might be linear (Figure M107, line C); however, these data plot above the ideal line (Figure M107, line A), and the calculated paleointensity would be lower than its actual value. This result emphasizes that linear PNRM-PTRM data are a necessary but not sufficient condition for obtaining reliable paleointensities.

The adverse effects of chemical alterations and CRM on paleointensity studies do not always arise from heatings in the laboratory. It is also possible that the NRM is not a pure TRM but contains a significant CRM component. Yamamoto *et al.* (2003) suggested that high temperature CRM contributes to the NRM of the Hawaiian 1960 lava, which results in higher than expected paleointensities. Alternatively, lowtemperature hydrothermal alteration might produce CRM in new magnetic particles that contribute to the NRM. If these particles have not grown significantly beyond their blocking volumes,  $v_{AB}$ , they would be demagnetized at  $T \ge T_A$ , leading to rapid decrease of the NRM. This scenario might explain the precipitous diminution of the NRM observed for some basalts, with decreases on the order of 20% to more than 50% in the first few temperature steps of the Thellier experiment. When this decrease in NRM cannot be attributed to viscous remanence, it is possible that the NRM is augmented by CRM. It is no longer pure TRM.

## **CRM in Sedimentary Rocks**

#### Oxidized Red Sediments

Red beds are a broad and loosely defined category of highly oxidized sediments with colors ranging from brown to purple, usually resulting from secondary fine particles of hematite, maghemite and/or ferric oxyhydroxide. The color is a complex function of the mineralogy, chemical composition and particle sizes of the iron oxides, as well as the impurity cations and their concentrations; however, for paleomagnetism, color is unimportant. Red sediments have been used extensively for paleomagnetism since the late 1940s, because they are widely distributed geographically and with respect to geologic time. In addition, the remanence of red sediments is often stable and sufficiently intense for paleomagnetic measurements, even with early-generation magnetometers. Already in the 1950s, it was deduced that low temperature oxidation was responsible for transforming the original magnetite to fine particles of hematite, maghemite, and/or goethite, which provide the pigment and CRM of red beds (Blackett, 1956).

Larson and Walker (1975) studied CRM development during early stages of red bed formation in late Cenozoic sediments; they showed that in their samples CRM occurred in several authigenic phases including hematite and goethite. The CRM, which obscured the original DRM, had formed over multiple polarity intervals, as indicated by different polarities in several generations of authigenic minerals. Complex multi-generation patterns of CRM, with several polarities within single specimens, have also been observed in Paleozoic and Mesozoic red beds. The influence of the secondary CRM on the primary remanence depends on the relative stability and intensity of the CRM carriers as compared with the primary DRM. In many cases the DRM may have been entirely obliterated by diagenetic processes, and the CRM is the dominant characteristic remanence. However, there are examples of red beds, where the primary DRM in specularite hematite remains the characteristic remanence with respect to CRM (e.g., Collinson, 1974). Sometimes distinct CRM components can be isolated by thermal demagnetization, selective leaching in acids (e.g., Collinson, 1967) and removal of altered phases of sediment by selective destructive demagnetization (Larson, 1981).

During the past more than five decades, paleomagnetic studies of red sediments have contributed significantly to magnetostratigraphy, plate tectonics and rock magnetism. Many data of apparent polarwander paths are from red beds, where it is assumed that the CRM was produced soon after deposition, so that the paleomagnetic pole accurately represents the depositional age of the sediments. Moreover, CRM is not subject to inclination shallowing, which often affects the primary DRM. The utility of red sediments for high resolution studies of the geomagnetic field and paleosecular variation is limited and depends on how pervasive the CRM is as compared to the primary DRM, the time lag between the CRM and initial DRM, and the duration of CRM production.

#### Non-red Sediments

Here we discuss CRM in a subset of non-red mostly carbonate sediments, whose remanence is usually much weaker than for red beds. The low remanence intensity of these sediments was a key reason that they were generally excluded from paleomagnetic investigations until the introduction in the early 1970s of cryogenic magnetometers, capable of measuring minute signals, down to the  $10^{-9}$ – $10^{-10}$  Gauss range. Since then, there has been an explosion of studies of weakly magnetized non-red sediments. For example, it has been shown that the characteristic remanence of some early Paleozoic carbonate sequences was acquired in the late Paleozoic, hundreds of millions of years younger than their biostratigraphic ages (e.g., McCabe et al., 1983). Magnetic extracts from these diagenetically altered sediments contained essentially pure magnetite particles, whose botryoidal and spheroidal forms have been used to infer their secondary origin, and they are thought to be responsible for the secondary characteristic remanence of these sediments. This conclusion has been buttressed by electron microscope observations (Figure M108) of in-situ authigenic magnetites in Paleozoic limestones (Suk et al., 1993). In the absence of evidence of significant heating of these sediments, their remanence has been attributed to low temperature CRM in secondary magnetite, which might have been produced by "diagenetic alteration of preexisting iron sulfides (e.g., framboidal pyrites)" (McCabe et al., 1983). For Miocene dolomites and limestones of the Monterey Formation, Hornafius (1984) concluded that the secondary remanence, presumably a low temperature CRM, resides in diagenetic magnetite produced by partial oxidation of pyrite upon the introduction of oxygenated meteoric groundwaters to the formation. CRM in some Paleozoic carbonates resides in hematite particles (e.g., Elmore et al., 1985) produced by diagenetic dedolomitization, where oxidizing fluids with high calcium contents cause calcite replacing dolomite (McCabe and Elmore, 1989).

The presence of magnetite (and siderite, FeCO<sub>3</sub>) in oil impregnated sediments was discovered by Bagin and Malumyan (1976), and Donovan *et al.* (1979) reported correspondence of near surface magnetic anomalies over an oil field with a higher concentration of magnetic minerals in the sediments. Paleomagnetic studies of remagnetized hydrocarbon-impregnated Paleozoic sediments (McCabe *et al.*, 1987; Benthien and Elmore, 1987) indicate a relationship between hydrocarbon migration and the precipitation of authigenic magnetite particles, carrying the secondary CRM. This scenario is supported by extracted magnetite spherules up to several tens of microns in diameter and

the presence of other authigenic textures in the sediments. All these studies suggest a net reduction of ferric ions in oxides, hydroxides and silicates, caused by the biodegradation (oxidation) of the hydrocarbons and the precipitation of more reduced iron oxide phases such as magnetite (Fe<sub>3</sub>O<sub>4</sub>), siderite (FeCO<sub>3</sub>) and wustite (FeO). Of these, only magnetite is ferrimagnetic; hence it is responsible for the CRM and for being preferentially extracted during magnetic separations.

Rapidly deposited marine and lacustrine sediments are increasingly being used to study high-resolution behavior of the Earth's magnetic field, including secular variation and relative paleointensities. However, to accurately interpret the sedimentary record, geochemical processes that influence the magnetic signal must be understood. In anoxic and suboxic environments, bacterial sulfate reduction produces H<sub>2</sub>S, which reacts with the detrital iron oxides to precipitate sulfide minerals (Berner, 1970, 1984). An abundance of sulfate favors reactions that produce relatively more stable pyrite (FeS<sub>2</sub>), which does not carry remanence. When the sulfate supply is more limited, the formation of ferrimagnetic pyrrhotite (Fe<sub>7</sub>S<sub>8</sub>) and/or greigite (Fe<sub>3</sub>S<sub>4</sub>) is preferred. Pyrrhotite formation is less common in sediments because it is thought to require pH > 11 (Garrels and Christ, 1965), which is outside the range of values measured in sedimentary pore waters. However, for extremely low sulfur activity, it is possible for pyrrhotite to form in sediments.

For anoxic sediments from the Gulf of California and suboxic hemipelagic muds from the Oregon continental slope with sedimentation rates exceeding 1m/kyr, Karlin and Levi (1983, 1985) documented very rapid, dramatic decreases with depth of the intensity of NRM and artificial remanences, paralleled by downcore decrease in porewater sulfate and systematic growth in solid sulfur, mainly as pyrite (Figure M109). In both environments, the remanence resides in finegrain nearly pure magnetite. These data suggest that early oxidative decomposition of organic matter leads to chemical reduction of the ferrimagnetic minerals and other iron oxides, which are subsequently sulfidized and pyritized with depth. Changes in the remanence intensity and stability are consistent with selective dissolution of the smaller particles, causing downcore coarsening of the magnetic fraction. In these environments, there was no evidence for the formation of authigenic magnetitic minerals. In this example, there is no CRM formation; rather, the sediments experience chemical demagnetization via dissolution. The chemical processes cause substantial reduction of the remanence intensity, while the directions appear to be unaffected.

In other suboxic marine environments, characterized by lower sedimentation rates, on the order of centimeters/kyrs, CRM in authigenic magnetite particles accompanies oxidative decomposition of organic matter immediately above the Fe-reducing zone (Karlin *et al.*, 1987; Karlin, 1990). Some of the smaller authigenic magnetite particles are subsequently dissolved downcore on entering the zone of Fe-reduction (Figure M110). In the past approximately fifteen years, an increasing number of paleomagnetic studies have identified CRM in ferrimagnetic iron sulfides, pyrrhotite and greigite, in a variety of marine and lacustrine settings (e.g., Roberts and Turner, 1993; Reynolds *et al.*, 1999; Weaver *et al.*, 2002; Sagnotti *et al.*, 2005). While in many cases the Fe-sulfides are formed during early diagenesis upon initial burial, they can also result from later diagenesis, deeper in the sections.

**Figure M110** Downcore profiles of the NRM intensity, partially AF demagnetized at 20 mT, and the saturation magnetization for core TT11 from NE Pacific Ocean (modified from Karlin, 1990).

Recently, Roberts and Weaver (2005) described multiple mechanisms for CRM involving sedimentary greigite. The resolution of paleomagnetic time series would be compromised in sediments where CRM occurs in authigenic magnetic minerals, formed below the remanence lock-in depths. In light of this analysis t, it is possible that sediments discussed earlier in this section experienced multiple episodes of CRM. The first might arise from diagenesis of magnetite and other iron oxides to iron sulfides during initial burial. A later CRM might be produced in magnetite due to diagenesis of iron sulfides or, possibly, in hematite due to dedolomitization in an oxidizing environment, depending on the sediment composition and prevailing geochemistry.

## **Concluding Remarks**

This report on CRM is not exhaustive and reflects the interests, biases and limitations of the author. It is an update of a similar article written over fifteen years ago (Levi, 1989). In the future, as paleomagnetists address more difficult tectonic and geomagnetic questions, requiring data from structurally more complex, metamorphosed, and older formations, it will be increasingly likely that CRM will contribute to the NRM. Paleomagnetists have become more adept at isolating different remanence components, using detailed and varied demagnetization procedures. It is usually assumed that the most resistant remanence, whether with respect to increasing temperatures, alternating fields, or a particular leaching agent is also the primary component. However, CRM stabilities are highly variable, and this assumption is unlikely to be satisfied universally. During the past fifteen years, there has been progress in understanding several aspects of CRM, including (a) the recognition that even for some very young subaerial lavas the NRM may comprise a low-temperature CRM component, and (b) that in some active sedimentary environments, diagenesis leads to CRM in ferrimagnetic iron sulfides. A more comprehensive understanding of CRM is needed to assist paleomagnetists to interpret complex, often multicomponent, NRMs with probable CRM overprints. This goal would be advanced by conducting controlled field and laboratory CRM experiments to (1) recognize the varied geochemical environments that produce different magnetic minerals and their associated CRMs; (2) determine the ranges of magnetic and mineralogical stabilities with respect to different demagnetization procedures and for isolating different CRM components; and (3) develop procedures for identifying the timing and sequencing of multi-component CRMs.

## MAGNETIZATION, DEPOSITIONAL REMANENT

The magnetization acquisition processes in unconsolidated sediments have been long studied (e.g., Johnson et al., 1948; King, 1955; Granar, 1958). The early studies showed that magnetic minerals in the sediments align along the ambient magnetic field during deposition through the water column. The magnetization resulting from the sedimentation process has been referred as depositional or detrital remanent magnetization (DRM). The magnetization acquisition process is still not well understood, and the role of the complex interplay of processes occurring during deposition, water-sediment interface processes, burial, and compaction, etc., require further analyses. The characteristics and stability of the remanent magnetization of unconsolidated sediments are determined by the composition, grain size, and shape of individual grains. During deposition in aqueous media, the magnetic particles are subject to the aligning force of the ambient magnetic field, plus the gravitational and dynamic forces. In tranquil conditions alignment of magnetic grains is relatively effective in depositional timescales, which are affected by Brownian forces. Nagata (1961) showed that equilibrium with the ambient magnetic field is attained in a scale of 1 s. Therefore, saturation magnetization should be expected in natural depositional systems, with the DRM intensity independent of the ambient magnetic field intensity. However, this is not the case, and the magnetization intensity is related to the intensity of the ambient magnetic field (Johnson et al., 1948). The DRM intensities lower than saturation values have been related to misalignment effects of Brownian motion of submicron ferrimagnetic grains (Collinson, 1965; Stacey, 1972). Near the water-sediment interface, flow conditions may become relatively stable and simple by having laminar flow (Granar, 1958) but still the deposition process is complex. The interplay and characteristics of the bottom sediments result in a variety of fabrics in the deposited sediments.

In general, reorientation of magnetic minerals occurring after deposition and before consolidation of the sediment is referred as postdepositional DRM. Perhaps, the most notable distinction between depositional DRM and postdepositional DRM is the occurrence of the so-called inclination error present in depositional DRM (Johnson *et al.*, 1948; King, 1955; Granar, 1958). If  $I_{\rm H}$  is the inclination of the ambient Earth's magnetic field at the time of sediment deposition, then the inclination of magnetization  $I_{\rm S}$  can be expressed in terms of

 $I_{\rm S} = \arctan(f \tan I_{\rm H})$ 

where f is a factor that is determined experimentally. The inclination error has been ascribed to deposition of elongated grains with alongaxis magnetizations tending to lie parallel to the sediment interface and deflecting the magnetization toward the horizontal plane. Laboratory experiments have been conducted to evaluate effects of the intensity of the ambient magnetic field, size and shapes of the magnetic grains, deposition on horizontal, inclined, and irregular surfaces, bottom currents, etc. (e.g., Johnson *et al.*, 1948; King, 1955; Rees, 1961). The inclination error has been observed in laboratory experiments, where the angular difference can be as high as  $20^{\circ}$  (King, 1955), but it is smaller (5–10°) or absent in natural sediments.

Barton *et al.* (1980) studied the change with time in the DRM acquisition process of laboratory-deposited sediments and found that in less than 2 days, there was no appreciable inclination error. In natural conditions, postdepositional DRM presents no significant inclination error. One of the major differences between laboratory experiments and natural conditions is the deposition rate. The time taken for realignment has been estimated in a few years and is apparently related to the water content of the sediments. Verosub *et al.* (1979) experimentally reexamined the role of water content in acquisition of postdepositional DRM and suggested that small-scale shear-induced liquefaction is the main magnetization process. There are also several additional factors involved; for instance bottom water currents, changing water levels, presence of organic matter, biological activity (bioturbation), particle flocculation, floccule disaggregation, dewatering, etc.

In general, it appears that rapidly deposited sediments show inclination and bedding inclination errors, similar to those observed in laboratory experiments. Slowly deposited or high-porosity sediments show small or no inclination error. Postdepositional DRM will realign the magnetization direction; this process may occur in short timescales of days or months, but may occur in periods of years or decades following deposition (Tarling, 1983).

In addition to studies of secular variation and magnetostratigraphy in sedimentary sequences, there has also been much interest in determining relative paleointensities from sedimentary records (Tauxe, 1993). Long records of relative paleointensities have been derived from marine and lake sedimentary sequences, and results have been compared with volcanic records and other records. There have been also several attempts to examine the effects of depositional factors in the DRM intensity, including for instance the effects of clay mineralogy, electrical conductivity of sediments, pH and salinity (Lu et al., 1990; Van Vreumingen, 1993; Katari and Tauxe, 2000). Katari and Bloxham (2001) examined the effects of sediment aggregate sizes on the DRM intensities, and proposed that intensity is related to viscous drag that produces misalignment of magnetic particle aggregates. They argue that interparticle attractions arising from electrostatic or van der Waals forces and/or biologically mediate flocculation results in formation of aggregates (which present a log-normal size distribution) preventing settling of individual smaller grains.

The depositional and postdepositional DRM in laboratory experiments and naturally deposited sediments have been intensively studied; nevertheless, further work is required to understand the complex interplay of processes and then develop magnetization acquisition models (e.g., Verosub, 1977; Tarling, 1983; Tauxe, 1993; Katari and Bloxham, 2001).

#### MAGNETIZATION, ISOTHERMAL REMANENT

#### Introduction

As indicated by the name, isothermal remanent magnetization (IRM) is a *remanent magnetization* (RM) acquired without the aid of changes in temperature. There are actually many processes that can produce RMs isothermally (see, e.g., *CRM*, *VRM*, *DRM*, and *ARM*), but by convention we restrict the use of the term IRM to denote a remanence resulting from the application and subsequent removal of an applied DC field. IRMs are thus intimately related to *hysteresis*. Conventional nomenclature uses  $M_R$  for the IRM determined by measurement of a hysteresis loop (and  $M_{RS}$  if the cycle reaches saturation), whereas IRM and SIRM are typically used for remanence measurements made with a zero-field magnetometer after magnetization on a separate instrument (electromagnet, pulse magnetizer, etc.).

Weak fields, such as the geomagnetic field, are generally very ineffective in producing IRMs, and therefore IRMs are rarely significant components of NRM. (A notable exception is found in rocks struck by lightning, as discussed below.) IRMs are therefore primarily of interest as laboratory-produced remanences, and are used in sample characterization, in studying the mechanisms affecting stable remanence, and as a normalizing parameter for estimation of relative *paleointensity*. The attributes of principal interest are: the *intensity* (dipole moment per unit mass or volume); the *coercivity* (range of fields over which significant acquisition occurs) or *stability* (resistance to demagnetization by thermal, alternating-field, and/or low-temperature methods); and the *anisotropy* (dependence on orientation of the applied field).

## Grain-scale processes and remanent states of individual particles

In a sufficiently strong applied field, the magnetic structure inside a ferromagnetic particle is simple: uniform magnetization parallel to the field, i.e., saturation magnetization  $(M_S)$ . With decreasing applied field intensity, interesting complexities develop in response to the internal demagnetizing field, magnetocrystalline anisotropy and stress: magnetization may rotate away from the applied field direction toward an easy axis determined by grain shape, crystal orientation or stress; the magnetization may become nonuniform, with spins arranged in "flower" or "vortex" structures; domains may nucleate and grow, with magnetizations oriented at high angles to those of neighboring domains. Upon complete removal of the saturating applied field, the particle reaches its saturated remanent state, with a net intensity  $M_{\rm RS} \leq M_{\rm S}$ , oriented in general with a positive component parallel to the applied field direction, i.e.,  $M_{RS//} > 0$  (although self-reversal of IRM has been reported in rare cases, e.g., Zapletal, 1992). The ratio  $M_{\rm RS}/M_{\rm S}$  for an individual particle thus ranges from 0 to 1, depending on the saturated remanent domain state, and  $M_{RS//}/M_S$  depends additionally on easy-axis orientation(s) with respect to the applied field direction.

For an ideal single-domain (uniformly magnetized) particle,  $M_{\rm RS}$  is equal in magnitude to  $M_{\rm S}$ , and the ratio  $M_{\rm RS//}/M_{\rm S}$  is thus determined by the particle anisotropy (number and symmetry of easy axes) and orientation (Gans, 1932; Wohlfarth and Tonge, 1957). For an ideal SD particle with uniaxial (e.g., shape) anisotropy, oriented at an arbitrary angle  $\phi$  to the applied field,  $M_{\rm RS//}/M_{\rm S} = \cos(\phi)$  and  $M_{\rm RS\perp}/M_{\rm S} =$  $\sin(\phi)$ ;  $M_{RS///}M_S$  thus ranges from 0 for an applied field perpendicular to the easy axis (i.e., the moment rotates 90° as the field is removed) to 1 for the parallel case. Magnetocrystalline anisotropy often involves multiple symmetrically equivalent easy axes (e.g., the cubic body diagonals in magnetite, and the cube edges in Ti-rich titanomagnetites). For a *multiaxial* SD particle, the maximum angle ( $\phi_{max}$ ) that may separate the applied field from the nearest easy axis is reduced (Figure M111), and the minimum ratio  $M_{\rm R}//M_{\rm S}$  is accordingly increased. For an individual cubic SD magnetite grain,  $\phi_{\text{max}} = 54.7^{\circ}$  and thus 0.577  $\leq M_{\rm RS//}/M_{\rm S}$ .

Above a threshold grain size, uniformly magnetized remanent states become energetically unfavorable, and vortex (Williams and Wright, 1998) or *multidomain* structures consequently develop, lowering the total energy by reducing the net remanence of the particle. In a two-domain particle with antiparallel domain magnetizations, the net remanence is primarily due to domain imbalance; in asymmetrically shaped grains the minimum-energy state may yield a significant net (imbalance) moment (Fabian and Hubert, 1999). Even when domain moments exactly cancel in two-domain grains, the domain-wall moment ("psark," Dunlop, 1977) provides a small but stable net particle moment. Increasing domain multiplicity generally results in more perfect mutual cancellation of both the domain moments and the wall moments (which have been observed to alternate in polarity across magnetite grains with several domains, Pokhil and Moskowitz, 1997), and there is consequently a strong reduction in  $M_{\rm RS//}/M_{\rm S}$  with increasing particle size.

#### Remanent states: ensembles of particles

Except in very coarse-grained rocks, even a centimeter-sized cubic or cylindrical specimen contains a very large number of ferrimagnetic particles. The net IRM of a population of grains is simply the vector sum of the individual grain remanent moments, and thus its magnitude depends on the number of remanence-carrying particles, their size (domain-multiplicity) distribution, particle-level anisotropy, and orientation distribution (i.e., population-level anisotropy) relative to the applied-field direction. In interacting assemblages, each particle is influenced not only by the externally applied field but also by the fields of neighboring particles, so the spatial distribution of grains is an additional important factor (Muxworthy *et al.*, 2003).

Figure M111 Cube edge <100> directions (diamonds) are the magnetocrystalline easy axes for high-Ti titanomagnetites. Due to the cubic symmetry, an applied field can be oriented no more than  $\theta_{max} = 54.7^{\circ}$  from the nearest easy axis of an individual grain. For a randomly oriented assemblage of ideal SD grains with <100> easy axes,  $M_{RS}/M_{S} = 0.832$  (Gans, 1932). This is most easily calculated in the particle coordinate system, by noting that an IRM parallel to the polar easy axis results from application of a sufficiently strong field oriented anywhere within the "capture area" comprised of the eight adjacent congruent spherical triangles (outlined in bold). For each particle,  $M_{\rm R//}/M_{\rm S} = \cos(\phi)$ , and for the assemblage  $M_{\rm RS}/M_{\rm S}$  is obtained by integrating  $\cos(\phi)$ over the "capture area." Body diagonal <111> directions (triangles) are the magnetocrystalline easy axes for magnetite at temperatures above the 130 K isotropic point; the "capture area" for these consists of six congruent spherical triangles, and integration of  $\cos(\phi)$  over this area yields  $M_{\rm R}/M_{\rm S} = 0.866$  for a randomly oriented assemblage of ideal SD grains with <111> easy axes.

#### Orientation distribution and bulk anisotropy

The simplest case to consider is that of a perfectly aligned population of identical single-domain particles, for which the ratio  $M_{\rm RS//}/M_{\rm S}$  of the assemblage equals that of each individual particle:  $M_{\rm RS//}/M_{\rm S} = \cos(\phi)$ , where  $\phi$  is the angle between the applied field and the nearest easy-axis direction in the aligned assemblage. Note that in this case, as for an individual particle, the net IRM generally has both parallel and transverse components.

A perfectly aligned population represents an extreme not often approached in natural materials, most of which are considerably closer to the opposite limiting case: isotropic (random or quasiuniform) orientation distribution (OD). For an ensemble of SD particles with an isotropic OD,  $M_{\rm RS//}/M_{\rm S}$  is determined entirely by the particle-level anisotropy (Gans, 1932; Stoner and Wohlfarth, 1948; Wohlfarth and Tonge, 1957), and the net transverse component is effectively zero. For uniaxial anisotropy, grain moments rotate on average 60° to the nearest easy axis when the applied field is removed, yielding  $M_{\rm RS//}$  $M_{\rm S} = M_{\rm RS}/M_{\rm S} = \cos(60^\circ) = 0.5$ . (This result is obtained by integrating parallel components over the assemblage, equivalent to integrating  $\cos(\phi)$  over the hemisphere surrounding the applied field orientation, within which the proximal easy axes are distributed.) With multiaxial anisotropies the average rotation angle is significantly reduced and  $M_{\rm RS}/M_{\rm S}$  is concomitantly increased. For an ensemble of cubic SSD particles with <100> easy axes (e.g., TM60) and a uniform OD, the expected  $M_{
m RS///} M_{
m S}$  ratio is calculated by integrating  $\cos(\phi)$  over the "capture area" surrounding a cube edge orientation (Figure M111),

yielding  $M_{\rm RSI}/M_{\rm S} = M_{\rm RS}/M_{\rm S} = 0.832$ . For <111> easy axes (e.g., magnetite), integration over the region surrounding a body diagonal orientation yields  $M_{\rm RSI}/M_{\rm S} = M_{\rm RS}/M_{\rm S} = 0.866$  (Gans, 1932; Stoner and Wohlfarth, 1948).

For the imperfect antiferromagnets hematite and goethite, as well as the hard ferrimagnet pyrrhotite, the applied fields typically used in rock magnetism ( $\leq 1$  T produced by electromagnets;  $\leq 5$  T produced by typical superconducting magnets) are insufficient to achieve saturation. When these minerals occur with fine-grain sizes and/or impure compositions, applied fields exceeding 60 T may be required to saturate the remanence (Mathé *et al.*, 2005). A hard magnetocrystalline anisotropy largely confines the remanence to the basal planes of hematite and pyrrhotite, and to the *c*-axis for goethite. Hematite's basal-plane anisotropy has both a weak triaxial magnetocrystalline component and a uniaxial magnetoelastic component (Banerjee, 1963; Dunlop, 1971). When the uniaxial anisotropy dominates  $M_{\rm RS}/M_{\rm S} = 0.637$ . In the absence of strong uniaxial anisotropy, the hexagonal symmetry results in much higher ratios, up to 0.955 (Wohlfarth and Tonge, 1957; Dunlop, 1971).

When particle moments are diminished by the development of nonuniform remanent states, the ratio  $M_{\rm RS}/M_{\rm S}$  of the population decreases proportionally. For magnetite there is a more or less continuous decrease in the remanence ratio with increasing grain size. Data compiled by Dunlop (1995) for the size range 40 nm  $\leq d \leq 400 \,\mu\text{m}$  show that  $M_{\rm RS}/M_{\rm S}$  varies in proportion to  $d^{-n}$  (0.5  $\leq n \leq 0.65$ ), with two separate size-dependent trends: stress-free hydrothermally grown grains have significantly lower remanence ratios than similarly sized crushed grains or grains grown by the glass ceramic method.

Bulk IRM anisotropy is controlled both by particle-level anisotropy and by the orientation distribution of the population. Like other bulk magnetic anisotropies, the anisotropy of IRM (AIRM) has been used to characterize rock fabric for geological applications and for evaluating directional fidelity of NRM (Fuller, 1963; Cox and Doell, 1967; Daly and Zinsser, 1973; Stephenson *et al.*, 1986; Jackson, 1991; Kodama, 1995). IRM differs from weak-field induced and remanent magnetizations (e.g., susceptibility, ARM, and TRM) in that it is generally a nonlinear function of applied field, and consequently the tensor mathematics used to describe linear anisotropic magnetizations are not valid for AIRM, except when very weak magnetizing fields ( $\leq$  a few millitesla) are used. Nevertheless it is a relatively rapid and very sensitive method of characterizing magnetic fabric (Potter, 2004).

#### "Partial IRMs" and coercivity spectrum analysis

Partial TRMs (pTRMs) and partial ARMs (pARMs) are generated when a weak but steady bias field is applied during some part, but not all, of the cooling or AF decay. Clearly no direct analog can exist for IRM, but "pIRM" equivalents can be produced physically (by partial demagnetization of an IRM), or calculated mathematically (by subtraction of IRMs acquired in different fields). Partial IRMs and their ratios are very widely used for sediment characterization in environmental magnetism (Thompson and Oldfield, 1986; King and Channell, 1991; Oldfield, 1991; Verosub and Roberts, 1995; Dekkers, 1997; Maher and Thompson, 1999). For example the hard fraction, HIRM, is determined by subtracting the IRM acquired in 300 mT (IRM<sub>300</sub>) from SIRM, to estimate the contribution of antiferromagnetic minerals (e.g., hematite and goethite) to the saturation remanence. HIRM, as conventionally defined, is an absolute, concentration-dependent parameter. The soft fraction is more often quantified in relative terms through the so-called S-ratios, calculated from measurements of SIRM and of the IRM subsequently acquired in an oppositely directed field of 100 mT (IRM<sub>-100</sub>) or 300 mT (IRM<sub>-300</sub>): S<sub>100</sub> =  $-IRM_{-100}/SIRM$ , and  $S_{300} = -IRM_{-300}/SIRM$ . These ratios range from -1 (for samples containing only hard antiferromagnets) to +1 (for samples dominated by soft ferrimagnets).

A more thorough method of deconstructing an SIRM uses application of two successive orthogonal applied fields of decreasing strength to reset the remanence of the intermediate- and low-coercivity fractions; the resultant "triaxial" IRM is then thermally demagnetized to determine the unblocking temperature distribution associated with each coercivity fraction (Lowrie, 1990). The threshold fields are selected for isolation of different mineralogical and grain-size fractions; Lowrie (1990) used 5 T for the initial SIRM (sufficient to magnetize hematite and goethite at least partially); 0.4 T for the first orthogonal overprint (to reorient the remanence of the ferrimagnets magnetite and pyrrhotite); and 0.12 T for the second overprint (to realign the remanence of soft MD carriers).

For many geological applications, recognition and quantification of a few discrete IRM-carrying fractions is adequate, but finer subdivision of SIRM into a quasicontinuous coercivity distribution can be made by differentiation of the IRM acquisition curve (Dunlop, 1972). Starting from a demagnetized state, application of successively stronger fields results in growth of IRM as domain structures change and single-domain moments are reoriented, each at a critical field determined by particle anisotropy and orientation. The resulting *coercivity spectrum* can be analytically decomposed if it assumed that the distributions each follow some prescribed form, typically lognormal (Figure M112) (Robertson and France, 1994; Stockhausen, 1998; Heslop *et al.*, 2002; Egli, 2003, 2004 a,b).

Starting from the SIRM state, application of successively larger opposite-polarity "backfields" causes the net remanence first to decrease and then to grow in the reverse direction, eventually reaching the negative SIRM state; this process is often termed "DC demagnetization" but it is perhaps more useful to think of it as a part of the isothermal remanent hysteresis cycle. The *remanent coercivity*  $H_{CR}$  is defined as the field-axis intercept of the remanent hysteresis loop, exactly as the bulk coercivity  $H_C$  is defined for the in-field loop.

#### Interaction effects

In the absence of interparticle interactions, the IRM acquisition curve for SD ensembles has a simple and direct relationship to the "DC demagnetization" curve (Wohlfarth, 1958). In each case, a particular applied field activates the same set of particles; in the former case randomly oriented moments (in the demagnetized ensemble) are replaced with a net IRM, whereas in the backfield case a net IRM is replaced with its opposite-polarity equivalent. The change in the latter case is exactly twice that in the former, and thus the relationship between the initial acquisition curve  $M_{\rm IRA}(H)$  and the backfield curve  $M_{\rm IRB}(-H)$  is:  $M_{\rm IRB}(-H) = \text{SIRM}-2M_{\rm IRA}(H)$ . For AF demagnetization, each peak AF erases the remanence imprinted by the corresponding DC applied field, so  $M_{\rm IR}(\tilde{H}) = \text{SIRM}-M_{\rm IRA}(H_{\rm DC})$ , i.e., there is a mirror symmetry of the IRM acquisition and AF demagnetization curves for noninteracting SD populations.

There are two commonly used graphical illustrations of these relationships. The *Henkel plot* graphs  $M_{\rm IRB}(-H)$  as a function of  $M_{\rm IRA}(H)$  (Henkel, 1964). For noninteracting SD ensembles, the relationship is linear, with a slope of -2 (Figure M113a). The *Cisowski plot* (Cisowski, 1981) or *crossover plot* (Symons and Cioppa, 2000) simultaneously graphs the acquisition curve  $M_{\rm IRA}(H_{\rm DC})$  together with the AF-demagnetization curve  $M_{\rm IR}(\tilde{H})$  and/or the appropriately rescaled DC-backfield curve  $M'_{\rm IRB}(H) = 0.5({\rm SIRM} + M_{\rm IRB}(-H))$ , as functions of the AC and DC fields (Figure M113b). On this plot, noninteracting SD populations are indicated by mirror symmetry, with an intersection at the point whose field coordinate is equal to both the median destructive field (MDF; also referred to as  $\tilde{H}_{1/2}$ , Dankers, 1981) and the median acquisition field (MAF; also referred to as  $H'_{\rm CR}$  (Dankers, 1981)), and whose magnetization coordinate is equal to 0.5\*SIRM.

A crossover ratio R < 0.5 (equivalent to a trajectory on the Henkel plot that "sags" below the line of slope -2) indicates that MAF > MDF, in other words that the ensemble is harder to magnetize than to demagnetize. Such behavior is a hallmark of either a negatively interacting SD population or MD carriers (for which self-demagnetization produces the equivalent effect); these two possibilities often cannot be definitively distinguished on the basis of IRM data alone (Dunlop and Özdemir, 1997). Crossover ratios R > 0.5 are virtually never observed, in part due to the extreme rarity of MD-free magnetic assemblages in natural materials, but further suggesting that interactions in SD assemblages, when they occur, are primarily negative.

Theoretical treatment of interactions in multidomain assemblages has been hindered by the analytical and numerical intractability of modeling interacting nonuniformly magnetized grains. However, recent results obtained at the resolution limit of micromagnetic modeling (Muxworthy *et al.*, 2003) shows that in general, interaction begins

**Figure M112** Coercivity spectrum analysis (methods of Heslop *et al.*, 2002), modeling the measured IRM acquisition (solid circles) as the sum of log-Gaussian distributions, in this case with three components (open symbols). Integrating and summing yields the model IRM curve (solid black). The individual components can be interpreted as different mineral and/or grain-size populations.

**Figure M113** *Top*: Henkel (1964) plot for a sample with ideal noninteracting SD behavior. *Bottom*: Cisowski (1981) plot of the same data (backfield data rescaled and reflected). After Worm and Jackson (1999), with permission of the authors and publisher.

to have significant effects for SD and PSD grains (30–250 nm) when the separation between particles is less than or equal to twice the particle diameter; this is comparable to the threshold for susceptibility interaction effects (Hargraves *et al.*, 1991; Stephenson, 1994; Cañon-Tapia, 1996). Interestingly, the model results show that IRM interactions are primarily negative (decreasing  $M_{\rm RS}/M_{\rm S}$ ) for single-domain ensembles, but positive (increasing  $M_{\rm RS}/M_{\rm S}$ ) for grains >100 nm.

#### Kinetic effects: time-dependent IRM (TDIRM)

Néel (1949a,b, 1955) theory provides the basis for understanding phenomena such as magnetic *viscosity, thermoremanence,* and *frequencydependent susceptibility,* by specifying how magnetization kinetics depend on factors including temperature, applied field, and particle size. At room temperature, and for typical experimental timescales of milliseconds to hours, thermal fluctuations are most significant for nanometric particles; for magnetite the transition from superparamagnetic to stable SD behavior occurs under these conditions at approximately 20–30 nm. A highly sensitive method of probing the SP-SSD threshold uses IRM acquisition with varying exposure times (Worm, 1999).

At any fixed absolute temperature T, the initial magnetization  $M_0$  of an assemblage of single-domain grains grows or decays in time (t), approaching an equilibrium value in a constant applied field H:

$$M(t) = M_0 e^{-t/\tau} + M_{eq} (1 - e^{-t/\tau})$$
(Eq. 1)

where the equilibrium magnetization  $M_{eq}$  is:

$$M_{\rm eq}(T,H) = M_{\rm S} \tanh\left(\frac{\mu_0 V M_{\rm S} H}{kT}\right)$$
(Eq. 2)

and the relaxation time  $\tau$  is:

$$\tau(T,H) = \tau_0 \exp\left(\frac{VM_{\rm S}(T)H_{\rm K}(T)(1-H/H_{\rm K}(T))^2}{2kT}\right)$$
 (Eq. 3)

In these equations V is grain volume,  $H_{\rm K}$  is microscopic coercivity, k is Boltzmann's constant (1.38 × 10<sup>-23</sup> J K<sup>-1</sup>),  $\mu_0$  is the permeability of free space (4 $\pi$  × 10<sup>-7</sup> H m<sup>-1</sup>), and  $\tau_0$  is approximately 10<sup>-9</sup> s. Very fine (small V) and/or very soft (low  $H_{\rm K}$ ) grains have shorter relaxation times, and equilibrate more quickly, than do larger and/or magnetically harder SD grains.

Note that relaxation time drops very sharply as the applied field Happroaches HK. IRM is thus acquired quickly, and then becomes stabilized ( $\tau$  increasing sharply) when the applied field is removed. Timedependent IRM is significant in populations of SD particles with narrow distributions of V and  $H_K$ , i.e., with a narrow distribution of relaxation times in the applied field H. Exposure times less than the mean relaxation time are too short for significant acquisition of remanence, but exposure times one or two orders of magnitude larger may allow substantial equilibration with the applied field. The timedependence of IRM in such assemblages is much stronger than the frequency-dependence of susceptibility ( $\chi_{fd}$ ). For example, ash-flow tuffs from Yucca Mountain Nevada have a  $\chi_{fd}$  of up to 35% per decade, the highest known for any geological material; in contrast their IRM intensities increase by as much as 800% with a tenfold increase in exposure time (Worm, 1999). The time-dependence is effectively amplified for IRM by the strong asymmetry between acquisition and decay rates.

#### Lightning strikes and IRM in nature

Lightning has long been recognized as a significant mechanism for overprinting natural remanence (Matsuzaki *et al.*, 1954; Cox, 1961; Graham, 1961), due primarily to the strong magnetic fields locally generated by the intense currents involved in lightning strikes. These currents, typically  $10^4-10^5$  A, are dominantly upward-directed (i.e., electrons flow down from the cloud to the ground along the ionized flow path), and most lightning flashes include three or four separate upward current pulses ("return strokes"), spaced about 50 ms apart (e. g., Krider and Roble, 1986).

The magnetic field *B* generated by a straight filamentary current *I* of effectively infinite length, at a point located at a perpendicular distance *r*, has a magnitude  $\mu_0 I/(2\pi r)$ . For example, a 30 kA current produces a field of 60 mT at r = 10 cm, sufficient to impart a significant IRM in most materials. The orientation of the field is perpendicular to both *I* and *r*, i.e., the field lines are circles, centered on and perpendicular to the filamentary current. Both of these characteristics, concentric directional geometry and 1/r field dependence, have been observed by Verrier and Rochette (2002) in IRM overprints in samples collected around known lightning strikes (Figure M114).

However in most cases the patterns are not so clear. Although the current in a lightning bolt flows along an effectively infinite (typically

5 km) and relatively straight vertical path between cloud and ground, the path along and below the ground surface is much shorter and more irregular, as shown by the geometry of fulgurites, which are formed when rocks or sediments are melted by lightning. (Temperatures in the ionized channel typically reach 30000 K, five times the temperature of the sun's surface). This irregularity may be expected to disrupt the simple cylindrical symmetry of the induced magnetic field. In the absence of simple directional symmetry, the diagnostic feature for identification of lightning-produced IRM is a combination of high NRM intensity (or more specifically, high NRM/SIRM ratios) and moderate-to-low resistance to AF demagnetization (Cox, 1961; Graham, 1961); thermal demagnetization is generally much less effective at separating lightning overprints (e.g., Tauxe *et al.*, 2003).

Quantitative estimates of lightning currents (Wasilewski and Kletetschka, 1999; Verrier and Rochette, 2002; Tauxe *et al.*, 2003) require both a paleointensity determination and an estimate of the separation between sample location and lightning strike. Wasilewski and Kletetschka (1999) and Tauxe *et al.* (2003) estimate lightning field intensities by finding the lab field that produces an IRM of the same intensity as the lightning overprint. Because lightning remanences may decay with time, this approach yields a minimum estimate of the magnetizing field associated with a strike. Verrier and Rochette (2002) use an alternative approach based not on the overprint intensity but on the AF amplitude required to erase it.

### MAGNETIZATION, NATURAL REMANENT (NRM)

Natural remanent magnetization (NRM) is remanent magnetization that has been acquired naturally (i.e., not artificially acquired in a laboratory). It is the remanent magnetization of a sample (such as rock or baked archaeological material) that is present before any laboratory experiments are carried out. Magnetization is usually measured normalized to either the sample volume (units of A m<sup>-1</sup>) or sample mass (units of A m<sup>2</sup> kg<sup>-1</sup>). NRM can consist of one or more types of magnetization depending on the history of the sample. Rock samples that have been exposed to the Earth's magnetic field for many millions of years may have experienced several different processes of magnetization during that time, producing multiple components of magnetization. Components acquired at the time of rock formation are termed primary and later components are termed secondary. The NRM is then the vector sum of all the naturally acquired components of magnetization:

$$NRM = Primary component + \sum_{i} Secondary components_i$$

i = 0, 1, 2, ..., n, where *n* is the number of secondary components. Both primary and secondary components in a rock can record geological events (for example, the time of formation, metamorphism, or an impact event) and are of interest in unraveling the geological history of the rock. Generally, however, it is the primary remanence acquired on formation that is of most interest to the paleomagnetist. Depending on the intensity and duration of the events responsible for secondary magnetizations (also known as overprints), the latter may partially or completely replace the primary magnetization.

**Figure M115** Example of thermal and AF demagnetization. Solid (open) symbols on the orthogonal vector plot (OVP) represent vertical (horizontal) components of magnetization. (a) Thermal demagnetization of Australian Tertiary basalt. There is a viscous secondary component that is removed by 200°C to leave the primary component of remanence. #### Primary and secondary remanence

When igneous rocks and baked archaeological materials cool on formation, they acquire a primary thermoremanent magnetization (TRM) (q.v.) in the ambient geomagnetic field as the temperature falls below the Curie temperature of the magnetic minerals. A later thermal event below the Curie point will unblock part of the TRM and replace it with a later partial thermal remanent magnetization (pTRM) secondary remanence. If magnetic minerals grow in the presence of a magnetic field, a chemical remanent magnetization (CRM) (q.v.) is formed when a critical blocking volume is attained. The remanence in sedimentary rocks is often a CRM. CRMs can also be produced in igneous and metamorphic rocks. In sediments, the primary remanence is usually a depositional remanent magnetization (DRM) (q.v.) acquired when ferromagnetic particles are aligned in the geomagnetic field during deposition. In sedimentary rocks, dewatering during the prolonged process of lithification will usually have enhanced the alignment of these grains with the geomagnetic field to produce a postdepositional detrital magnetization (PDRM).

Samples may acquire a magnetization at ambient temperatures over prolonged lengths of time in a weak magnetic field such as the Earth's. This is called viscous remanent magnetization (VRM) (q.v.) and its importance is a function of time spent in the field, the strength of the field, and the grain size and composition of the material. VRM is the most common form of secondary remanence and is present, to varying degrees, in all palaeomagnetic samples. Lightning reaching the ground is capable of inducing magnetization in rocks in a very strong, essentially instantaneous magnetic field. This is called an *isothermal remanent magnetization (IRM)* (q.v.) and can often completely obscure the primary remanence. Meteorites are extraterrestrial samples that can acquire a secondary shock remanent magnetization (SRM), both in the event that excavated the material from the parent body and during impact at arrival on Earth.

Provided the rock has isotropic properties, each of these types of magnetization is in the direction of the magnetic field at the time of formation. The intensity of magnetization is dependent on many things (for example, the number, composition, and grain size of magnetic minerals) and also depends on the strength of the magnetic field. It is only possible to determine the absolute intensity of the field from samples containing a TRM (see *Palaeointensity*).

#### Isolation of NRM components

To isolate the different components of NRM, partial demagnetization techniques are used, as the different components will normally have different stabilities to the demagnetization procedures. The techniques used to resolve the components are thermal and alternating field (AF) demagnetization. Components acquired by differing mechanisms will usually have contrasting blocking temperature and coercivity spectra. During thermal demagnetization, samples are heated to successively higher temperatures in a magnetic field-free space so that magnetization below the treatment temperature is unblocked and randomized. As the temperature increases, more and more of the remanence will be removed until the Curie temperature is reached and the sample is completely demagnetized. With AF demagnetization, the peak AF field is increased until magnetic minerals with the highest coercivity are demagnetized (or maximum laboratory peak AF field is reached). Figure M115 shows an example of thermal and AF demagnetization. The characteristic remanent magnetization (ChRM) is the earliest acquired component of magnetization that can be isolated. So for both examples in Figure M115 this is the primary TRM that the basalt acquired on cooling.

#### MAGNETIZATION, OCEANIC CRUST

In the late 1950s, the first magnetometers adapted to sea surface measurements became available for the scientific community, leading to the discovery of magnetic lineations on the oceanic crust. Since this discovery, first described by Fred Vine and Drummond Matthews in 1963 (the work of Morley and La Rochelle at the same time should also be mentioned), the nature and thickness of the magnetized crust has long been a subject of debate. The depth of the Curie point isotherm for magnetite (580°C) is on the order of a few hundred meters to tens of kilometers below the seafloor (depending on crustal age) and represents a depth limit for remanent magnetization. Below this isotherm, all rocks from the oceanic crust could give rise to a remanent magnetic anomaly signal. However, several decades of magnetic studies on the oceanic crust showed that magnetization is complex and varies by several orders of magnitude depending on the structure of oceanic crust, types of oceanic rocks, and alteration processes.

Magnetic properties of the oceanic crust can be studied by the analysis of magnetic surveys made using sensing instruments mounted on submersibles, towed by ships, or incorporated in satellites. Depending on the distance between the survey and the crustal sources, the focus of remote magnetic analysis can be at very different scales. Submersible surveys can be used to map, for example, the meter scale contrast of magnetization above hydrothermal structures or between flows along ridge axes. By contrast, satellite surveys will give information on the properties of wide oceanic areas and the deepest magnetic sources. In between these extreme scales, sea surface magnetic surveys adapted to the kilometer scale are the reference. Local information can also be collected using downhole magnetometer tools in holes drilled within the crust. When available, the magnetic characterization of drilled or dredged oceanic rocks is a way to directly access magnetization of different rock types and is complementary to remote sensing measurements. Ophiolites, ancient ocean-crust fragments on continents, offer a way to easily access properties of deeper lithologic units. However, the obduction process probably affects mineralogical properties of rocks in such material, and it has been observed that less intense magnetizations are found compared to drilled or dredged oceanic samples. Altogether the fragmented information collected since the early 60's allows a global pattern of magnetization of the oceanic crust to be retreived.

In the following, we present the global structure of the oceanic crust and its variability, then we review the magnetic properties of the extrusive and intrusive basalts, the gabbroic sections, and peridotites.

#### Global structure of the oceanic crust

In 1972, a model for "typical" oceanic crust structure was derived from ophiolite observation and seismic velocity analysis. Often referred to as "Penrose structure," following the name of the international conference on ophiolites where it was established, this layered oceanic crust is as follows: 500 m of basalts, 1500 m of dikes, and 5000 m of gabbros, which together give an average thickness of 7 km of oceanic crust upon unaltered mantle. Since the establishment of this basic model, drilling and dredging show that deep materials, consisting of altered mantle rocks and gabbros, can be seen at outcrops. This more complex three-dimensional structure of the crust is due to spatial and temporal variations of the magmatic and tectonic processes and is more likely to be

**Figure M116** Sketch illustrating (a) the uniform oceanic crust following the model of a Penrose layered crust and (b) an example of idealized portion of crust with a discontinuity in its center allowing exposure of ultramafic outcrops (modified after Cannat *et al.*, 1995). adapted to slow spreading ridges. Ultramafic rocks such as serpentinized peridotites, also called serpentinites, are notably reported in these new crustal models (Cannat *et al.*, 1995). Two "idealized" views of ocean crust are represented in Figure M116, showing a Penrose "layer cake" crust and a discontinuous crust with serpentinite emplaced at the surface. Serpentinized peridotites are altered mantle rocks but will be considered as part of the magnetic oceanic crust, which is described below.

#### Basalt layer

The extrusive basalt layer, also referred to as seismic layer 2A (layer 1 being the sediment cover), consists of pillow and sheeted lava erupted at the ridge axes, pillows being more widely associated with slow spreading ridges and sheet flows with fast spreading ridges. The surface of flows often consists of a few centimeters of rapidly quenched glasses. Magnetic properties of extrusive basalts of the oceanic crust were the subject of numerous studies as a result of the important amount of dredged and drilled samples made available to the scientific community. The magnetic minerals in oceanic basalts are predominantly titanomagnetites associated with various amounts of titanomaghemites, an alteration product of titanomagnetites. The primary natural remanent magnetization (NRM) of basalts is acquired during the extrusion process and is a thermal remanent magnetization. Magnetic properties can show significant variations between flows depending, in particular, on iron and titanium content but also at the within-flow scale depending on local crystallization conditions and alteration progression. On average, NRM of young basalts is in the range of  $10-20 \text{ A m}^{-1}$ , but can reach extreme values on the order of 80 A  $m^{-1}$  or higher for young flows with high iron content. The Koenigsberger parameter, which is defined as a ratio of remanent magnetization to induced magnetization, is almost always greater than one in basalts and can often reach 100 confirming that magnetization of the basalt layer is dominantly of remanent origin. This property favors the magnetic recording of past inversions of the polarity of Earth's magnetic field leading to the pattern of lineated magnetic anomalies. Microscopic observations and Curie temperatures dominantly within 150-250°C for young unoxidized basalts characterize a primary population of titanomagnetic grains with 60% ulvospinel (called TM60). In addition to this dominant population within the bulk part of the lava, fine-grained titanomagnetite with a broader composition (between 0% and 50% ulvospinel) is observed in the rapidly quenched glassy part (Zhou et al., 2000). As a consequence, higher Curie temperatures and lower NRMs are commonly found at the pillow margin. However, magnetic anomalies are caused by basalts rather than the thin glassy part and the high magnetization of young basalts led some authors during the late 1960s to suggest that rocks from only the first few hundred meters belonging to the extrusive basaltic layers could actually be responsible for most, if not all, of the magnetic signal observed by Vine and Mathews (e.g. Klitgord et al., 1975). This led to the first magnetic models of the oceanic crust as a uniformly highly magnetized basalt

layer. However, extensive magnetic measurements on oceanic rocks made available, in particular by the Deep Sea Drilling Project (DSDP) program, in the late 1970s and early 1980s showed that magnetization of the basaltic extrusive layers was not homogeneous. This is mostly a consequence of the low temperature alteration of titanomagnetites to titanomaghemite, caused by circulation of seawater in the rocks pores and cracks (O'Reilly, 1984). During the process, Curie temperature progressively increases, whereas NRM decreases typically down to values on the order of a few A  $m^{-1}$ . A secondary, less intense remanent magnetization replace part of the original thermal remanent magnetization. The magnetic record of Earth's magnetic field inversions in the upper oceanic crust is nevertheless well preserved, because this secondary magnetization remains parallel to the original direction despite its chemical origin (for a review on this topic see Dunlop and Ozdemir, 1997). Depending on the alteration environment, secondary minerals can also be created at the expense of magnetite, iron sulfides being an example often associated to hydrothermal alteration. The common occurrence of secondary viscous magnetization contributes to lowering of the magnetic signal. These findings corroborate the idea that to account for the magnetic anomaly signal, deeper seated rocks are more highly magnetized than first expected.

#### Dike layer

Below the extrusive basalt layer, dike complexes are the first intrusive bodies. Oceanic intrusive rocks have been the subject of fewer studies than basalts due to increasing difficulties in sample accessibility. Rocks from escarpments, tectonized areas, and ophiolites are thus overrepresented and might not represent the norm. From what we know, the sheeted dike layer (also called layer 2B) shows contrasting magnetizations. The much slower cooling rate of intrusive rocks results in an initial magnetic population of large multidomain titanomagnetite grains. Curie temperatures are reported to be quite homogeneous and close to 580°C indicating magnetite as the main carrier of the magnetization. This is the result of widespread oxidation-exsolution of titanomagnetite grains. This process by which the multidomain grains exsolved to a solid solution with pure magnetite could take place during the slow initial cooling (the so-called deuteric oxidation common in subaerial lavas) but the presence of the characteristic lamellar structures associated with such a process is not always observed in submarine dikes. It is likely that low temperature and hydrothermal alteration make a significant contribution to exsolution in this context. Hydrothermal alteration also plays an important role in the loss of iron from grains, recrystallization of magnetite, and replacement of titanomagnetite crystals by silicate minerals (Smith and Banerjee, 1986). Typical remanent magnetization in dikes is typically  $10^{-1}-10^{-2}$  A m<sup>-1</sup>, but stronger magnetizations on the order of 1 A m<sup>-1</sup> are found in the freshest samples. Koenigsberger ratios are lower than in basalts but usually above one (ophiolites dikes have lower Koenigsberger ratio) showing that magnetization of submarine dikes is for its most part of remanent origin. This remanent magnetization is mainly acquired during alteration and its relationship with the geomagnetic field at the time of emplacement is not yet clear.

#### Gabbros

Gabbros are found below oceanic basalts and are coarse-grained igneous rocks (seismic layer 3). The dominant magnetic mineral in gabbros is magnetite, occurring as a primary mineral produced by the exsolution of large titanomagnetite crystals at high temperature and as a secondary mineral typically as recrystallization along cracks. Curie temperatures in gabbros are consequently dominantly found in the range  $550^{\circ}C-590^{\circ}C$ . The intensity of magnetization is quite variable spanning several orders of magnitude and depends on the concentration of magnetic minerals, which is often rather low, giving on average NRM in the range  $10^{-1}$  A m<sup>-1</sup>. In a few sites, ferrogabbro and gabbros rich in olivine were reported and give rather high NRM

598

values due to their high concentration of magnetite of primary origin (in the case of ferrogabbro) or resulting from serpentinization (in the case of olivine-rich gabbros) (Dick et al., 2000). The Koenigsberger ratio is often close to one, but usually shows that remanent magnetization is dominant over induced magnetization. Remanent magnetization is often reported to be quite resistant to alternating field demagnetization showing good stability, this magnetic behavior, characteristic of fine-grained population, arises from the subdivision of magnetite in lamellae structures within exsolved coarse titanomagnetite crystals, secondary magnetite is often observed as fine-grained population as well. The contribution of secondary magnetization of chemical origin (CRM) is difficult to isolate and seems relatively low. Presumably gabbros can preserve a faithful record of the magnetic field acquired during the cooling of the units shortly after intrusion at the spreading axis. Gabbros could contribute to the magnetic anomalies but their low NRM and depth usually make them marginal contributors. Gabbros show important chemical variability and the effect of alteration on magnetic properties is difficult to single out; studies made on sets of metamorphosed gabbros show NRMs and Curie temperatures in the same range as unaltered gabbros (Kent et al., 1978).

#### Contribution from deeper material: Peridotites

In "typical" Penrose crust, the lower crust is restricted to the gabbroic layer and no contribution from deeper material is reported. However, as the occurrence of serpentinized peridotites (also called serpentinites) within the crust was more and more observed (see Figure M116), their contribution to magnetic signal became obvious. Unaltered peridotites in the mantle have a paramagnetic behavior. Magnetization of peridotites is acquired during the serpentinization process, which is the reaction of the silicate minerals of peridotites (mostly olivine) with water producing serpentine and pure magnetite. The amount of magnetite

produced during the serpentinization process is not proportional to the serpentinization progression resulting in complex iron remobilization history (Oufi et al., 2002). Even in fully serpentinized peridotites, a very different behaviors are described with, in particular, Koenigsberger ratios well below or above unity. Curie temperatures are clustering around 580°C as expected for magnetite. Remanent magnetization is variable in the range of  $10^{-1}$  -10 Å m<sup>-1</sup>, peak values of 25 Å m<sup>-1</sup> have been reported, which makes these serpentinite samples as magnetized as young basalts (Oufi et al., 2002). From microscopic observation, magnetite grains can be large and are concentrated along the veins of serpentines, which is believed to indicate the preferential direction of fluid circulation. In this case, large grains contribute to a low NRM and Konigsberger ratio and a strong induced magnetization. Magnetite is also found as small single-domain grains disseminated in the serpentinized peridotite matrix, higher NRM and larger Koenigsberger ratios are then observed. Serpentinites with such a magnetic mineralogy could be important contributors to magnetic anomalies. Nevertheless no clear evidence of serpentinized peridotites recording a reverse magnetization have yet been established.

#### Conclusion

The typical range in two of the most used magnetic parameters, NRM and Curie temperature, are synthesized on Figure M117 for different rocks within the crust. The effect of serpentinization and low temperature alteration is represented. As shown and discussed earlier, postemplacement alteration has a significant effect on magnetic properties of rocks and contributes to the magnetic heterogeneity of the crust. Due to their shallow depth, strong magnetic intensity and remanent behavior oceanic basalts are thought to be the most important contributors to marine magnetic anomalies allowing the establishment of the sequence of reversals of the Earth's magnetic field. In addition,

**Figure M117** NRM and Curie temperatures frequently observed in oceanic rocks from drilled or dredged samples. Bold lines represent the average values for "fresh" rocks, the black arrow represents the evolution with serpentinization and small grey arrows show the evolution of these magnetic properties during low temperature alteration process. Scale bar for photo is 5 mm.

although this is still a matter of debate, oceanic basalts could provide a record of the magnetic field intensity variations within polarity intervals, as suggested by the worldwide occurrence of small scale magnetic variations (called "tiny wiggles") within the main magnetic anomaly pattern (Cande and Kent, 1992). In any case, it should be mentioned again that the local crustal architecture is probably complex (Karson *et al.*, 2002) and is a major factor to take into account in the analysis of marine magnetic signals.

# MAGNETIZATION, PIEZOREMANENCE AND STRESS DEMAGNETIZATION

With the advent of paleomagnetic studies in the 1940s, scientists began to wonder how the effect of stress, from burial, folding, etc., would influence the magnetic remanence of rocks. By the mid-1950s, an intense research effort was underway aimed at understanding piezoremanence, which is the remanent magnetization produced by stress, as well as the opposite effect of stress demagnetization. The laboratory experiments suggested that the magnetic signals of rocks were sensitive to stresses typically found around fault zones; and it was calculated that such stress-induced changes would in turn modify the local magnetic field. Scientists thought that earthquakes could be predicted by monitoring magnetic-field variations.

#### How pressure (stress) affects magnetic remanence

The origin of a spontaneous magnetic remanence is commonly associated with electron exchange between iron (or other transition metals such as Cr, Ni, etc.) atoms. For the iron oxide magnetite (Fe<sub>3</sub>O<sub>4</sub>), the most abundant magnetic mineral in the Earth's crust, the exchange is indirect, passing through an oxygen atom. The spontaneous magnetization of magnetite is generated in magnetic lattices established by the crystallographic arrangement of the atoms. The sum of the magnetic moments from the lattices comprises the net spontaneous magnetization of the mineral. The bond lengths and bond angles between iron and oxygen atoms of a particular lattice control the magnetic intensities and directions of that lattice. Thus, when a stress acts on a material, the bond lengths and angles change, which will in turn modify the lattices' magnetic moments. This is why the nature of the stress, be it uniaxial, hydrostatic (equal on all sides), compressive, or tensile, can have important consequences on the magnetic properties of materials. If a material compresses isotropically under a pure hydrostatic stress, bond lengths will decrease, yet bond angles will remain unchanged; whereas, uniaxial or shear stress will change the bond angles as well as the bond lengths. Such changes depend on the volumetric compressibility of the magnetic mineral. For example, the volume of magnetite decreases by about 2% per gigapascal (GPa) (note that 1 GPa = 10 kilobars (kbar); for the Earth, 1 kbar corresponds to 3.5 km depth). This is why one needs very large stresses to significantly modify the electronic configuration and the magnetic lattice networks.

Size and shape are other factors influencing the magnetic properties of materials. In extremely small grains, electron exchange exists, but the spontaneous moment does not remain in a fixed direction within the crystal due to thermal fluctuations, even at room temperature. These grains are called superparamagnetic because they have no spontaneous moment in the absence of an external magnetic field, yet in the presence of even a small external field, the randomizing thermal energy is overcome, and the grains display magnet-like behavior. At a critical size, about 0.05 µm for needle-shaped magnetite grains, the spontaneous magnetic moment becomes fixed within the crystal, thus resembling a dipolar magnet with a positive and a negative pole. Such grains are called single domain. At even greater volumes, the magnetic energy of the grain becomes too great and new magnetic domains grow such that the magnetic vectors of the neighboring domains are oriented in directions that diminish the overall magnetization of the crystal. These are called multidomain grains. Multidomain grains often have a net moment because the sum of the magnetic vectors of all the domains does not exactly equal zero.

The magnetizations of single- and multidomain grains react differently to an imposed stress, just as they do with temperature or applied fields. Hydrostatic stress may cause the net spontaneous moment in a single-domain grain to reorient to a new position depending on the grain's shape, presence of crystal defects, etc. Under subhydrostatic stress, the magnetization in a single-domain grain will rotate and change in intensity because different crystallographic axes will experience different stresses, which will deform the exchange network. Under any stress condition, the individual domains in a multidomain grain may grow or shrink to compensate for the deformation, which will modify the magnetic intensity and direction of the grain. Uniaxial stresses are more efficient than hydrostatic stresses at causing domain reorganization.

In sum, two processes contribute to the piezoremanent behavior of materials, both of which can act independently or simultaneously at a given stress condition. The first is a microscopic effect that modifies the electron exchange couple, and the second is more of a macroscopic effect where the magnetization becomes reoriented within a grain. Each type of magnetic mineral and the domain states of each mineral have their own particular piezoremanent and stress demagnetization characteristics. Because rocks are usually composed of a spectrum of magnetic grain sizes, and sometimes more than one type of magnetic mineral, in order to understand how and why the magnetic properties of a rock change in response to an imposed stress, one must know the composition of the magnetic phases and their size distributions. Understanding how stress affects a rock must be viewed in a statistical sense by summing the changes in magnetization of each grain. The type of imposed stress must also be specified.

## Details surrounding magnetic measurements at high pressure

Magnetic measurements at high pressures are difficult for several reasons. For one, the pressure vessel apparatus must be non-, or only slightly, magnetic. This is a tall order because most materials strong enough to transmit high pressures are steel alloys-most of which are magnetic or interfere with the electronics of the detector. Second, the sample's magnetic strength should be detectable by the measuring system and be significantly higher than the pressure vessel. In order to maximize the magnetic signal, one wants as many magnetic grains as possible in the sample. It follows that larger samples are more magnetic, and more easily measured than smaller ones-not because the density of magnetic grains is greater, but because of a greater number (or mass) of magnetic grains. As pressure equals force divided by area, a trade-off exists between pressure and sample size, which explains why most experimental work on this problem has focused on large, rock samples. The majority of experiments have been performed using uniaxial stresses and pressures of less than 1 GPa. Indirect measurements of the magnetic states of minerals at much higher pressure cells have been employed since the 1960s using Mössbauer spectroscopy, which measures magnetic interactions between electrons and the nucleus. Although Mössbauer data yields important information about the existence and type of magnetic network in materials, it does not quantify the strength or direction of the moment or their stress dependencies and thus is beyond the scope of this summary. Direct measurements of the full magnetic vector to significantly higher pressures (to 40 GPa) are now becoming possible with the development of diamond anvil cell technology. This new method also allows one to experiment on magnetic minerals whose composition and domain state are well characterized.

An important observation of the high-pressure experiments preformed under uniaxial stress is that magnetic properties change in relation to the maximum stress axis direction. For stress demagnetization (i.e., stress applied in the absence of an applied magnetic field), the magnetization intensity decreases faster parallel to the maximum stress direction rather than perpendicular to it. When pressure is applied in the presence of a magnetic field, magnetic vectors in the grains rotate toward the direction perpendicular to the maximum stress direction. Both magnetic susceptibility and magnetization increase perpendicular to the maximum stress direction and decrease parallel to the maximum stress direction (Figure M118). This has important implications because several experimental apparatuses can only measure magnetic parameters in one direction. Obviously this will lead to a bias of the interpretations of the data.

A special case of stress demagnetization and piezoremanent magnetization is called shock demagnetization and shock magnetization. The term shock is added when the application and removal of a stress occurs in a brief instant in time, such as during a meteorite impact or by firing a projectile at a magnetic sample. To date no study has established that either stress demagnetization or piezoremanence is a time-dependent process, so the difference in terminology should be considered semantic.

#### Stress demagnetization

Despite the experimental restrictions, several things are known about the magnetic properties of rocks and minerals under stress. The effect of stress in the absence of an external magnetic field has a permanent demagnetizing effect on a rock composed of several magnetic grains. In this case, permanent means that once the pressure is released, the magnetic moment does not grow back to its original, precompressed value because the magnetic vector directions of the grains have been randomized, thus lowering the net magnetization of the rock. It does not mean that the individual magnetic grains have lost their capacity to be magnets. This makes stress demagnetization similar to alternating field demagnetization. Place a rock in a decaying alternating field in a null or very weak external field and the rock will demagnetize. However, the magnetic intensity of a rock placed in a decaying alternating field in the presence of an external field will often increase to levels

**Figure M118** Relative change in magnetic susceptibility ( $\chi$ ) measured perpendicular and parallel to the maximum compression direction in two titanomagnetite samples (Curie temperatures of 250°C and 200°C, respectively) (after Kean *et al.*, 1976).

higher than its starting intensity. The same is true for pressure (stress) demagnetization and its converse, piezoremanent magnetization.

Figure M119 shows a good example of the differences between hydrostatic and uniaxial stress demagnetization of a diabase rock containing large (20–300  $\mu$ m) titanomagnetite (Curie temperature = 535°C) grains. The pressures employed in these experiments are relevant to the Earth's crust, as 100 MPa (which equals 1 kbar or about 3.5 km depth) is well within the seismogenic zone, i.e., the upper region of the Earth's crust where earthquakes are generated. One quickly sees that uniaxial stress demagnetizes this material about two times faster than hydrostatic stress; e.g., at 100 MPa, hydrostatic and uniaxial pressures demagnetize roughly 20% and 40% of the original, noncompressed magnetization intensity, respectively. This is true whether the material is under pressure, or if it has been decompressed. Upon decompression, a demagnetization effect also exists, which is greater under uniaxial than hydrostatic stress. It should also be noted that during pressure cycling, once a rock has been compressed and then decompressed from a given pressure, it resists further stress demagnetization up until the maximum pressure that the rock has previously experienced. Once that pressure is exceeded, the rock continues demagnetizing in a manner coherent with the previously defined path. The pressure history dependence can be likened to a work or magnetic hardening effect owing to the strain state

**Figure M119** An example of the differences between hydrostatic and uniaxial stress demagnetization for a diabase sample containing multidomain titanomagnetite (after Martin and Noel, 1988).

of the grains. Multidomain grains are more sensitive to stress than single-domain grains because the magnetic remanence of multidomain grains is controlled by domain wall migration, which is highly sensitive to dislocations and other imperfections in the crystal.

#### Piezoremanent magnetization

Imagine a rock that has acquired its magnetization by cooling in the presence of the Earth's magnetic field. The magnetic intensity of the rock will be proportional to the strength of the field in which it cooled, the number and type of magnetic grains, their sizes and shapes, and the way the grains are geometrically distributed in space. For a rock whose grains are randomly distributed (no preferred orientation), the magnetic moment of each nonspherical grain will tend to lie parallel to its long-axis, favoring the long-axis direction pointing toward the magnetic field direction. If a relatively low magnetic field is then applied, say three times that of the present Earth's field, the rock's magnetization will slightly increase, proportional to the amount of magnetic material in the rock (as defined by its magnetic susceptibility). After the field is removed, the magnetization will decay reversibly back to its original value. When relatively high fields, say 100 times the Earth's field, are applied, the magnetization directions of the grains rotate parallel to the field, leading to a greater net magnetization of the rock. Upon removal of the field, the rock's magnetic intensity will decrease, but will still remain above the value prior to the application of the strong field. This is due to an irreversible reorganization of the individual moments in each grain. As successively higher fields are applied and then removed, the magnetic moments of the grains become more and more aligned parallel to one another, again due to irreversible rotation, leading to greater and greater magnetic intensities. At some applied field value, the moments of all the grains become aligned to the extent that successively higher fields can no longer cause irreversible rotations and the rock's magnetic intensity remains constant. This point is called the saturation remanence of isothermal remanent magnetization (SIRM) and the plot of magnetic intensity as a function of applied field is an isothermal remanent magnetization (IRM) curve (Figure M120).

When a magnetic material is subject to stress in the presence of a magnetic field, the material will acquire a remanence proportional to the strength of the field and the level and type of stress. Figure M120 shows four IRM curves obtained from the same titanium-free, multidomain magnetite sample (a) in the stress-free state (had never been subjected to any pressure), (b) when the sample was compressed and held at a hydrostatic pressure of 3.13 GPa, (c) when the sample was further compressed and held at a hydrostatic pressure of 5.96 GPa, and (d) after decompression (P = 0) from P = 5.96 GPa. Piezoremanence refers to the phenomenon where the application of stress in the presence of a magnetic field increases the material's magnetization above the level that it would have acquired if the same field had been applied in the absence of stress; e.g., by definition, a piezoremanent magnetization lies anywhere in the gray region above the IRM curve (a) in Figure M120. For this multidomain magnetite example, one observes that the magnetization gained at any applied field increases with increasing pressure (Figure M120, curves b and c). This means that pressure (stress) enhances irreversible rotations of the grains' moments, by domain reorganization, more than an applied field does in the absence of stress. After pressure is released, the domain structures of the grains are even more disposed to irreversible rotation than before (Figure M120, curve d).

The sequence that stress and magnetic fields are applied in will modify a rock's magnetism in different ways and is again dependent on the species of magnetic mineral and its domain state. For the case in Figure M120, one observes that the net magnetization of a multidomain magnetite sample having been (1) brought up in pressure, (2) subject to an applied field, and then (3) removed from the field (curves b and c) is less than having been (1) brought up in pressure, (2) removed from pressure, (3) subject to an applied field, and then

**Figure M120** Isothermal remanent magnetization (IRM) curves for the same sample of titanium-free, multidomain magnetite at (a) initial (zero pressure), (b) and (c) under hydrostatic pressures, and (d) at zero pressure after decompressing from 5.96 GPa. Any point lying in the gray area is a piezoremanent magnetization. (S. Gilder, M. LeGoff, J.C. Chervin and J. Peyronneau, unpublished data).

(4) removed from the field (curve d). The opposite is generally true for single-domain magnetite grains. The reason for this is partly due to the way domains facilitate irreversible rotation. Other contributions to irreversibility may come from grain-size reduction (e.g., breaking multidomain grains into single-domain grains) or a permanent modification of the exchange couple. Note that the magnetization of a sample (1) brought up in pressure, (2) subject to an applied field, (3) removed from the field and then (4) removed from pressure may or may not exhibit piezoremanence. This depends on whether compressive stress produces more irreversible rotation than the demagnetization effect that accompanies decompression.

#### Piezoremanence and stress demagnetization in nature

On Earth, piezoremanent magnetization and stress demagnetization are relevant anywhere transient or permanent stresses provoke a measurable change either in a short-term sense (e.g., during an earthquake) or in a long-term sense (e.g., during the build up or relaxation of stress in the crust due to tectonic motion). Mathematical models of fault motion during earthquakes estimate local deviations in the magnetic field intensity and may reach 1-10 nT (the present Earth's field intensity ranges from 30000 to 60000 nT), which is well within the measurable limit of about 0.1 nT. The size of the seismomagnetic effect depends on several parameters including: magnetic mineralogy, domain state, magnetization direction and intensity of the country rock, direction and intensity of the Earth's field, strike and dip of the fault, sense and amount of motion on the fault, and earthquake magnitude and depth. An important unknown is the stress history of the rock. As shown above in Figure M119, rocks undergo a magnetic hardening during stress demagnetization. So, for a significant change in the rock's magnetization to occur, the rock must be stressed to higher levels than it has previously seen. This could be why piezoremanent effects during an earthquake have never been witnessed. On the other hand, it is difficult to set up and maintain an array of magnetometers over very long time-periods. As earthquakes cannot be predicted, the chances of being at the right place at the right time are extremely low.

Long-term changes in the local magnetic field have been documented around faults and are thought to coincide with nonseismic stress loading due to plate motion. Moreover, long-term changes in the local magnetic environment were observed when large reservoirs were filled with water. The changes were attributed to ground loading and the piezomagnetic effect. Magnetic field variations around volcanoes have been observed during or preceding volcanic eruptions. Although the changes were originally attributed to stress-field changes during the charge or withdraw of magma, closer examination of the data suggests that the magnetic variations were induced by fluid circulation. A similar debate exists for certain subduction zones that exhibit long wavelength magnetic anomalies. Subduction of cold lithosphere depresses the Curie isotherm to depths down to 100 km. Thus, magnetic minerals can be displaced to, or form at, great depths and still be above the Curie isotherm. Note that the Curie temperature of titanomagnetite increases by 2° kbar<sup>-1</sup>. Some workers attribute the anomalies to piezoremanence while others believe it is related to fluid flow in the subduction zone.

Meteorite craters are among the most likely place to find the effects of piezoremanence or stress demagnetization. The presence of shatter cones, pseudotachylite, microscopic textures such as planar deformation features, and large volumes of melted rocks, all suggest that pressures during impact range from about 5 to more than 30 GPa, for reasonably sized (>20 km diameter) craters. However, finding clearcut evidence that the magnetism of the country rocks has been affected by shock is not so easy because most craters are old (>1 Ga) and have been severely eroded, deeply buried, or the thermal effects of the impact have not been eroded deeply enough to expose the shocked rocks. Moreover, after several hundreds of millions of years, the original magnetic mineralogy of the shocked rocks may become altered by oxidation, or new magnetic minerals may grow. However, the fact that aeromagnetic anomalies are characteristic features of meteorite impacts, there must be some long-term memory of the country rock's magnetization. Some scientists have found that the shocked rocks are remagnetized in the direction of the Earth's field at the time of impact. If true, one can perform an impact test by collecting samples along a radial transect away from the center. The remagnetization direction should be most prevalent near the center and eventually die out with distance.

An intriguing case for shock demagnetization has been proposed for Mars. The southern hemisphere of the Martian crust is highly magnetic except for two very large (>500 km diameter) circular regions that have significantly lower magnetic intensities. Some scientists believe these areas of low magnetic intensity are due to stress demagnetization that occurred during meteorite impacts. Although the magnetic mineral in Martian rocks is presently thought to be magnetite, little is known about the piezomagnetic and stress demagnetization behavior of this substance at the cold  $(-9^{\circ}C \text{ to } -128^{\circ}C)$  temperatures of the red planet's surface. Despite some 50 years of research, our knowledge of piezoremanence and stress demagnetization remains limited. A renaissance in this research field, partially due to recent space exploration, will surely lead to exciting discoveries in the future.

## MAGNETIZATION, REMANENT, AMBIENT TEMPERATURE AND BURIAL DEPTH FROM DYKE CONTACT ZONES

#### Introduction

Nagata (1961, p. 320) proposed using the directions of remanent magnetization in the contact zone of an igneous intrusion as a geothermometer. Carslaw and Jaeger (1959) and Jaeger (1964) applied heat conduction theory to calculate the variation in maximum reheating temperature with distance from a cooling intrusion of simple geometry. Schwarz (1976, 1977) carried out the first study in which the paleomagnetism across a dike contact and theoretical maximum temperature curves were used to estimate the ambient temperature of the host rocks and the depth of burial of the present erosion surface at the time of dike intrusion.

In principle, the depth of burial method can be applied to the contacts of a variety of intrusions with different shapes. However, calculating the maximum reheating temperature in the vicinity of an intrusion with complicated geometry is difficult. To date, depth of burial studies that use remanent magnetization have usually been confined to dike contacts. The case of a dike contact is used to illustrate the method in this article.

#### Magnetic overprinting in the vicinity of a dike

The depth of burial method is based on the thermal overprinting of remanent magnetization in host rocks near dike contacts. It has been reviewed by Buchan and Schwarz (1987).

When a dike intrudes, temperatures in adjacent host rocks rise above the highest magnetic unblocking temperatures ( $T_{ub}$ ). During subsequent cooling in the Earth's magnetic field, the dike and this adjacent

**Figure M121** Directions of remanent magnetization with distance from the contact of an igneous intrusion. It is assumed that the magnetic mineralogy of the host rock is similar throughout the profile and that overprinting in the baked and hybrid zones is a thermoremanent magnetization.

"baked" zone acquire magnetic remanences with similar directions (Figure M121). Far from the dike contact, in the "unbaked" zone, peak temperatures are insufficient to thermally reset even the lowest blocking temperature component (see Baked contact test). Between the baked and unbaked zones lies a region of hybrid magnetization where reheating is only sufficient to result in thermal resetting of the lower blocking temperature portion of the host rock magnetization. If, in this "hybrid" zone,<sup>1</sup> the older and younger components of magnetization can be separated on the basis of their blocking temperature spectra, then the maximum temperature  $(T_{max})$  reached following dike intrusion can be determined as a function of distance from the contact (Schwarz, 1977). This maximum temperature may be corrected for the effects of magnetic viscosity during prolonged heating in the field. Using heat conduction theory (Carslaw and Jaeger, 1959; Jaeger, 1964), the ambient temperature of the host rock just prior to dike intrusion can then be calculated. Depth of burial of the present erosion surface is determined by dividing the ambient temperature of the host rock by the estimated geothermal gradient at the time of intrusion.

It should be noted that the study of the magnetic hybrid zone according to the procedure of Schwarz (1977) also yields the most rigorous type of baked contact test (the baked contact profile test), a field test for establishing the primary nature of the remanent magnetization of an intrusion (see *Baked contact test*).

#### Assumptions

Several assumptions are made in the following discussion of the depth of burial method applied to the remanent magnetization across a dike contact (Buchan and Schwarz, 1987).

- 1. The dike can be approximated by an infinite sheet.
- 2. The dike was formed by a single magma pulse of short duration.
- 3. Heat transfer occurs solely by conduction.
- Dike intrusion results in a (partial) thermal resetting of the remanence of the host rock, without chemical changes.
- Magnetic mineralogy in the hybrid zone is relatively simple, so that the effects of magnetic viscosity can be estimated from published time-temperature curves.

Complicating factors such as prolonged duration of magma flow in the dike, multiple magma pulses, groundwater, volatiles escaping from the dike, and chemical resetting of remanence in the hybrid zone are

<sup>1</sup>In some publications the baked, hybrid, and unbaked zones are referred to as the contact, hybrid, and host (magnetization) zones, respectively.

604

usually difficult to take into account (see Buchan *et al.*, 1980; Delaney, 1982, 1987; Delaney and Pollard, 1982; Schwarz and Buchan, 1989). They are not addressed in this article.

#### Sampling

Oriented paleomagnetic samples are collected along a continuous profile that includes the dike, and the baked, hybrid, and unbaked zones of the host rocks (e.g., Figure M122). The horizontal distance of each sample from the contact is recorded, along with the horizontal width of the dike. If the dike is tilted from vertical, the perpendicular distance of each sample from the contact and the thickness of the dike should be calculated.

# Determining maximum reheating temperature $(T_{max})$ in the hybrid zone

Each hybrid sample is thermally demagnetized in a stepwise fashion. In general, purely viscous components are eliminated at low temperatures to reveal magnetization that is the sum of a host component and a component acquired at the time of emplacement of the igneous unit (Figure M121). Upon thermal demagnetization to higher temperatures, the remanence direction of each hybrid sample moves progressively along a great circle path to the host direction (e.g., Figure M123). This reflects the fact that the  $T_{\rm ub}$  spectra of the overprint and host magnetization components are essentially discrete, with the overprint  $T_{\rm ub}$  spectrum occupying a range immediately below that of the host component.

 $T_{\rm max}$ , the maximum temperature attained at a given locality in the hybrid zone following dike intrusion is given by the highest  $T_{\rm ub}$  of the overprint component. It can most easily be obtained using an

**Figure M122** Sampling profile perpendicular to contact of a ca. 2200–2100 Ma Indin diabase dike of the Slave Province of the Canadian Shield (modified after Schwarz *et al.*, 1985). The dike intrudes Archean metavolcanic rocks.

orthogonal component (or Zijderveld) plot of the horizontal and vertical projection of the thermal demagnetization data (e.g., Figure M124).  $T_{\rm max}$  is given by the temperature at which the straight-line segments through the overprint and host components intersect (Dunlop, 1979; McClelland Brown, 1982; Schwarz and Buchan, 1989; Dunlop and Özdemir, 1997). In the example that is shown in Figure M124 the intersections are fairly sharp so that  $T_{\rm max}$  values are readily determined. Note that the interpretation of more complicated orthogonal component plots involving multiple magnetic minerals and chemical overprinting are discussed in Schwarz and Buchan (1989).

The  $T_{\text{max}}$  values determined from the orthogonal component plots of Figure M124 decrease progressively across the hybrid zone with increasing distance from the dike contact as expected for thermal overprinting due to the dike emplacement.

#### Correcting $T_{max}$ for magnetic viscosity

The maximum blocking temperatures  $(T_{\text{max}})$  that are reset in a given thermal event are dependent upon the length of time over which the elevated temperatures are maintained (Dodson, 1973; Pullaiah *et al.*, 1975). Therefore,  $T_{\text{max}}$  must be corrected using published time-temperature curves for the appropriate magnetic mineral (e.g., Pullaiah *et al.*, 1975).

# Determining ambient temperature of host rock at time of dike emplacement ( $T_{amb}$ )

The maximum temperature  $(T_{\text{max}})$  attained at a particular locality in the host rock following dike intrusion equals the sum of the maximum temperature increase  $(\Delta T_{\text{max}})$  due to heat from the dike and the ambient temperature  $(T_{\text{amb}})$  of the present surface just before the dike was emplaced.

Therefore, in the hybrid zone, where  $T_{\text{max}}$  falls within the overall unblocking spectrum,  $T_{\text{amb}}$  is calculated from the equation:

$$T_{\rm amb} = T_{\rm max} - \Delta T_{\rm max} \tag{Eq. 1}$$

Different heat conduction models can be utilized to determine the maximum increase in temperature ( $\Delta T_{max}$ ) in the contact zone of a dike (Carslaw and Jaeger, 1959; Jaeger, 1964; Delaney, 1987).

The simplest model that accounts for the latent heat of crystallization of the dike magma is one in which the heat released during solidification is added to the initial magma temperature as an equivalent temperature increase (Jaeger, 1964). This model gives a reasonable approximation to more rigorous models for distances greater than a quarter of a dike width from the contact, and has been employed in a number of studies of dike contacts where the hybrid zone is relatively far from the contact (e.g., Schwarz, 1977; Buchan and Schwarz, 1981; Schwarz and Buchan, 1982; Schwarz *et al.*, 1985; Hyodo *et al.*, 1993; Oveisy, 1998).

Using this simple model, the maximum temperature increase at a distance x from the center of a dike of thickness 2d is calculated using the following equations from Jaeger (1964), modified slightly to allow for nonzero  $T_{amb}$ :

$$\Delta T_{\max} = [V + (L/c) - (T_{\max} - \Delta T_{\max})] \\ \times \frac{1}{2} [\operatorname{erf}\{(x+d)/2d\tau^{1/2}\} - \operatorname{erf}\{(x-d)/2d\tau^{1/2}\}]$$
(Eq. 2)

where  $\tau = \kappa t/d^2$ ,  $\kappa = k/(\rho c)$ , and erf (u) is the error function.

*V* and *L* are respectively the intrusion temperature and latent heat of crystallization of the dike magma,  $\kappa$ , k,  $\rho$ , and *c* are respectively the diffusivity, conductivity, density, and specific heat of the host rock, *t* is the time elapsed since intrusion of the dike, and  $\tau$  is dimensionless time.

**Figure M123** Thermal demagnetization characteristics of selected samples from the Indin dike profile of Figure M122 (after Schwarz *et al.*, 1985). Distance to the contact is given for each sample. Directions are plotted on equal area nets with closed (open) symbols indicating positive (negative) inclinations. Heat-treatment temperatures are indicated in degree Celsius. Data points that represent the great circle between dike and host magnetization directions are connected by a dashed line.  $T_{max}$  values, estimated from the experimental data before correction for magnetic viscosity, are given for hybrid zone and host zone samples.

 $\tau_{max}$  is determined from the equation:

$$\tau_{\max} = (x/d) / \ln[(x+d)/(x-d)]$$
 (Eq. 3)

which is satisfied when the temperature reaches its maximum value,  $T_{\text{max}}$ .

In this model, the required thermal parameters are assumed to be constant. Typical values are:  $V = 1150^{\circ}$ C and  $L = 3.77 \times 10^{5}$  J kg<sup>-1</sup> for mafic dike rocks;  $c = 1.26 \times 10^{3}$  J kg<sup>-1</sup>°C<sup>-1</sup> for mafic host rocks; and  $c = 1.09 \times 10^{3}$  J kg<sup>-1</sup>°C<sup>-1</sup> for granitic host rocks (e.g., Touloukian *et al.*, 1981).

The simple heat conduction model described above is not valid within a quarter of a dike width of the contact (Jaeger, 1964), because it does not adequately account for the release of the latent heat of crystallization during cooling of the dike or the temperature dependence of thermal conductivity and diffusivity (Delaney, 1987). In some magnetic studies, hybrid samples have been obtained close to the dike (Buchan *et al.*, 1980; Symons *et al.*, 1980; McClelland Brown, 1981), so that the simple model is inappropriate. The authors in these studies applied more rigorous analytical or numerical models described by Carslaw and Jaeger (1959).

The most sophisticated analysis of heat conduction models for a dike cooling by conduction has been described by Delaney (1987, 1988). He demonstrated the advantage of numerical solutions over analytical solutions, especially at and close to the dike contact. Delaney

(1988) published computer programs to calculate the temperature in a dike and host rocks as they cool conductively, in which the temperature dependence of thermal properties and the latent heat of crystallization are taken into account. These programs have been applied to the case of remanent magnetization in a dike contact by Adam (1990).

Finally it should be noted that  $T_{amb}$  may be determined in one of two ways. It can be calculated from individual  $T_{max}$  values (e.g., Schwarz and Buchan, 1982). Alternatively, when there is a sufficiently wide hybrid zone,  $T_{amb}$  can be determined by comparing the whole experimentally determined profile of  $T_{max}$  values with the theoretical  $T_{max}$  curves of maximum temperature based on conductive heating of the dike (McClelland Brown, 1981; Buchan and Schwarz, 1987).

# Determining depth of burial of the present erosion surface at the time of dike emplacement

The depth of burial of the present erosion surface can be determined by dividing  $T_{amb}$  (determined from Eq. (1)) by the paleogeothermal gradient for the sampling area at the time of dike intrusion. To estimate the paleogeothermal gradient, the present-day geothermal gradient must be corrected for the decrease in heat generation resulting from the decay of radiogenic isotopes since the time of dike intrusion (e.g., Jessop and Lewis, 1978), and in some areas for the effects of

glacial perturbation (e.g., Jessop, 1971). The uncertainties involved in estimating the paleogeothermal gradient are significant and can lead to relatively large uncertainties in the depth of burial, even if  $T_{amb}$  is well constrained (see Schwarz *et al.*, 1985; Hyodo *et al.*, 1993).

Baked Contact Test

#### MAGNETIZATION, REMANENT, FOLD TEST

Establishing the age of the remanence acquisition with respect to the origin of the rock unit or age of structural deformation events is critical in the interpretation of paleomagnetic data. It is also important to establish that the magnetic minerals carry a stable magnetization over geological timescales. These two related questions remain difficult problems, which often affect the application of paleomagnetism to tectonic, stratigraphic, and paleogeographic problems (Cox and Doell, 1960; Irving, 1964). It is therefore not surprising that early in the development of the paleomagnetic method, several field and laboratory tests were developed and applied to a range of geological contexts. Among them, an elegant simple answer was put forward to constrain the age of remanence acquisition by using field information by Graham (1949). He realized that in folded rocks a simple test based on rotation of the magnetization directions about the local strike could determine if the remanence was acquired before the deformation event -if magnetization directions were dispersed in present-day coordinates and clustered upon tilt rotation (Figure M125a). Magnetization directions that cluster in present-day coordinates and disperse upon tilt rotation indicate that remanence acquisition occurred after the deformation event (Figure M125b). At the time Graham (1949) developed this test, the multivectorial nature of natural remanent magnetization (NRM) had not been properly recognized, and the demagnetization techniques for isolating remanent components had not been developed. The fold test nevertheless worked well as applied to the deformed sedimentary strata of the Rose Hill Formation from Maryland, mainly because the NRMs are univectorial and the strata are tilted to large angles without major structural complexities (French and Van der Voo, 1979). The Graham fold test can be applied to study single deformed structures, including a fold within an undeformed sequence, or over wide deformed areas with sampling at sites with varying bedding tilts.

The impact of paleomagnetic data in the study of regional tectonic processes, particularly in the establishment of the continental drift theory, and the increasing use of demagnetization and statistical techniques in investigating multi-vectorial remanences made the use of field tests fundamental tools for paleomagnetists (Irving, 1964; McElhinny, 1973). Field tests to investigate the magnetization stability and the timing and mode of remanent magnetization acquisition include

Figure M125 Paleomagnetic fold test.

the (a) fold test, (b) conglomerate test, (c) baked contact test, (d) reversal test, and (e) consistency test. Looking at the many applications developed over the years can easily assess the importance of the field tests in paleomagnetic research.

Development of the fold test in paleomagnetism has involved incorporation of statistical criteria to evaluate the significance of the test, advances in separating multicomponent magnetizations, advances in paleomagnetic instrumentation providing more sensitive instrumentation and methods to measure weak magnetizations, and application to a wide range of deformed rock units as well as local and regional tectonic structures.

#### Statistical criteria

Application of statistical criteria in evaluating the test significance was first attempted by McElhinny (1964), by using the concentration parameter k of the Fisher (1953) statistics to distinguish between pre- and postfolding magnetization data sets. The criterion is an application of the statistical test for comparing the precisions using the Fisherian concentration parameter of two separate groups of sample directions with the precision of unfolded directions ( $k_a$ ) compared with the precision for *in situ* directions ( $k_b$ ). The ratio  $k_a/k_b$  is referred to *F*-ratio tables at given confidence limits and with equal degrees of freedom (2N - 1), where *N* is the number of sample directions studied.

The application of statistical criteria permitted the use of the fold test in a wide range of deformed structures, and McElhinny (1964) fold test is still used in paleomagnetic studies. The test is applied in spite of the problem noticed by McFadden and Jones (1981) that the use of Fisher statistics for directional data sets, which are not Fisher distributed, is not valid. This occurs either way if magnetizations are pre- or postfolding. For instance, if directions are Fisher distributed in *in situ* coordinates, then they are not tilt-corrected coordinates.

McFadden and Jones (1981) proposed a test based on comparison of Fisher distributed data sets derived from opposite limbs of a fold in *in situ* and tilt-corrected coordinates. The new test again implies no internal distortion of magnetization and more intensive field sampling, but it can be applied under less stringent conditions than the McElhinny (1964) test.

Two further statistical significance tests based on comparison of distributions of magnetization directions, which require less demanding sampling strategies than the test by McFadden and Jones (1981), have been proposed by McFadden (1990) and Bazhenov and Shipunov (1991). The test of Bazhenov and Shipunov (1991) considers different structural attitudes by making division of bedding plane data into groups, which gives greater flexibility in the sampling strategy. Nevertheless, the tests have been little used in paleomagnetic studies mainly because their statistical significance is relatively weak (e.g., Weil and Van der Voo, 2002).

Evaluation of fold test data sets has also been examined in terms of a parameter estimation problem, by applying simple bootstrap or Monte Carlo approaches. In these tests, large numbers of sample data are generated to determine confidence limits and significance of the maximum clustered directional distribution (Fisher and Hall, 1990; Tauxe *et al.*, 1991; Watson and Enkin, 1993; Tauxe and Watson, 1994). Tauxe and Watson (1994) developed a test using eigen analysis of directional data sets that estimates the degree to which directions from different structural attitude sites are parallel. In this way, directional data sets do not need to conform to a Fisher distribution, and confidence limits are derived from bootstrap and parametric bootstrap techniques according to data set size.

McFadden (1998) discussed the underlying assumption of parametric estimation fold tests that the magnetization directions show maximum clustering with the strata in the position magnetization was acquired. This is not the case when folding does not conform to simple cylindrical horizontal axis geometry and additional factors are involved like plunging folds, unaccounted overprints, etc.

#### MAGNETIZATION, THERMOREMANENT

#### Introduction

Thermoremanent magnetization (TRM) is acquired when magnetic minerals cool in a weak magnetic field H from above their Curie temperatures. TRM is the most important remanent magnetization used in paleomagnetism. It is almost always close to parallel to the field which produced it, and its intensity is proportional to the strength of the field for weak fields like the Earth's. The TRM of rocks is therefore a vast storehouse of recorded information about past movements of the Earth's lithospheric plates and the history of the geomagnetic field.

The primary natural remanent magnetization of an igneous rock or a high-grade metamorphic rock is a TRM. Newly erupted seafloor lavas at mid-ocean ridges acquire an intense TRM on cooling below the Curie temperature  $T_{\rm C}$ . Rapid cooling also results in fine grain size, which makes the TRM highly stable, so that oceanic basalts are excellent recorders of the paleomagnetic field. However, the TRM is largely replaced within at most a million years of formation by chemical remanent magnetization (CRM) of reduced intensity.

The magnetic signal recorded in archeological materials such as pottery, bricks, and the walls and floors of the ovens in which they were fired at high temperature is also a pure TRM residing in single-domain (SD) and pseudosingle-domain (PSD) grains. These materials should be ideal for determinations of the paleointensity of the Earth's field at the time of firing because they are strongly magnetized and the minerals have been stabilized physically and chemically well above their Curie temperatures before their initial cooling.

TRM results from thermally excited changes in magnetization. In the case of SD grains, it is a frozen high-temperature equilibrium distribution between two microstates in which the spins of all atoms are either parallel or antiparallel to an applied field H. At temperatures below  $T_{\rm C}$ , there are large perturbations of a crystal's spin structure, leading to transitions between structures of different types. With cooling, transitions become more difficult, as evidenced by a rapidly increasing relaxation time  $\tau$ . Eventually, decreasing thermal energy and increasing energy barriers  $E_{\rm B}$  between states prevent further transitions and TRM is frozen in very abruptly at a blocking temperature  $T_{\rm B}$ .

The TRM of multidomain (MD) grains results from the blocking of domain walls at positions determined by the externally applied field H, the internal demagnetizing field  $H_D$  of the grain, and the pinning effect of lattice defects.

Theories of TRM and reviews of experimental data have been given by Néel (1949, 1955), Everitt (1961, 1962), Stacey (1958), Schmidt (1973), Day (1977), and Dunlop and Özdemir (1997).

#### Relaxation time and single-domain TRM

Néel's (1949, 1955) theory of relaxation time deals with noninteracting uniaxial SD grains with saturation magnetization  $M_S$  and volume *V*.  $M_S$  results from the parallel exchange coupling of atomic spins and is a strong function of temperature *T* near  $T_C$ , but is weakly dependent on *T* at low temperatures. Néel's SD theory makes use of Stoner and Wohlfarth's (1948) results for coherent rotation in spheroidal SD grains aligned with a weak field H. The magnetic moment  $VM_S$  has a choice of orientations controlled by the easy axes of anisotropy. Uniaxial shape anisotropy is dominant in minerals such as magnetite with high  $M_S$ . Shape anisotropy produces two energy minima, corresponding to spins in one or the other direction along the longest axis of the grain. These two minima define the two SD microstates. At 0 K, spins would be exchange coupled exactly parallel; but at ordinary temperatures, thermal excitations perturb the spin lattice, resulting in a steady decrease in  $M_S(T)$ . At high temperatures, reversals of grain moments are also excited as  $M_S(T)$  drops rapidly toward zero at  $T_C$ .

At ordinary temperatures, spontaneous reversals of an SD grain are unlikely because the energy barrier between microstates due to shape anisotropy is much larger than the available thermal energy ( $\approx 25kT$ for experimental times of a few minutes, where k is Boltzmann's constant). Close to  $T_{\rm C}$ , where  $E_{\rm B}$  is small, the energy barrier becomes comparable to 25kT and SD moments can reverse with the help of thermal excitations. This thermally excited condition is called superparamagnetism. The transition from a superparamagnetic state to a stable magnetic state is quite sharp and defines the blocking temperature  $T_{\rm B}$ .

At any time, SD particles are either in state 1, in which moments are aligned with H, or state 2, in which moments are antiparallel to H. The transition probability set by the energy barrier  $\Delta E_{\rm B}$  between states leads to a relaxation time for exponential magnetization decay

$$\frac{1/\tau = 1/\tau_0 \exp(-E_B/kT) = 1/\tau_0 \exp[-(\mu_0 V M_S H_K/2kT)}{(1 - H/H_K)^2}$$
 (Eq. 1)

where  $\tau_0 = 10^{-9} - 10^{-10}$  s is the atomic reorganization time for transitions between microstates and microcoercivity  $H_{\rm K} = (N_{\rm b} - N_{\rm a})M_{\rm S}$  for shape anisotropy.  $N_{\rm a}$  and  $N_{\rm b}$  are the demagnetizing factors when  $M_{\rm S}$  is directed parallel or perpendicular, respectively, to the long axis. The thermally activated transitions between states 1 and 2 cause the average moment of a grain ensemble to relax to a thermal equilibrium value

$$M(t) = M(0) \exp(-t/\tau) + M(\infty)[1 - \exp(-t/\tau)].$$
 (Eq. 2)

The thermal equilibrium magnetization above and at the blocking temperature  $T_{\rm B}$  is

$$M_{\rm eq} = M(\infty) = M_{\rm S} \tanh(\mu_0 V M_{\rm S} H/kT).$$
 (Eq. 3)

The dependence of  $\tau$  on temperature by Eq. (1) is very significant. As *T* decreases, the energy barriers increase and  $\tau$  grows exponentially, changing from a few seconds to millions of years over a narrow temperature interval. This rapid change leads to the concept of the blocking temperature at which  $\tau = t$  (experimental time).

$$T_{\rm B} = [\mu_0 V M_{\rm SB} H_{\rm KB} / 2k \ln(t/\tau_0)] (1 - H/H_{\rm KB})^2, \qquad ({\rm Eq.}\ 4)$$

where  $M_{\rm SB}$  and  $H_{\rm KB}$  are the values of  $M_{\rm S}$  and  $H_{\rm K}$  at the blocking temperature.

Equation (1) also predicts a strong dependence of  $\tau$  on grain size. SD grains only slightly above superparamagnetic size have relaxation times greater than the age of the earth, but relaxation times of only a few minutes at  $T_{\rm B}$  of a few hundred degrees Celsius.

Thus, on cooling below  $T_{\rm B}$  in an applied field, all of the orientations of the SD moments remain fixed as their  $M_{\rm S}$  increases and TRM is frozen in:

$$M_{\rm TRM} = M_{\rm RS}(T) \tanh(\mu_0 V M_{\rm SB} H / k T_{\rm B}), \qquad (\rm Eq. 5)$$

where  $M_{\rm RS}$  is the saturation value of TRM. Single-domain  $M_{\rm TRM}$  should be relatively intense because  $\tanh(\alpha)$  saturates rapidly as  $\alpha = \mu_0 V M_{\rm SB} H/kT_{\rm B}$  increases and TRM then approaches the SD saturation remanence  $M_{\rm RS}$ .

The high thermal stability of TRM is also accounted for, because  $M_{\text{TRM}}$  can only be unfrozen and reset to zero by reheating to the unblocking temperature  $T_{\text{UB}}$  in H = 0. According to Eq. (4), if  $H \ll H_{\text{K}}$ , then  $T_{\text{UB}} \approx T_{\text{B}}$ . TRM can only be demagnetized by reheating to its original high blocking temperature.

#### Experimental single-domain TRM

According to Eq. (5), the intensity of weak-field TRM is proportional to the applied field strength *H*, since  $tanh(\alpha) \propto \alpha$ for small  $\alpha$ . The proportionality between  $M_{\text{TRM}}$  and *H* in weak fields (Figure M126) has been verified by measuring TRM acquisition curves in the weak-field region for synthetic oxidized SD titanomagnetites Fe<sub>2.3</sub>Al<sub>0.1</sub>Ti<sub>0.6</sub>O<sub>4</sub> over a range of oxidation parameters 0.15 < z < 0.41 (Özdemir and O'Reilly, 1982). Figure M126 also shows a decrease in the intensity of TRM with increasing degree of maghemitization. This fall in intensity is about the same as that reported to take place in submarine basalts with increasing distance from mid-ocean ridges.

Although Eq. (5) gives a reasonable match to observed absolute TRM intensity in the weak-field region, the Néel SD theory is less successful in explaining TRM acquisition for higher fields,  $H \gtrsim 1$  Oe or 0.1 mT. The TRM intensity predicted by Eq. (5) reaches saturation at quite low fields. Experimentally, SD TRM usually saturates in much larger fields, on the order of 100 Oe or 10 mT (Figure M127). This discrepancy has been attributed to either angular dispersion of particle axes (Stacey and Banerjee, 1974) or particle interactions. Dunlop and West (1969) modified Eq. (5) by introducing an interaction field distribution that was estimated from experimental Preisach diagrams.

**Figure M126** The acquisition of TRM in weak fields for single domain titanomaghemites with composition  $Fe_{2.5}AI_{0.1}Ti_{0.4}O_4$  (ATM/60). TRMs are linear with *H* and decrease with increasing oxidation parameter *z* (after Özdemir and O'Reilly, 1982).

**Figure M127** Experimental TRM acquisition curves for a number of synthetic magnetites with mean grain sizes from 0.04 to 0.22 μm compared to the prediction of Néel's (1949) theory of noninteracting SD grains. The theory cannot explain the rapid initial rise of the experimental curves combined with their gradual approach to saturation (after Dunlop and West, 1969).

TRM intensity varies strongly with grain size *d*. Eq. (5) predicts an increase in  $M_{\text{TRM}}$  in proportion to increasing grain volume *V*. Figure M128 shows the grain-size dependence of TRM intensity for SD hematites.  $M_{\text{TRM}}$  increases in almost exact proportion to grain size *d*, not  $d^3$ . A similar dependence is observed for magnetite grains smaller than the critical SD size  $d_0 \approx 0.1 \,\mu\text{m}$ , the threshold between SD and non-SD states (Figure M129). Above  $d_0$ ,  $M_{\text{TRM}}$  decreases with increasing grain size, as  $d^{-1}$  below 1  $\mu\text{m}$  and as  $d^{-0.55}$  above 1  $\mu\text{m}$ . Thus, the Néel SD theory does not explain experimental TRM data for magnetite over most of its natural grain-size range. However, Néel's SD theory is more relevant to TRM in SD hematites because hematite has a small  $M_{\text{S}}$  ( $\approx 2 \,\text{kA m}^{-1}$ ) and a large  $d_0$ .

One of the important properties of SD TRM is the equality of the blocking temperature  $T_{\rm B}$  during field cooling and the unblocking temperature  $T_{\rm UB}$  during zero-field reheating. Experimentally, as in Figure M126, and theoretically according to Eq. (5), the intensity of a weak-field TRM, and the intensities of all the partial TRMs with different  $T_{\rm B}$  values that compose it, are proportional to the applied field strength. The equality of  $T_{\rm B}$  and  $T_{\rm UB}$  for weak fields and the proportionality of TRM and pTRM intensities to field *H* form the basis for determining paleofield intensity by the Thellier and Thellier (1959) method.

Field dependence of blocking temperature has been examined by Sugiura (1980) and Clauter and Schmidt (1981).  $T_{\rm B}(H)$  as predicted by Eq. (4) has been verified directly by measuring pTRMs covering the entire blocking-temperature spectrum for SD magnetites. Sugiura (1980) obtained a close match of theoretical and experimental  $T_{\rm B}$  spectra by assuming a single value of V and subdividing the  $H_{\rm K}$  spectrum into 11 fractions (Figure M130). The blocking-temperature spectrum shifts to lower temperature as H increases. Unblocking temperatures during zero-field heating are therefore always higher than blocking temperatures observed during in-field cooling (Dunlop and West, 1969).

Equation (4) predicts that blocking and unblocking temperatures vary with grain volume *V*. Experimentally determined blocking temperatures (Dunlop, 1973) agree well with the theoretical blocking temperatures calculated with a 3D micromagnetic model (Winklhofer *et al.*, 1997). Small SD grains have lower blocking and unblocking

**Figure M128** Grain-size dependence of TRM intensity for the single-domain hematites. The dashed line has slope 1.04 showing that  $M_{\text{TRM}}$  is very nearly proportional to *d*. temperatures than large SD grains. The predicted quadratic dependence of  $T_{\rm B}$  on the applied field is confirmed experimentally.

The dependence of TRM intensity on the rate of cooling is of practical interest to paleomagnetists studying slowly cooled orogens.

**Figure M129** Weak-field TRM as a function of magnetite grain size *d*.  $M_{\text{TRM}}$  decreases approximately as  $d^{-1}$  between 0.1 and  $\approx 1 \, \mu\text{m}$  and less strongly as  $d^{-0.55}$  above 1  $\mu\text{m}$  (after Dunlop and Argyle, 1997).

**Figure M130** Continuous cumulative TRM spectra measured during cooling of single domain magnetite (points and solid curves) compared with theoretical stepwise spectra for H = 2, 100, and 400 Oe (after Sugiura, 1980).

Dodson and McClelland-Brown (1980) and Halgedahl *et al.* (1980) predicted that the intensity of TRM in SD grains should increase for longer cooling times, possibly by as much as 40% between laboratory and geological settings. Experiments by Fox and Aitken (1980) for baked clay samples containing SD magnetites showed that there was about a 7% decrease in the intensity of TRM when the cooling time changed from 2.5 h to 3 min.

#### Partial TRM and paleofield intensity determination

According to Eq. (4),  $T_{\rm B}$  depends on grain volume V and microscopic coercivity  $H_{\rm K}$ . Any real rock has a distribution  $f(V, H_{\rm K})$  of both V and  $H_{\rm K}$ , and as a result will have a spectrum of blocking temperatures. Therefore, the total TRM of a rock will consist of a spectrum of partial TRMs, each carried by grains with similar  $(V, H_{\rm K})$ . When a rock cools from  $T_1$  to  $T_2$  in a field H, SD ensembles with  $T_2 \leq T_{\rm B} \leq T_1$  pass from the unblocked to the blocked condition, acquiring a partial TRM,  $M_{\rm PTRM}$   $(T_1, T_2, H)$ .

Thellier (1938) showed that SD partial TRMs follow experimental laws of additivity, reciprocity, and independence. *Independence*: Partial TRMs acquired in different temperature intervals are mutually independent in direction and intensity. Each partial TRM disappears over its own blocking-temperature interval. *Additivity*: Partial TRMs produced by the same H have intensities that are additive. This is expected theoretically because the blocking-temperature spectrum can be decomposed into nonoverlapping fractions, each associated with one of the partial TRMs. The total TRM is the sum of partial TRMs covering the entire blocking-temperature interval from  $T_C$  to room temperature because each partial TRM contains a unique part of the  $T_B$  spectrum of the total TRM. *Reciprocity*: The partial TRM acquired between  $T_1$ and  $T_2$  during cooling in H is thermally demagnetized over the interval  $(T_2, T_1)$  when heated in zero field. In other words, the blocking and unblocking temperatures are identical for weak fields.

Since partial TRM acquired at  $T_{\rm B}$  during cooling is erased at  $T_{\rm B}$  during heating, one can replace the natural remanent magnetization (NRM)  $M_{\rm NRM}$  of a rock in a stepwise fashion with a laboratory TRM. This is done in practice by a series of double heatings, the first in zero field and the second in a known laboratory field  $H_{\rm LAB}$ . If the NRM of a rock was acquired as a TRM in an ancient geomagnetic field  $H_{\rm A}$ ,  $M_{\rm NRM}$  should be proportional to  $H_{\rm A}$ . The intensity of the ancient geomagnetic field is then given by

$$H_{\rm A} = M_{\rm NRM} H_{\rm LAB} / M_{\rm TRM}$$

each pair of heating steps giving an independent estimate of  $H_A$ . This is the Thellier and Thellier (1959) method of paleointensity determination as modified by Coe (1967).

#### Multidomain TRM

In large grains containing many domain walls, TRM acquisition results from several processes: domain wall pinning, domain nucleation or denucleation, and nucleation failure. A multidomain grain contains crystal imperfections such as inclusions, voids, and line defects such as dislocations, all of which create surrounding stress fields. These defects tend to pin domain walls. Voids and inclusions reduce the volume of a wall and create magnetic poles, affecting both the wall energy and demagnetizing energy. Dislocations pin walls by the magnetoelastic interaction between their stress fields and the spins in the wall, which are rotated out of easy axes (Özdemir and Dunlop, 1997).

Pinned domain walls can be thermally activated just as SD moments can. Wall displacements in response to a weak field applied at high temperatures, like reversals of SD grains, can be frozen in by cooling to room temperature, resulting in TRM. The Néel (1955), Everitt (1962), and Schmidt (1973) multidomain TRM theories consider the wall-defect interaction and the field dependence of the blocking temperature. These theories follow Néel (1949) SD theory fairly closely except that V becomes the volume of one Barkhausen jump of a domain wall and  $H_{\rm K}$  becomes the critical field for such a Barkhausen jump.

McClelland and Sugiura (1987) observed that during cooling below the blocking range, after H had been zeroed, multidomain partial TRM did not remain constant but decreased in real terms, i.e.,  $M(T)/M_{\rm S}(T)$ . This observation compromises the concept of the blocking temperature, because evidently, magnetization can partially relax during cooling below  $T_{\rm B}$ . Later Shcherbakov *et al.* (1993) developed a kinetic model that invokes nucleation or denucleation of domain walls as a way of explaining changes in M(T) below  $T_{\rm B}$ .

The only direct observations of domain nucleation during zero-field warming or cooling are by Heider *et al.* (1988) and Ambatiello *et al.* (1999) for magnetite and by Metcalf and Fuller (1987) and Halgedahl and Fuller (1983) for titanomagnetite. In each case, any changes in the number or widths of domains occurred either close to  $T_{\rm C}$  or in a range of *T* where anisotropy changes rapidly, just above room temperature in magnetite. In intermediate *T* ranges, where most observations of partial TRM relaxation have been made, there is no evidence for nucleation.

A related phenomenon is nucleation failure. Titanomagnetite grains field-cooled from  $T_{\rm C}$  sometimes nucleate fewer than the equilibrium number of domain walls, and occasionally none at all (Halgedahl and Fuller, 1980). The latter structure is of particular interest because single-domain TRM is so intense that a small fraction of such grains in metastable SD states could account for multidomain TRM. In particular, the size dependence of TRM in grains larger than SD size is then explicable.

There are fundamental differences between SD and most MD TRM models. The internal demagnetizing field  $H_D = -NM$  favors a configuration of domain walls with minimum net moment. Loosely pinned domain walls may undergo a series of Barkhausen jumps during heating and cooling. Therefore, there is no single blocking temperature for a given domain wall or for a grain containing many walls since a jump by one wall alters the internal field at the location of every other wall. This is an alternative way of explaining TRM relaxation below  $T_B$ .

#### Néel and Schmidt two-domain TRM theories

Néel's (1955) 2D theory is based on the temperature dependence of the wall-defect interaction and the wall displacement driven by the internal demagnetizing field  $H_D = -NM$  where *M* is the local magnetization vector. A domain wall, which has been displaced by *H*, will reequilibrate its position at each new temperature during cooling under the influences of  $H_D$  and of local potential wells created by interaction

**Figure M131** Total energy,  $E_W + E_D + E_H$ , as a function of wall displacement *x* for various fields (after Schmidt, 1973). Downward arrows show successive local energy minima in which the wall is trapped as *H* increases from 0 to 50 Oe. Upward arrows indicate minima where the wall is pinned as *H* decreases from 50 to 0 Oe. The wall occupies different minima in increasing and decreasing fields of the same strength, giving rise to magnetic hysteresis and remanence.

between the domain walls and lattice defects (Dunlop and Özdemir, 1997). The pinning strength is measured by the microcoercivity  $H_{\rm C}$ and determined by the barrier height between adjacent local energy minimums (LEMs). Figure M131 shows the total energy in a twodomain grain with many identical wall energy  $(E_W)$  barriers, each with the same coercivity  $H_{\rm C}$  for positive and negative jumps. The central position of the wall is favored by the parabolic energy well due to the demagnetizing energy  $E_{\rm D}$ . As the applied **H** increases, the parabolas are tilted to the right by the field energy  $E_{\rm H}$  and the wall jumps from one LEM to another in a series of Barkhausen jumps. Repeated jumps of the wall generate the ascending part of the hysteresis loop, which has a slope 1/N. The barriers to wall motion are not symmetric in increasing and decreasing H. As H decreases, the wall is pinned in a different set of LEMs and generates a descending loop with the same slope 1/N. When H becomes zero, the grain is left with a displaced wall and a net moment, which is an isothermal remanent magnetization.

As the temperature decreases, the demagnetizing field and the barriers between wells grow. At the blocking temperature  $T_{\rm B}$ , the potential barriers  $E_{\rm W}$  begin to grow more rapidly than the demagnetizing field  $H_{\rm D}$  pushing the wall back toward the demagnetized state and the wall is trapped. TRM is frozen in. The basic result of Néel's 2D theory is that

$$M_{\rm TRM} = 2H^{1/2} H_{\rm C}^{1/2} / N.$$
 (Eq. 6)

Equation (6) predicts absolute TRM intensity at room temperature. The TRM is blocked by the growth of energy barriers to wall motion and thermal fluctuations are ignored. This is referred to as field-blocked TRM.

Néel (1955) pointed out that field blocking of TRM occurs very close to  $T_{\rm C}$  if *H* is small. At such high temperatures, thermal fluctuations can unpin a domain wall below its blocking temperature  $T_{\rm B}$ . Néel introduced a thermal fluctuation field  $H_{\rm F}$  such that a wall cannot be blocked until

$$H_{\rm C}(T_{\rm B}) = H_{\rm F},\tag{Eq. 7}$$

where  $H_{\rm C}(T_{\rm B})$  is the thermal fluctuation blocking temperature. TRM intensity in the presence of thermal fluctuations is given by

$$M_{\rm TRM} = H_{\rm F}^{1/2} H_{\rm C}^{1/2} H/N.$$
 (Eq. 8)

Thermally blocked TRM should be proportional to H as observed experimentally for small fields.

Schmidt's (1973) MD model is based on the temperature variation of total energy in a two-domain grain with a single wall (Figure M131). The model has the same physical basis as Néel's 2D theory, but the coercivity appears only as a derived quantity. The total energy has contributions due to the interactions between the domain wall and the applied field, the demagnetizing field, and lattice defects. The temperature dependence of wall-defect interaction is contained in a term  $m^p$ , where *m* is the reduced domain magnetization  $m(T) = M/M_S(T)$ . The index *p* takes a value between 2 and 10 depending on the relative importance of magnetostriction or magnetocrystalline anisotropy in the wall pinning. The basic results of the Schmidt model are that

$$H_{\rm C}(T) \propto m(T)^{p-1},\tag{Eq. 9}$$

$$M_{\rm TRM} \propto H^{1-1/(p-1)},$$
 (Eq. 10)

$$M_{\rm TRM} \propto H_C^{1/(p-1)}$$
. (Eq. 11)

These are identical to Néel's predictions (Eq. (6)) when p = 3.

#### Stacey multidomain TRM theory

Stacey (1958) considered the blocking temperature  $T_{\rm B}$  to be independent of the applied field and neglected the interaction between the domain wall and lattice defects. At high temperatures,  $T_{\rm B} < T < T_{\rm C}$ , the walls are highly mobile and take up positions in which the internal field  $H_{\rm I} = H - NM$  is zero. Above  $T_{\rm B}$ , the magnetization is given by M = H/N. During cooling below  $T_{\rm B}$ , the walls' displacements are frozen, so that M changes only by the reversible increase in  $M_{\rm S}(T)$ . At room temperature, the TRM is given by

$$M_{\rm TRM} = H M_{\rm S} / [N M_{\rm SB} (1 + N \chi_0)],$$
 (Eq. 12)

where  $\chi_0$  is the initial volume susceptibility. Equation (12) seemingly predicts the linear dependence of TRM on the applied field observed experimentally for weak fields. In reality, as Néel (1955) showed, blocking temperature  $T_{\rm B}$  is itself dependent on *H*. TRM as given by Eq. (12) actually varies approximately as  $H^{1/2}$ , a dependence observed experimentally only when H > 1 mT.

#### Fabian phenomenological TRM model

Fabian (2000) has proposed a phenomenological approach in which a sample is described in terms of a distribution function  $\chi(T_{\rm B}, T_{\rm UB})$ . This formulation establishes no direct link between  $(T_{\rm B}, T_{\rm UB})$  and physical properties like grain size and coercivity, but recognizes that for MD grains  $T_{\rm B} \neq T_{\rm UB}$  in general, i.e., Thellier reciprocity does not hold. With this simple approach, it is possible to explain many

observed properties of multidomain partial TRMs and to justify the kinematic equation for partial TRM relaxation during cooling or heating (Shcherbakov *et al.*, 1993). Although not a theory of TRM acquisition in the fundamental sense, the Fabian model is useful in describing and connecting a body of experimental data and making predictions about the TRM properties of a particular sample based on its measured  $\chi(T_{\rm B}, T_{\rm UB})$ .

### **Experimental multidomain TRM**

There are relatively few testable predictions of multidomain TRM theories. The prediction that TRM intensity should increase with increasing  $H_{\rm C}$  (Eqs. (6), (8), (11)) was verified in a general way in Néel's original paper and the test has not been improved upon since. The predicted dependence on applied field H has received more attention. Tucker and O'Reilly (1980) showed that in the low-field region ( $H \leq 1 \text{ kA m}^{-1}$ , where 80 A m<sup>-1</sup>  $\approx 1$  Oe = 0.1 mT), the TRM of large titanomagnetite crystals, as predicted by Eq. (8), was more or less proportional to H (Figure M132). For intermediate field strengths, the field dependence was as a power of H < 1 (Eqs. (6) or (10)), and saturation occurred around 10 kA m<sup>-1</sup>. Similar results for magnetite and magnetite-bearing rocks were reported by Dunlop and Waddington (1975) and for pyrrhotite by Menyeh and O'Reilly (1998).

**Figure M132** TRM acquisition curves for millimeter-size single crystals of titanomagnetite with composition Fe<sub>2.4</sub>Ti<sub>0.6</sub>O<sub>4</sub> (TM60), plotted bilogarithmically (after Tucker and O'Reilly, 1980). The experimental data have been fitted by a series of linear segments corresponding to power law dependences of TRM on applied field. TRM intensity is proportional to *H* for fields below about 2 mT, then increases approximately as  $H^{1/2}$  until it saturates at the value  $M_{\rm RS} = H/N$ , in agreement with Néel's (1955) theory of TRM due to domain wall displacement limited by self-demagnetization.

**Figure M133** Comparison of experimental (points and solid curves) and theoretical (dashed curves) TRM values for SD and MD hematites and magnetites (Dunlop and Kletetschka, 2001). The contrast in TRM intensities for two minerals is due to the internal demagnetizing field  $H_D = -NM$ . At saturation,  $H_D \approx 200$  mT for magnetite, but for hematite  $H_D \approx 1$  mT, making it much easier for a small field like the Earth's to push the magnetic domain walls to their limiting positions.

**Figure M134** Stepwise thermal demagnetization of partial TRMs produced by a small field applied during cooling from 370 to 350°C in magnetites ranging from small PSD to MD size. About 50%–90% of the remanence unblocks at temperatures below or above the PTRM blocking temperature range. Tailing of thermal demagnetization curves is not confined to large MD grains but is significant even for fairly small PSD grains (after Dunlop and Özdemir, 2001).

An interesting sidelight on multidomain TRM behavior is the fact that for *H* of the order of the Earth's magnetic field, weakly magnetic hematite ( $M_{\rm S} \approx 2$  kA/m) in a multidomain state has a much stronger TRM than MD magnetite ( $M_{\rm S} = 480$  kA m<sup>-1</sup>) or SD hematite (Figure M133). The reason is that the weak  $M_{\rm S}$  of hematite results in a negligible demagnetizing field  $H_{\rm D}$ , so that even a small *H* is sufficient to drive walls to their limiting positions and saturate the TRM (Dunlop and Kletetschka, 2001). MD magnetite does not approach saturation TRM except in fields 3 orders of magnitude larger because of its correspondingly greater  $H_{\rm D}$ .

The model of Fabian (2000) was a response to recent experimental work on multidomain partial TRMs. The thermal demagnetization data of Figure M134 are one example. Partial TRMs produced by applying *H* over a narrow blocking interval  $T_{\rm B} = 370-350\,^{\circ}{\rm C}$  are demagnetized over increasingly broad intervals of unblocking temperature  $T_{\rm UB}$  as the grain size increases. While partial TRMs of 1 and 6  $\mu$ m magnetites demagnetized mainly over the original  $T_{\rm B}$  interval, partial TRMs of 110 and 135  $\mu$ m grains demagnetized almost entirely outside the 370°C-350°C interval. This almost total violation of reciprocity led Fabian (2000) to treat  $T_{\rm B}$  and  $T_{\rm UB}$  as independent variables.

#### Thermoremanent magnetization

Perhaps the best understood of the primary magnetizations, of natural rocks and specimens, is thermal remanent magnetization (TRM). Most of the natural rocks are magnetized primarily by the geomagnetic field ( $\sim$ 30000 nT) and acquire natural remanent magnetization (NRM). Magnetic minerals acquire TRM when they are contained within the rock that is cooled in an external magnetic field from temperatures above the minerals' blocking temperatures. Blocking of remanent magnetization at a specific temperature results in locking of a specific direction and intensity of magnetization as it becomes stable on the timescale of the TRM acquisition.

The generally recognized first-order theory of TRM can be applied only to small uniformly magnetized grains (Néel, 1949) and it provides a reasonable explanation for the intensity of TRM vs inducing field. The theory explains the changes of stability of TRM with temperature and with the inducing field, explaining how a rock can maintain a TRM record for billions of years. This theory can also provide an explanation on how the secondary component of magnetization of a rock can be removed from the primary one.

However, besides being useful only for small single-domain (SD) grains it is also less successful in explaining TRM acquisition for more intense ambient fields ( $\sim 1$  mT). According to Neel's theory, the TRM reaches saturation, in lower fields than actually measured on specimens ( $\sim 10$  mT). This effect was assigned to particle interaction and long axis dispersions (Stacey and Banerjee, 1974).

In general, the TRM is not carried only by a small single-domain (SD) fraction of magnetic mineral grains. When the volume of the grain is larger (>0.5  $\mu$ m for magnetite mineral) the demagnetizing field (caused by magnetic sources distributed on the surface of the grain) has a slightly different geometry than the pattern of the uniform magnetization (Figure M135). This geometry causes inhomogeneity of magnetization of the larger grains that is replaced by more energetically favorable state containing domain walls bounding volume with reversed magnetic moments.

Neel first attempted to construct the theory for multidomain materials (Néel, 1955). Stacey (1963) and Everitt (1962) applied a concept of Barkhausen discontinuities, small jumps of the domain walls into the new position, believed to be due to crystal imperfections. The resistance of the domain wall motion was thought to be responsible for remanent magnetism in MD grains. As the smaller MD grains were

**Figure M135** Intensities of the ambient magnetic field *B* (tesla) against thermoremanent efficiencies  $\varepsilon$  of hematite (Fe<sub>2</sub>O<sub>3</sub>), magnetite (Fe<sub>3</sub>O<sub>4</sub>), iron-nickel alloy (FeNi) and iron (Fe). The pyrrhotite data (Fe<sub>7</sub>S<sub>8</sub>) are from Dekkers (1989). Straight lines are drawn according to  $B = aJ\varepsilon$ , where *a* is a dimensionless constant equal to 0.0046 (see Figure M137a) at 300 K, and  $J = \mu_0 J_s$  where  $\mu_0$  is permeability of vacuum and  $J_s$  is saturation magnetization at 300 K. Magnetization efficiency  $\varepsilon$  is defined as  $\varepsilon = M_{tr}/J_{sr}$ , the ratio of thermoremanence to saturation remanence. Single-domain (SD) and acicular (elongated crystal parallel to the applied field) magnetite data are redrawn from Dunlop and Argyle (1997) and Dunlop and West (1969), respectively.

more stable than larger MD grains, Stacey invented the term pseudosingle-domain (PSD) grains for grains slightly larger than SD grains (Stacey, 1963).

Because, in general, small grains of magnetite have 2–3 orders of magnitude larger TRM intensity than larger MD grains. For some time it was thought that the TRM of MD grains is negligible (Hargraves and Young, 1969; Hoye and Evans, 1975). More small grains are present in rocks than apparently visible, resulting from the formation of the iron oxides through oxidation inside the silicates.

The intensity of the remanent magnetization acquired by rocks is determined by an unknown strength of the ambient magnetic field, an unknown magnetic mineral composition, and an unknown temperature history of the sample. Stacey pointed out in his theory of multidomain TRM (Stacey, 1958) that because the demagnetizing energy falls off more slowly with temperature than any other, the condition under which TRM is first acquired is simply the minimization of the internal field. This guarantees that at least at this temperature the TRM is related only to the magnetostatic energy and the demagnetizing energy.

Néel's theory of MD TRM is incomplete since it fails to describe many aspects of pTRM (partial TRM) behavior (Néel, 1955; Shcherbakova et al., 2000). There the blocking occurs at temperature  $T_{\rm b}$  when magnetic coercivity increases high enough to pin domain walls against the demagnetizing field. For TRM of SD grains at room temperature,  $M_{\rm tr}(T_{\rm r})$ , magnetic remanence was frozen in high temperature equilibrium distribution achieved by thermally excited transitions among the different magnetic states. Transitions cease below the  $T_{\rm b}$ , because in the course of cooling, the energy barriers between different magnetization states grow larger than the available thermal energy. For both SD and MD states the resulting magnetization, composed of many magnetic moments, is in the direction of and for mineral specific field range (Kletetschka et al., 2004) proportional to the applied magnetic field B. Efficiency  $\varepsilon(T_r)$  of  $M_{tr}(T_r)$  of SD grains of saturation remanence  $J_{sr}(T_r)$ , volume V, and saturation magnetization  $J_s(T_b)$  is (Néel, 1949):

$$\epsilon(T_{\rm r}) = \frac{M_{\rm tr}(T_{\rm r})}{J_{\rm sr}(T_{\rm r})} = \tanh\left(\frac{\mu V J_{\rm s}(T_{\rm b})B}{kT_{\rm b}}\right),\tag{Eq. 1}$$

with  $\mu_0 = 4\pi \times 10^{-7}$ , and  $k = 1.38 \times 10^{-23}$  J K<sup>-1</sup>. On the timescale 50–100 s:

$$\left(\frac{\mu_0 V J_{\rm s}(T_{\rm b}) B_{\rm c}(T_{\rm b})}{k T_{\rm b}}\right) = 2 \ln(f_0 t) \approx 50,$$

where  $B_{\rm c}(T_{\rm b})$  is a critical field for moment rotations in the absence of thermal energy (microcoercivity), and frequency of moment fluctuation  $f_0 \approx 10^9 \, {\rm s}^{-1}$ . Therefore, from Eq. (1) one can derive for small fields ( $\epsilon \ll 1$ ):

$$\epsilon(T_r) = \frac{50B}{B_c(T_b)}$$
(Eq. 2)

In most fine-grained magnetic material, a typical efficiency  $\epsilon(T_r)$  of thermoremanent magnetization  $M_{tr}(T_r)$  acquired in the geomagnetic field is about 1% (Wasilewski, 1977, 1981; Cisowski and Fuller, 1986; Kletetschka *et al.*, 2000a). This small efficiency is consistent with the  $M_{tr}(T_r)$  acquisition curves for magnetite (Dunlop and Waddington, 1975; Tucker and O'Reilly, 1980; Özdemir and O'Reilly, 1982) with grain sizes covering the range from the single-domain (SD) to multidomain (MD) magnetic states. However,  $M_{tr}(T_r)$  experiments with hematite (Kletetschka *et al.*, 2000b,c; Dunlop and Kletetschka, 2001; Kletetschka *et al.*, 2002) showed  $\varepsilon > 10\%$ .

#### Experimental TRM constrains for theory

The following part is largely reiteration of the results from Kletetschka *et al.* (2004). There in an attempt to reconcile the contrast between TRM acquisition of hematite and magnetite series of magnetic  $M_{\rm tr}$ 

acquisitions performed using distinct magnetic materials (Kletetschka *et al.*, 2004): iron (Fe), iron-nickel (FeNi), magnetite (Fe<sub>3</sub>O<sub>4</sub>), hematite ( $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>), and resistance wires MWS-294R and ALLOY52. Figure M135 shows the field *B* required to reach efficiency  $\epsilon(T_r)$  of the  $M_{tr}(T_r)$  acquisition for equidimensional samples and a literature sample of acicular magnetite (Dunlop and Argyle, 1997) in which the crystals are highly elongated parallel to the applied field. Data near and at saturation, where the simple power law breaks down (see Figure M136), were excluded from the data set. The data set includes literature data for pyrrhotite (Dekkers, 1989). Remarkably, each mineral is restricted to its own line with the unit slope in the log*B*-log $\epsilon$  space. Another important feature reported in Kletetschka *et al.* (2004) is that the larger the  $J_s(T_r)$  (see legend) the larger the field *B* required to achieve a predefined efficiency level  $\epsilon$ .

An increase of the minerals'  $J_s(T_r)$  is equivalent to a similar increase in opposing demagnetizing field  $H_d(T_r)$  (Dunlop and Özdemir, 1997; Kletetschka *et al.*, 2000b, c; Dunlop and Kletetschka, 2001) as well as critical fields *B* requiring material to reach the saturation magnetization at  $T_b$ . The demagnetizing field at saturation relates to  $B_c(T_b)$ , above which the energy minima become unstable causing the magnetic moment to irreversibly rotate in an absence of thermal fluctuations. Low  $J_s(T_r)$  value is associated with low value of both  $B_c(T_b)$  and  $H_d$ and leads to a large critical SD size and large magnetic domain wall spacing while large  $J_s(T_r)$  implies large  $B_c(T_b)$  (or  $H_d$ ) causing a fine scale of the individual domains. Other effects, like magnetostriction, anisotropy, and exchange constants, may also cause changes in the overall magnetic domain size.

Data in Figure M135 are representative of multidomain (MD) magnetic materials (1 mm grain size). However, the  $M_{tr}(T_r)$  varies with the grain size according to the domain type (Kletetschka *et al.*, 2004). For example, MD magnetite has  $M_{tr}(T_r)$  that increases with decreasing grain size (Dunlop, 1990). Similar grain size dependence has been observed at saturation for  $J_{sr}(T_r)$  (Dunlop, 1990) ( $\epsilon = 1$ ). Thus, efficiency  $\epsilon(T_r)$  of  $M_{tr}(T_r)$  rather than just  $M_{tr}(T_r)$  reduces the grain size dependence to a minimum, and a line separation in the log *B*-log  $\epsilon$  plot can be used to identify the magnetic mineralogy in ideal circumstances.

The insensitivity of the  $\log B \cdot \log \epsilon(T_r)$  plot to various grain sizes is illustrated in Figure M135, where the  $M_{tr}(T_r)$  efficiency for SD magnetite (literature data; Dunlop and Argyle, 1997) correlates with MD magnetites; this breaks down when mineral size becomes so small that it is near or in the superparamagnetic size range (Dunlop and Argyle, 1997). The grain size independence is resolved in Figure M136 where we have literature data of various  $M_{tr}(T_r)$  acquisitions of titanomagnetite with disparate magnetic domain states identified by the specific grain sizes (Dunlop and Waddington, 1975; Tucker and O'Reilly, 1980; Özdemir and O'Reilly, 1982). Despite much stronger  $M_{tr}(T_r)$  of fine vs large magnetic grains, all sizes appear to have identical acquisitions when normalized by saturation remanence  $J_{sr}(T_r)$ .

When neglecting effects near saturation ( $\epsilon < 0.3$ ), this linear dependence predicts approximate maximum values of the magnetic field that can be recorded by a specific material (Figure M135). Near the saturation, the magnetization is not linear with the applied field (Figure M136) owing to Eq. (1) when  $\epsilon \approx 1$ . Thus, the magnetic fields at which  $\epsilon \approx 1$  should be the magnetic fields that define the values of intrinsic  $B_c(T_b)$  for the specific mineral. Knowledge of  $B_c(T_b)$  fields in principle can be used for dating of the magnetization according to known magnetization viscous decay curves (Heller and Markert, 1973; Borradaile, 1996).  $B_c \propto M_s$  for shape anisotropy,  $B_c \propto \lambda/M_s^n$  for magnetoelastic anisotropy (Syono and Ishikawa, 1963b; Moskowitz, 1993) (for n > 2) and  $B_c \infty K/M_s^n$  for crystalline anisotropy (Syono and Ishikawa, 1963a; Fletcher and O'Reilly, 1974) (for n > 8) where n is the experimentally determined exponent. Both K and  $\lambda$  go to zero much faster than  $M_{\rm s}$  when approaching Curie temperature  $T_{\rm c}$ . Energy minimum, related to magnetic ordering, becomes shallower when approaching  $T_{\rm b}$  due to thermal fluctuations (Stacey, 1958). Thus, for the purpose of magnetic remanence blocking near T<sub>c</sub> we may consider only the shape anisotropy:  $B_{\rm k} \propto M_{\rm s}$ . The distribution of demagnetization field vectors (tensors in general; Dunlop and Özdemir, 1997) relates to  $B_{\rm c}(T_{\rm b})$ , the nature of the resulting  $M_{\rm tr}(T_{\rm r})$  and the  $\epsilon$  (T<sub>r</sub>) dependencies. The  $B_{\rm c}(T_{\rm b})$  fields are small in minerals with low  $J_{\rm s}(T_{\rm r})$  causing them to reach saturation ( $\epsilon(T_r) = 1$ ) in much lower applied fields B

**Figure M136** Acquisition fields are plotted against thermoremanent efficiency for contrasting domain states of titanomagnetite. Data for multidomain and pseudosingle-domain mineral are from Tucker and O'Reilly (1980). Data for single-domain minerals are from Özdemir and O'Reilly (1982).

**Figure M137** Magnetic acquisition fields are plotted against  $J\epsilon$ , which is the saturation magnetization  $J = \mu_0 J_s$  multiplied by efficiency  $\epsilon$  of various materials at 300 K. (a) Equidimensional grains of iron, iron-nickel, magnetite, pyrrhotite, and hematite define a straight line that is a result of a linear fit to all of the data. For  $J_s$  at 300 K this fit has the form of  $B = (4.6 \pm 0.3) \times 10^{-3} J\epsilon$ . The linear regression coefficient is R = 0.97. (b) Effect of shape (nonequidimensional crystals) on thermoremanent acquisition fields for wire materials (MWS-294R and ALLOY52) with small (1/5) and large (1/14) predefined length to diameter ratios compared with the predicted acquisition (solid line) for equidimensional materials. Measurements were made with wires aligned parallel to the applied field.

(Kletetschka *et al.*, 2000c; Dunlop and Kletetschka, 2001). Larger  $B_{\rm c}(T_{\rm b})$  in minerals with large  $J_{\rm s}(T_{\rm r})$  creates larger resistance against acquisition of  $M_{\rm tr}(T_{\rm r})$  and requires larger magnetizing fields to achieve the saturation ( $\epsilon(T_{\rm r}) = 1$ ). For example, because magnetoelastic and crystalline constants go to zero much faster than  $M_{\rm s}$  close to  $T_{\rm C}$ , hematite has low  $B_{\rm c}(T_{\rm b})$  (due to shape anisotropy) at the point at which TRM is acquired in contrast to its high  $B_{\rm c}$  at room temperature caused by high magnetoelastic anisotropy.

The fundamental role of  $J_s(T_r)$  in mineral specific  $M_{tr}(T_r)$  acquisition can be crystal clear by taking the data from Figure M135, multiplying the magnetic efficiency  $\epsilon(T_r)$  by  $J(T_r) = \mu_0 J_s(T_r)$  (Figure M137a). Remarkably the resulting data set completely eliminates the effect of the demagnetizing field during the  $M_{tr}(T_r)$  acquisition. Figure M137a suggests that mineral  $M_{\rm tr}(T_{\rm r})$  acquisitions can be in general approximated (linear regression coefficient R = 0.97) by following a linear fit:

$$B = a(T)J(T)\epsilon(T_{\rm r}), \tag{Eq. 3}$$

where  $a = (4.6 \pm 0.3) \times 10^{-3}$  with 95% confidence level for  $T = T_r =$ 300 K. The product  $J_s(T_r)\epsilon(T_r)$  is essentially the  $M_{tr}(T_r)$  normalized by the squareness ratio  $J_{sr}(T_r)/J_s(T_r)$  of the hysteresis loop. This linear behavior (Figure M137a) indicates that all magnetic minerals should contribute to a planetary thermoremanent magnetic anomaly (e.g., intense magnetic anomalies detected on Mars (Acuña *et al.*, 1999) with the same, squareness  $J_{sr}(T_r)/J_s(T_r)$ -normalized,  $M_{tr}(T_r)$  intensity. Because  $J_s(T_r)$  620

eliminates the mineral dependence observed in Figure M135 produced byvariation in  $B_c(T_b)$  in different minerals,  $B_c(T_b) = 0.23J_s(T_r)$  in Eq. (2) leads to the empirically observed relationship equation (3). Equation (3) breaks down if the Curie temperature of the magnetic material gets near or below 300 K. With decreasing temperature,  $J_s$  increases and reaches a maximum at absolute zero temperature unless the material undergoes a phase transition (e.g. Verwey transition for magnetite). Extending the trend of the published  $J_s(T)$  curves (Dunlop and Özdemir, 1997) into 0 K (ignoring any phase transitions) results in increase of  $J_s$ by a factor of 1.05 for iron, 1.00 for hematite, 1.10 for magnetite, and 1.25 for pyrrhotite. This change of  $J_{\rm s}$  values has a negligible effect on Eq. (3) and still results in a near perfect linear relationship where  $a = (4.2 \pm 0.3) \times 10^{-3}$  with 95% confidence level for  $T=T_0=0$  K and  $B_{\rm c}(T_{\rm b}) = 0.21 J(T_{\rm 0})$ . Using magnetic constants at absolute zero temperature, the problem of Curie temperature is eliminated and Eq. (3) can be applied for any magnetic material.

As the microcoercivity  $B_{\rm c}(T_{\rm b})$  modifies the  $M_{\rm tr}(T_{\rm r})$  acquisition, the shape, magnetostriction, and crystalline anisotropy of the carriers should have significant influence on the  $M_{tr}(T_r)$  acquisition curves. For example, the length vs diameter ratio of the carrier should reduce or increase the effect of  $B_{\rm c}(T_{\rm b})$  or the demagnetizing field (Dunlop and Özdemir, 1997) for sample lengths parallel or perpendicular to the field and thus shift the  $M_{tr}(T_r)$  acquisitions into lower or higher field intensities, respectively. In Figure M135,  $M_{tr}(T_r)$  acquisition for acicular (elongated crystals parallel to the applied field) magnetite (Dunlop and West, 1969) with diameter to length ratio 1:7 violates the equidimensionality assumption. Although the data are for magnetic fields near saturation of the magnetite, the demagnetizing field due to elongation causes these grains to acquire magnetization at lower fields than equidimensional magnetite grains. This shape effect was verified experimentally (Kletetschka et al., 2004) by measuring  $M_{tr}(T_r)$  acquisition in industrial wires (MWS-294R and ALLOY52) with length to diameter ratios 1:5 and 1:14 (Figure M137b), where the longer wires, parallel to the field, required lower fields to acquire the predicted intensity of magnetization.

The effect of placing wires perpendicular to the applied field should be equal and opposite to placing them parallel. Consequently for a large number of randomly oriented, elongated grains (such as is frequently the case in igneous rocks)  $\epsilon$  should follow the same relationships as for the single equidimensional grains used in this study. This makes the TRM relationship far more applicable to those who study natural materials. However, this information would have to be accompanied by the caveat that, for the relationship to hold for multiple grains, the grains would have to be identical in size and composition (equal  $J_s$ ,  $J_{sp}$  and  $M_{tr}$ ).

It is important to emphasize that a substitution of  $\epsilon$  to Eq. (3)

$$B = a(T_0)J_s(T_0)\frac{M_{\rm tr}(T)}{J_{\rm sr}(T)}$$
(Eq. 4)

represents the first ever means to obtain a paleointensity determination using measurable quantities that does not involve the comparison of a TRM imparted in the lab with that acquired in nature. Practical considerations may pose a serious hindrance to it ever being used as such because the above equation would not be satisfied by bulk values and natural grains, capable of retaining a remanence over geological time, would be too small to be measured individually. Possible solutions involve isolating and amassing grains with sufficiently similar properties, decomposition of bulk values using FORC diagrams, and so on to satisfy the requirements of Eq. (4).

### MAGNETIZATION, VISCOUS REMANENT (VRM)

#### Introduction

Viscous magnetization is the gradual change of magnetization with time in an applied magnetic field H. Brief exposure of a ferromagnetic material to a field results in isothermal remanent magnetization (IRM). The additional remanence produced by a longer field exposure is *viscous remanent magnetization* (VRM). The longer the exposure time t, the stronger is the VRM.

Viscous remagnetization is the time-dependent change of VRM or other remanences, such as thermoremanent magnetization (TRM), depositional remanent magnetization (DRM), or chemical remanent magnetization (CRM), in response to a change in the direction or strength of *H*. In nature, such field changes are due to secular variation, excursions, polarity transitions, or plate motion. In laboratory experiments, but never in nature, samples may be exposed to zero field and the viscous decay of their magnetization measured.

The natural remanent magnetization (NRM) of rocks, sediments, and soils usually includes a VRM produced at ambient temperature by exposure to the weak ( $\leq 100 \mu$ T) Earth's magnetic field during the Brunhes normal polarity epoch. This VRM obscures the useful paleomagnetic information residing in older components of the NRM. Removing the VRM is the purpose of standard "cleaning" procedures, such as alternating field (AF) and thermal demagnetization.

Brunhes-epoch VRM is distinctive because it is roughly parallel to the present-day local geomagnetic field. It is usually weaker than TRM and DRM and also "softer" or more easily cleaned than these older NRMs. However, magnetically "hard" or high-coercivity minerals like hematite, goethite, pyrrhotite, and some compositions of titanomagnetites and titanohematites have hard VRM that is not easy to AF demagnetize.

Rocks that have been exposed to the Earth's field at elevated temperatures for long times acquire *thermoviscous magnetization* (TVRM), which may replace part or all of their primary NRM. Usually these rocks are slowly cooling plutons, or have been deeply buried in sedimentary basins, volcanic piles, or mountain belts. TVRM blurs the distinction between thermal processes like TRM and partial TRMs and time-dependent processes like VRM and viscous remagnetization.

In reality, even ambient temperature is sufficiently high compared to 0 K that time t and temperature T are interwoven in VRM and viscous overprinting. The fundamental mechanism of all viscous processes is the slow, continuous approach of the magnetization M to its thermal equilibrium value in field H at T, aided by thermal fluctuations of the magnetization in each crystal. Fortunately, the approach to equilibrium is usually extremely sluggish (hence *viscous*) at ordinary temperatures. If this were not so, there would be no surviving NRM of ancient origin, and no paleomagnetism or seafloor magnetic anomalies to track plate tectonic movements.

Although most viscous magnetization changes are driven by thermal fluctuations, another possible source of viscous effects is slow diffusion of lattice defects that pin domain walls in multidomain crystals. This *diffusion after-effect* is most significant in titanomagnetites over geologically short times (Moskowitz, 1985).

#### Theory of single-domain VRM

The Néel (1949, 1955) theory of time- and temperature-dependent magnetization deals for simplicity with ensembles of N identical uniaxial single-domain grains, all mutually aligned and having volume V, anisotropy constant K(T), and spontaneous magnetization  $M_s(T)$ . At time t = 0, magnetic field H is applied parallel to the anisotropy axis. At time t,  $n^+$  grains have their moments  $+VM_s$  in the direction of H and  $n^-$  grains have their moments  $-VM_s$  opposite to H.

The distribution function  $n(t)/N = (n^+ - n^-)/N$ , which equals  $M(t)/M_s$ , obeys the kinetic equation

$$\mathrm{d}n/\mathrm{d}t = -[n(t) - n_{\mathrm{eq}}]/\tau, \qquad (\mathrm{Eq. 1})$$

where the equilibrium value  $n_{eq}/N = \tanh(VM_sH/kT)$  and the *relaxation time*  $\tau$ , due to thermal activation of moments over the energy barrier VK due to anisotropy, is

$$1/\tau = 2f_0 \exp[-VK(T)/kT],$$
 (Eq. 2)

with  $f_0 \approx 10^{-10} \text{ s}^{-1}$ .

At constant temperature, the solution to Eq. (1) is

$$n(t) - n_{\rm eq} = [n(0) - n_{\rm eq}] \exp(-t/\tau),$$
 (Eq. 3)

an exponential decay of the out-of-equilibrium distribution function and magnetization. Néel introduced an approximation that replaces the real exponential decay by a step function,

$$n(t) = n(0) \quad \text{if } t \le \tau$$
  

$$n(t) = n_{\text{eq}} \quad \text{if } t > \tau.$$
(Eq. 4)

In the case of TRM, where  $\tau$  changes rapidly with small changes in *T*, Néel's approximation leads to the definition of the *blocking temperature*  $T_{\rm B}$ , at which the ensemble rapidly passes from a thermal equilibrium state to an out-of-equilibrium state during cooling, or the reverse during heating, e.g., in thermal demagnetization. The blocking concept is less useful in isothermal viscous magnetization because  $\tau$  remains constant and all changes are a result of changing *t*.

Any real sample contains many ensembles with different values of V and K. The grain distribution f(V, K)dV dK is generally poorly determined, but the formal solution of Eq. (3) for acquisition of magnetic moment m(t) by all ensembles, starting from a demagnetized state, is

$$m(t) = \iint VM_{\rm s} n_{\rm eq} [1 - \exp(-t/\tau)] f(V, K) dV dK.$$
 (Eq. 5)

Numerical solutions can be found for specified forms of f(V, K).

#### Time and temperature dependence of VRM

If f(V, K) is constant or nearly constant over a range of (V, K), the convolution of the exponential time dependence for a single ensemble (Eq. (3)) with f(V, K), as expressed by Eq. (5), leads to a logarithmic dependence of m(t) on t (see Dunlop, 1973, or Dunlop and Özdemir, 1997, Chapter 10 for details). Experimentally most ferromagnetic materials on a laboratory timescale exhibit viscous changes that are indeed approximately proportional to  $\log t$ . Figure M138 illustrates

the measured time dependence of VRM for oxidized and unoxidized pyroclastics on a t scale from 15 min to 28 days (about 4 decades of t). Only a limited range of (V, K) is activated in a few decades of t and the VRM increases more or less linearly on a log t scale.

According to Eq. (2), for *T* constant, *VK* is proportional to  $\log 2f_0\tau$ . Using Néel's blocking approximation (4), it is then possible to transform f(V, K) directly into the corresponding distribution  $g(\log t)$ . In this way, one can predict the *viscosity coefficient*  $S = \partial M / \partial \log t$  for a sample whose grain distribution f(V, K) is known.

Another approach (Walton, 1980) is to calculate *S* directly from Eq. (5) without explicitly invoking a blocking approximation. If we replace *K* by a suitable average value and approximate  $n_{eq}/N$  by  $VM_sH/kT$ , since *H* is small, we find

$$S = \iint (M_{\rm s}^2 H/kT)(t/\tau) [1 - \exp(-t/\tau)] V^2 N f(V) dV.$$
 (Eq. 6)

The integrand is of the form  $x(1-e^{-x})$ , with x itself exponential. It peaks sharply at x = 1 or  $t = \tau$ , which is in fact the blocking condition. All nonexponential factors can be assigned their blocking values, e.g.,  $V \rightarrow V_{\rm B} = (kT/K) \log 2f_0 t$ , and taken outside the integral, giving

$$S = Ik^2 N (M_s^2 T^2 / K^3) H (\log 2f_0 t)^2 f [kT/K) \log 2f_0 t], \qquad (Eq. 7)$$

the integral I being approximately 1.

Assuming that the anisotropy is due to grain shape, so that  $K(T) \propto M_s^2(T)$ , and that the grain distribution is uniform over the range of ensembles affected in time *t*, we obtain

$$S = C H (T/M_s^2)^2 (\log 2f_0 t)^2,$$
 (Eq. 8)

whereas if  $f(V) \propto 1/V$ , as for the larger grains in a lognormal distribution,

$$S = C' H (T/M_s^2)^2 \log 2f_0 t,$$
 (Eq. 9)

*C*, *C'* being constants. Either Eq. (8) or (9) predicts a  $\log t$  dependence for VRM intensity over times short enough that  $\log t \ll \log 2f_0 \approx 23.7$ , i.e., for a few decades of *t*, as observed. Deviations from  $\log t$  dependence will become obvious even at short times for very viscous samples, which scan larger fractions of the grain distribution, and at longer times for all samples. Deviations will appear earlier if Eq. (8) applies rather than Eq. (9).

#### VRM of multidomain and interacting grains

Viscous magnetization due to thermal activation of domain walls has been treated theoretically in the weak-field limit by Néel and in the

**Figure M138** Viscous remanent magnetization measured after exposure times of 15 min to 4 weeks to a 200 μT field (data: Saito *et al.*, 2003). presence of self-demagnetizing fields by Stacey (see Dunlop, 1973, for a review). All theories predict a log*t* dependence of VRM for geologically short times. The viscosity coefficient *S* varies with temperature as  $T/M_s$  or  $(T/M_s)^{1/2}$ . The theories resemble single-domain formulations with *V* in Eq. (2) replaced by the volume  $V_{act}$  activated in a single Barkhausen jump. The frequency constant  $f_0$  is  $\approx 10^{-10}$ s<sup>-1</sup>, as for single-domain grains. Viscous magnetization due to activation of entire walls should be negligible because  $V_{act} \gg V$  of a singledomain grain. It must be that segments of walls are activated past single pinning sites.

In nature, titanomagnetite and pyrrhotite crystals sometimes fail to renucleate equilibrium domain structures following saturation, resulting from heating to the Curie temperature. A possible mechanism for multidomain viscous magnetization is thermally activated nucleation of domains in parts of the crystal where the internal field is close to the critical nucleation field. This process has been termed *transdomain VRM*. Nucleation events have been observed in magnetite during small changes of T (Heider *et al.*, 1988) but are not yet documented for changing t at constant T.

Interacting single-domain grains have been approached in two different ways. One method is to treat them collectively by increasing V from the single-grain value. This approach preserves the experimentally observed log t behavior but it is not known at what level of interaction the picture breaks down. Another approach is to deal with individual particles under the influence of a randomly varying interaction field. Walton and Dunlop (1985) predicted deviation from log t behavior when the interactions are strong. Their theory gave a good fit to viscous magnetization data for an interacting single-domain assemblage with known f(V).

#### **Experimental results**

#### Grain size dependence of viscosity coefficients

Room-temperature viscosity coefficients *S* have their highest values in single-domain grains with volumes *V* just above the critical superparamagnetic volume  $V_{\rm B}$ . Figure M139 illustrates the data for magnetite. Data sets for other minerals are even smaller. Between the magnetite critical superparamagnetic size (0.025–0.03 µm) and the maximum size for single-domain behavior (0.07–0.08 µm), *S* decreases by at least a factor 4. The decrease may actually be larger and more precipitous than shown. Even in carefully sized samples, there is always a fraction of very fine grains. This fine fraction probably controls the short-term viscous behavior, because, according to Eqs. (2) and (4), only grains with very small *V* will be activated in the short times used in laboratory experiments. Similar "contaminating" ultrafine grains may explain the constant baseline value of *S* in grains larger than single-domain size.

The twofold increase in S over the upper pseudosingle-domain region (2–15  $\mu$ m) is probably real and due to the increasing ease with which segments of walls can escape from their pins as the scale of the domains grows. On the other hand, large multidomain grains 80–100  $\mu$ m in mean size have significantly lower S values.

In summary, strong viscous magnetization is found mainly in the finest single-domain grains. However, small multidomain (so-called pseudosingle-domain) grains are also significantly viscous.

Observations on lunar rocks and soils (see Dunlop, 1973 and Dunlop and Özdemir, 1997, Chapter 17 for summaries) confirm this trend. Lunar soils and loosely welded soil breccias containing nearly superparamagnetic iron particles are among the most viscous materials known, whereas crystalline rocks and mature breccias containing multidomain iron exhibit a consistent but small viscous magnetization. The viscous nature of lunar samples greatly complicated the study of their other magnetic properties during the Apollo missions.

#### Temperature dependence of viscous magnetization

Viscous magnetization data for a single-domain magnetite sample (mean grain size  $0.037 \ \mu$ m) at and above room temperature appear in Figure M140. Zeroing the field *H* for each measurement would have changed the initial state for subsequent measurements. Therefore viscous induced magnetization in the presence of *H* was measured.

Over the short time-spans examined (2.4 decades of *t*),  $M_{vr}$  is linear in log *t*, as predicted by Eqs. (2), (8), and (9). The viscosity coefficient *S*, the slope of each data run, increases steadily with increasing *T*. This too is as predicted by theory. However, the inherent temperature dependence of *S*, in Eqs. (8) and (9) for example, tends to be obscured by the variability of the grain distribution f(V, K), which is scanned with a narrow thermal "window," as expressed by the factor  $f(kT/K)\log 2f_0t$ ] in Eq. (7).

Very different temperature dependences of viscous magnetization have been reported for magnetite and titanomagnetites of various grain sizes by different authors. In many cases, the higher-*T* results are distinctly nonlinear in log *t*. However, a good theoretical match is evident in Figure M140 between the single-domain magnetite data (Dunlop, 1983) and the theory of equations (6)–(9), using the measured f(V)of this sample (Walton, 1983).

#### Field dependence of viscous magnetization

Experiments confirm the theoretical prediction (e.g., Eqs. (6)–(9)) that VRM intensity is proportional to field strength *H* for weak fields. The most detailed studies are those of Creer (1957) on single-domain hematite and Le Borgne (1960) on soils containing single-domain magnetite and maghemite. Linear behavior was observed for 0.05 mT  $\leq H \leq 1$  mT.

# Viscous magnetization at short times: frequency dependent and quadrature susceptibility

Viscous changes in magnetization can be detected over very short times by measuring initial susceptibility  $\chi$  (short-term induced *M*, normalized by *H*) as a function of the frequency *f* of an alternating field (AF)  $\tilde{H}$ . In effect, each cycle of the AF restarts the viscous magnetization experiment. A second method is to measure the quadrature (90° out-of-phase) component of susceptibility  $\chi_q$ , which represents a time-delayed response to  $\tilde{H}$ .

In the classic experiments of Mullins and Tite (1973) on soils containing single-domain size magnetite and maghemite,  $\partial \chi / \partial \log f$  and  $\chi_q$  were constant over the tested range of f(66-900 Hz, 1.4 decades of t). No frequency dependence or quadrature susceptibility was detected for multidomain magnetite.

A pair of measurements of  $\chi$  at two standard frequencies is routinely used in environmental magnetic studies as a test for the presence of nearly superparamagnetic magnetite or maghemite. Because the frequencies are preset, there is no attempt to tune the viscosity measurement to other minerals or to domain states other than single-domain. Much more granulometric information could be obtained with a little extra effort by scanning a wider range of *f* and by extending the measurements to temperatures other than room temperature (e.g., Jackson and Worm, 2001).

## **Demagnetizing VRM**

#### AF demagnetization

The AFs  $\tilde{H}$  used in frequency-dependent susceptibility measurements have small amplitudes, usually ~0.1 mT, and do not seriously modify preexisting remanences. If larger AFs are applied, they entrain singledomain moments or domain walls, causing them to oscillate and destroy VRM (or any other remanence, for sufficiently large  $\tilde{H}$ ). To demagnetize a previously magnetized sample,  $\tilde{H}$  is slowly decreased from its maximum value at a rate  $\ll f$ , leaving about equal numbers of moments or domains in one or the other polarity. AF demagnetization is carried out in a stepwise fashion. The maximum field is increased in steps, starting from small values, so as to gradually erase remanence components of increasing AF coercivity.

VRM is often the NRM component of lowest coercivity and therefore erased first. Indeed the strategy of AF cleaning in paleomagnetism is firmly rooted in this assumption. Strong fields lower the energy barrier VK to rotation of single-domain moments or the corresponding "barrier" (pinning energy) for domain wall motion. In the single-domain case, Eq. (2) is modified to

One consequence is hard VRM in minerals with high  $K/M_s$ , like hematite, goethite, pyrrhotite, elongated single-domain iron, and many compositions of titanomagnetite, titanomaghemite, and titanohematite. VRM is produced by a weak field and Eq. (2) applies, but it is demagnetized by a strong field  $\tilde{H}$  for which Eq. (10) is

$$1/\tau_{\rm H} = f_0 \exp[-(VK(T)/kT)(1 - M_{\rm s}H/2K)^2].$$
 (Eq. 10)

**Figure M141** AF demagnetization of some of the VRMs of Figure M138 (data: Saito *et al.*, 2003). VRM of the unoxidized titanomagnetite is erased by  $\approx$ 2.5 mT. VRM of the oxidized sample containing titanohematite is much more resistant.

**Figure M142** AF demagnetization of VRMs produced by 2.5 h exposure to a 50  $\mu$ T field at the temperatures shown (after Dunlop and Özdemir, 1990). VRMs produced at higher temperatures are increasingly resistant to AF cleaning.

appropriate. Using the blocking approximations  $\tau = t$  for the last ensemble to acquire VRM and  $\tau_{\rm H} = 1/f$  when  $H = \tilde{H}$  for AF cleaning of this same ensemble, we have by combining (2) and (10),

$$\tilde{H} = (2K/M_{\rm s}) \left[1 - (\log f_0/f)^{1/2} / (\log 2f_0 t)^{1/2}\right].$$
 (Eq. 11)

The resistance of VRM to AF cleaning is thus proportional to  $K/M_s$ , the other factor being independent of mineral properties.

Figure M141 confirms this prediction. One sample is an unoxidized pyroclastic containing iron-rich titanomagnetite with low coercivity  $K/M_s$ . VRMs produced over all ranges of *t* are very soft, demagnetizing almost completely for  $\tilde{H} = 2.5$  mT. The other sample is oxidized and its VRM is carried by titanohematite of much higher coercivity. VRMs for this sample are more resistant to AF demagnetization, surviving to  $\tilde{H} = 10-20$  mT. This is only a moderately hard VRM, because in fact both these samples contain multidomain-size grains, not single-domain material to which Eq. (11) strictly applies. However, practically any rock whose NRM is due mainly to hematite has VRM that cannot be entirely removed by  $\tilde{H} = 100$  mT (Biquand and Prévot, 1971).

VRM produced in nature at above-ambient temperature and subsequently AF cleaned at room temperature is also relatively hard. Figure M142 shows an example for a single-domain magnetite sample that was given VRMs in 2.5 h runs at temperatures as high as 552°C (the Curie point is 580°C). The effect of *T* is to shift the window of f(V, K) affected viscously in t = 2.5 h to grains with increasingly high *K* (see Dunlop and Özdemir, 1997, Chapter 10).

Ambient-temperature VRM in magnetically hard minerals and elevated-temperature VRM in both hard and soft minerals are both difficult to remove completely or cleanly (without removing part of the primary NRM as well) by AF demagnetization. A more satisfactory method is thermal demagnetization.

#### Thermal demagnetization

Because VRM is a thermoviscous relaxation phenomenon, thermal demagnetization should be the most efficient way of erasing VRM. Randomizing single-domain moments or domain wall positions is accomplished by random thermal excitations, resulting in a truly demagnetized state, not the polarized condition that follows AF cleaning. From Eq. (2), the laboratory temperature  $T_L$  to which a single-domain sample must be heated (in zero field) on a timescale  $t_L$  (typically an hour or less) to erase VRM produced over a long time  $t_N$  in nature at temperature  $T_N$  is given by

$$T_{\rm L} \log 2f_0 t_{\rm L} / M_{\rm s}^2(T_{\rm L}) = T_{\rm N} \log 2f_0 t_{\rm N} / M_{\rm s}^2(T_{\rm N}),$$
 (Eq. 12)

(Pullaiah *et al.*, 1975), assuming  $K(T) \propto M_s^2(T)$  as for shape anisotropy.

Substituting  $t_{\rm N} = 0.78$  Ma for VRM acquired over the Brunhes epoch at surface temperatures, one obtains for magnetite  $T_{\rm L} \approx 250^{\circ}$ C. This is indeed the typical reheating temperature needed to completely erase magnetite VRM, although AF cleaning often serves very well in this case. For pyrrhotite, with a different Curie temperature (320°C) and  $M_{\rm s}(T)$  variation, the corresponding  $T_{\rm L}$  is  $\approx 130^{\circ}$ C.

Figure M143 illustrates how complete erasure of VRM is detected. The NRM vector of this sample (Milton Monzonite, SE Australia), plotted in vector projection, reveals four components whose removal requires successively higher heatings. The VRM, produced by the Earth's field over  $\approx 100$  ka at  $\approx 165^{\circ}$ C (Dunlop *et al.*, 2000), and the primary TRM are carried by single-domain pyrrhotite, the two CRMs by magnetite and hematite. The junction between the VRM and TRM vectors is sharp because single-domain thermoviscous remanences separate cleanly in heating. The vector direction changes abruptly at the junction temperature because the TRM was produced by a reverse-polarity field and the VRM by a normal-polarity field. The junction temperature  $T_L$  is >130°C because  $T_N$  was above ambient while the rock was buried and VRM was being produced. Using

**Figure M143** Thermal demagnetization of NRM of a sample of the Milton Monzonite (after Dunlop *et al.*, 1997). The pyrrhotite primary TRM and VRM separate cleanly in thermal demagnetization to 222°C. Triangles and circles: vertical- and horizontal-plane vector projections, respectively.

 $t_{\rm N} = 100$  ka,  $T_{\rm N} = 165^{\circ}$ C, and  $M_{\rm s}(T)$  for pyrrhotite in Eq. (12) yields  $T_{\rm L} = 222^{\circ}$ C, as observed.

Contours of constant (*V*, *K*) are often plotted on a time-temperature diagram (Pullaiah *et al.*, 1975), which can then be used as a nomogram for locating matching (*T*, *t*) pairs. Figure M144 is such a diagram, with contours for magnetite based on Eq. (12). It is clear from the data plotted, some of which are from the Milton Monzonite, that single-domain magnetite samples (0.04  $\mu$ m, A) obey Eq. (12) but samples with pseudosingle-domain (20  $\mu$ m, B) and multidomain (135  $\mu$ m, C) magnetites follow contours with smaller slopes. That is, these latter grains require more heating to remove their VRMs than the single-domain theory predicts.

Observations of "anomalously high" unblocking temperatures in thermal demagnetization of VRM are well documented in the literature. Initially it seemed possible to reconcile the data by using the Walton (1980) single-domain theory outlined in an earlier section. From Eq. (9),

**Figure M144** Theoretical time-temperature contours based on Eq. (12) compared to data from thermal demagnetization of VRMs produced at elevated temperatures for synthetic magnetites and samples of the Milton Monzonite (after Dunlop and Özdemir, 2000). Single-domain samples agree well with the contours. Larger pseudosingle-domain and multidomain samples are more difficult to demagnetize than predicted.

$$T_{\rm L}(\log 2f_0 t_{\rm L})^2 / M_{\rm s}^2(T_{\rm L}) = T_{\rm N}(\log 2f_0 t_{\rm N})^2 / M_{\rm s}^2(T_{\rm N}), \qquad \text{(Eq. 13)}$$

which produces shallower contours resembling the trend of some of the deviant data (Middleton and Schmidt, 1982).

However, on reflection it became clear that Eqs. (12) and (13) actually answer different questions (Enkin and Dunlop, 1988). Equation (13) tells us what exposure time  $t_{\rm L}$  to field H at temperature  $T_{\rm L}$  will produce the *same VRM intensity* as the original exposure to H for time  $t_{\rm N}$  at  $T_{\rm N}$ . The question that is relevant to erasure of VRM by thermal demagnetization, and is answered by Eq. (12), is what exposure  $t_{\rm L}$  to H at  $T_{\rm L}$  will reactivate the *same ensembles* (*V*, *K*) as the exposure in nature to H for time  $t_{\rm N}$  at  $T_{\rm N}$ . Because VRM intensity increases with rising T even if f(V, K) is constant (e.g., Eq. (7)), the two answers will always be different.

This has now been shown beyond doubt by the experiments of Jackson and Worm (2001), shown in Figure M145. They carried out experiments on the magnetite-bearing Trenton Limestone below room temperature at fixed, very short times t and varied T to either achieve unblocking of the same (V, K) ensembles (upper graph) or produce the same viscous magnetization intensity (lower). The former data sets agree well with the Pullaiah *et al.* (1975) contours from Eq. (12), while the latter are close to the predicted Walton-Middleton-Schmidt contours from Eq. (13).

Discrepancies between the predictions of Eq. (12) and thermal demagnetization results for rocks are mainly attributable to VRMs of grains larger than single-domain size. The larger the grain size, the greater the discrepancy, as illustrated by Figure M144. It is well known that the Thellier (1938) law of independence of partial TRMs is increasingly violated as grain size increases. One manifestation of this violation is that partial TRMs produced over narrow T intervals do not demagnetize over the same intervals, so that a clean separation of partial TRMs is no longer possible using thermal demagnetization.

VRMs behave analogously. The *average* demagnetization temperature of both VRMs and partial TRMs is close to that predicted by Eq. (12) (Dunlop and Özdemir, 2000) but domain walls continue to move toward a demagnetized state at higher T, producing a "tail" of unblocking temperatures. Unfortunately only the ultimate highest unblocking temperature is easily detected experimentally, and it is not predictable by any current theory.

To further complicate matters, the initial state of a multidomain grain can strongly affect its magnetic behavior, including thermal demagnetization. Figure M146 demonstrates that VRMs produced in an AF demagnetized sample or in one thermally demagnetized and then heated in a zero field to the VRM production temperature are subsequently erased by further heating of  $\leq 100^{\circ}$ C. But a sample cooled in a zero field directly from the Curie point to the VRM temperature acquires a VRM that requires  $\approx 250^{\circ}$ C of further heating to remove. These experiments use continuous thermal demagnetization, which differs from standard stepwise demagnetization by not revisiting room temperature for each measurement. Although these results may not be directly applicable to standard paleomagnetic practice, they do make the point that any multidomain sample retains a memory of its entire past history and this may influence its later behavior in as yet unpredictable ways.

#### Applications of viscous magnetization

#### Magnetic granulometry

Viscous magnetization is a sensitive probe of narrow (V, K) bands of the grain distribution. If K has a narrow spread compared with V, inversion of Eq. (5) by Laplace transforms yields  $f(\tau)$ , i.e., f(V). A cruder estimate, which is adequate in most cases, is to use a blocking approximation as in Eq. (7) to obtain  $f(V_{\rm B}) = f(kT\log 2f_0t/K)$ . Small  $V_{\rm B}$  can be accessed by using the frequency dependence of  $\chi$ . Large  $V_{\rm B}$  can be activated in VRM experiments above room temperature.

#### Estimating Brunhes-chron VRM

In very viscous rocks, particularly unoriented or partially oriented seafloor samples, one would like to know if a large part of the NRM is

**Figure M145** Comparison of equivalent ( $\tau$ , T) sets determined from frequency-dependent susceptibility data at low temperatures for the magnetite-bearing Trenton Limestone (after Jackson and Worm, 2001). The upper data compare reactivation of equivalent grain ensembles (V, K) and are in good agreement with Eq. (12). The lower data compare equal viscosity coefficients at different T and agree reasonably well with Eq. (13).

VRM produced during the Brunhes chron (the past 0.78 Ma). For samples magnetized during an earlier normal-polarity chron, there is not much difference between the directions of primary TRM and recent VRM. No sharp junctions like those of Figure M143 appear in thermal demagnetization trajectories.

Since relaxation times of  $\sim 1$  Ma are inaccessible in laboratory experiments, two different methods have been used. First is simple extrapolation of laboratory data, assuming *S* remains constant over many decades of *t* beyond the laboratory scale. This is certainly unjustified with the more viscous shallow oceanic rocks, e.g., doleritic flows (Lowrie and Kent, 1978). With less viscous rocks, like those of Figure M138, simple extrapolation implies that a substantial part of the NRM could be VRM, but a precise quantitative estimate is not possible (Saito *et al.*, 2003).

The second method is to activate long relaxation times in the laboratory in mild heatings above room temperature. For titanomagnetite of mid-ocean ridge compositions, the heatings must remain below the Curie point (150–200°C). Another criterion is that chemical alteration must be prevented. Thermal demagnetization of the NRM, using Eq. (12) or Figure M144 as a guide to the ( $T_L$ ,  $t_L$ ) combination needed, is a better approach than production of a new VRM. In the latter experiment it is not possible to reactivate at  $T_L$  all the ensembles (V, K) that carried the room-temperature VRM.

#### Paleothermometry

If the approximate residence time  $t_N$  over which VRM was acquired can be estimated (within about an order of magnitude, since log  $t_N$  is involved), but the burial temperature during VRM production is unknown, Eq. (12) or Figure M144 can again be used to analyze laboratory thermal demagnetization data and estimate  $T_N$ . This method is useful for estimating depth of burial in a sedimentary basin as a guide to hydrocarbon potential. It of course only works well if the VRM has single-domain carriers. A recent variant, which is capable

**Figure M146** Continuous thermal demagnetization of VRMs produced at 225°C in a synthetic multidomain magnetite sample with different initial states: crosses, AF demagnetized; solid circles and triangles, thermally demagnetized and then heated to 225°C; open circles, zero-field cooled from the Curie point to 225°C (after Halgedahl, 1993).

in principle of estimating both  $t_N$  and  $T_N$  independently, is to analyze thermal demagnetization data for VRMs carried by *two* minerals, e.g., magnetite and pyrrhotite (Dunlop *et al.*, 2000).

#### Cooling-rate dependence of TRM

Another thermoviscous effect is the variation of TRM intensity depending on cooling rate. For single-domain grains, about 5% increase in intensity is predicted for the slowest versus the fastest practical laboratory cooling rates. The theory is not simple because T and t vary simultaneously but the few experimental data that exist agree quite well with predictions (Fox and Aitken, 1980). There is some evidence that for multidomain grains, TRM intensity may *decrease* for slower cooling (Perrin, 1998). The enormous range of cooling rates present in nature when metamorphic terrains are uplifted over millions or tens of millions of years by erosional unroofing may lead to much larger changes than can be measured in the laboratory. So far no method of simulating or estimating changes over these very long time-scales has been proposed.

#### VRM as an archeological dating tool

When blocks of stone were reoriented in building historical or more ancient structures, viscous remagnetization of their NRMs began. This "clock" is less than ideal because the changes in *M* are roughly in proportion to  $\log t$ , so that the resolution  $dM/dt = t^{-1} dM/d\log t = S/t$ decreases with increasing age. The classic study by Heller and Markert (1973) found reasonable values, 1.6–1.8 ka, for the age of Hadrian's Wall (Roman, northern England) from the viscous behavior of two of three blocks tested. This success is somewhat unanticipated because it implies that *S* is constant for times of historical length, contrary to most laboratory observations. Multidomain grains, with their lower *S* values, may perhaps succeed where single-domain grains would fail.

More recently, Borradaile has successfully used ad hoc relations between  $t_N$  and  $T_N$  for specific limestones used in the construction of buildings and monuments in England and Israel to interpret VRM thermal demagnetization data of samples from other structures of unknown age (see Borradaile, 2003 and references therein). The success of this approach depends on constructing a calibration ( $t_N$ ,  $T_N$ ) curve using samples from buildings of known age. It is specific to a certain area and a particular building stone, and requires substantial labor in establishing the calibration curve, but is undeniably useful to archeologists thereafter.

#### VRM in rocks

Lunar rocks owe their magnetic properties to metallic iron. Lunar soils and low-grade breccias contain ultrafine ( $\leq 0.02 \mu m$ ) single-domain grains which are potently viscous. High-grade breccias, basalts, and anorthosites have weaker viscous magnetizations originating in multidomain iron. For a full discussion, see Dunlop (1973) or Dunlop and Özdemir (1997, Chapter 17).

Terrestrial submarine basalts are rather weakly viscous. Coarsegrained massive flows, on the other hand, can be extremely viscous (Lowrie and Kent, 1978). The VRM is likely due to large homogeneous titanomagnetite grains with easily moved walls. VRM of titanomaghemites is very dependent on the degree of oxidation (see Dunlop and Özdemir, 1997, Chapter10).

For Tertiary and early Quaternary subaerial basalts, Brunhes epoch VRM averages about one-quarter of total NRM intensity (Prévot, 1981). Soft VRM is due to homogeneous multidomain titanomagnetite grains (cf. Figure M141). Relatively hard VRM is carried by single-domain size magnetite-ilmenite intergrowths formed by oxyexsolution. Thermal cleaning to  $\leq$ 300°C erases all Brunhes epoch VRM, as Eq. (12) suggests.

Red sediments of all types have relatively strong and hard VRMs. Creer's (1957) study remains the classic. Among magnetite-bearing sedimentary rocks, limestones have been the most thoroughly studied (e.g., Borradaile, 2003).

Plutonic rocks, especially intermediate and felsic ones, tend to be quite viscous. The VRM is generally due to multidomain magnetite in grains  $\approx 100 \ \mu\text{m}$  in size and is easily AF demagnetized ( $\tilde{H} < 10 \ \text{mT}$ ). The primary TRM sometimes resides in elongated single-domain magnetite grains within silicate host minerals, and is physically as well as thermoviscously distinct from VRM.

Soils and baked clays, e.g., pottery and bricks, owe their viscous magnetization to fine single-domain magnetite and maghemite. The classic study is Le Borgne (1960).

## MAGNETOCONVECTION

Magnetoconvection refers to the thermal driving of flow within an electrically conducting fluid in the presence of an imposed magnetic field. In rapidly rotating systems like the Earth's fluid outer core, magnetoconvection offers a key insight into the intricate interaction between the effects of rotation and magnetic field. The simplest problem of magnetoconvection is given by a rotating plane horizontal layer of an electrically conducting Boussinesq fluid across which a uniform vertical magnetic field is imposed (Chandrasekhar, 1961; Roberts, 1978; Soward, 1979; Aurnou and Olson, 2001). The mathematical simplicity of the problem provides an essential understanding of the fundamental magnetohydrodynamic processes taking place in the Earth's fluid core. We shall use this example to illustrate these primary features of general magnetoconvection. For convenience and to avoid unnecessary complication, we assume that the fluid has constant viscosity v, thermal diffusivity  $\kappa$ , and magnetic diffusivity  $\lambda$ . The thickness of the horizontal layer is taken to be d. We further suppose that magnetoconvection is stationary and that the amplitude of the convection is sufficiently small so that the nonlinear effects can be safely ignored. The lower boundary of the layer is heated to maintain a constant negative vertical temperature gradient  $\beta$ . When  $\beta$  is small, magnetoconvection cannot occur and the static equilibrium is described by

$$\mathbf{u}_0 = 0, \quad \mathbf{B} = \mathbf{k}B_0, \quad \nabla T_0 = -\beta \mathbf{k}, \quad \nabla p_0 + \mathbf{k}g\rho = 0 \quad (\text{Eq. 1})$$

where  $\mathbf{u}_0$  is the fluid velocity,  $\mathbf{k}$  is the unit upward vector,  $p_0$  is the total pressure (kinematic plus magnetic),  $\rho$  is the density of the fluid, g is the acceleration due to gravity,  $\mathbf{B}$  is the imposed vertical uniform magnetic field, and  $T_0$  is the conduction temperature. When  $\beta$  is sufficiently large, magnetoconvection takes place and modifies the basic static state. The problem of magnetoconvection is characterized by the Rayleigh number R, the Taylor number  $T_a$ , and the Chandrasekhar number Q, which are defined as

$$R = \frac{\alpha \beta g d^4}{\nu \kappa}, \quad T_{\rm a} = \left(\frac{2\Omega d^2}{\nu}\right)^2, \quad Q = \frac{B_0^2 d^2}{\mu \nu \rho \lambda} \tag{Eq. 2}$$

where  $\mu$  is the magnetic permeability and  $\Omega$  is the angular velocity of the Earth. The Rayleigh number *R* provides a measure of the vertical buoyancy force, the Chandrasekhar number *Q* represents the ratio of the Lorentz force to the viscous force, and the Taylor number *T*<sub>a</sub> is the squared ratio of the Coriolis force to the viscous force. The main characteristics of magnetoconvection can be elucidated in terms of these three physical parameters.

By assuming that the fluid layer has an infinitely horizontal extent, solutions of stationary magnetoconvection at onset can be expressed in the form

$$\mathbf{u}(x, y, z) \to \mathbf{u}(z) \exp[i(a_x x + a_y y)], \qquad (\text{Eq. 3})$$

where **u** is the velocity of the magnetoconvection, and  $a_x$  and  $a_y$  are the horizontal wave numbers with the total horizontal wave number *a* defined as

$$a^2 = a_x^2 + a_y^2.$$
 (Eq. 4)

When the temperatures of the upper and lower boundaries are held constant, the flow velocity is stress-free at the boundaries and the magnetic field satisfies the stress-free-type condition discussed by Chandrasekhar (1961), the Rayleigh number R at the onset of magnetoconvection is given by

$$R = \frac{\xi^2}{a^2 [\xi^4 + Q\pi^2]} \left[ (\xi^2 + Q\pi^2)\xi^4 + T_a \pi^2 \xi^2 + Q(\xi^4 + Q\pi^2)\pi^2 \right],$$
(Eq. 5)

where  $\chi^2 \equiv a^2 + \pi^2$ . The physically realizable form of magnetoconvection is characterized by the smallest value of the Rayleigh number, which is referred to as the critical Rayleigh number  $R_c$ . The subtle physics contained in Eq. (5) can be clearly unfolded by considering a number of extreme cases.

#### Magnetoconvection with strong field, weak rotation

When the system is slowly rotating in the absence of an imposed magnetic field, Chandrasekhar (1961) showed that the critical Rayleigh number  $R_c$  and the corresponding critical wave number of magnetoconvection  $a_c$  are given by

$$R_{\rm c} \approx \frac{27\pi^4}{4}, \quad a_{\rm c} \approx \frac{\pi}{\sqrt{2}}, \quad \text{for } Q = 0$$
 (Eq. 6)

However, both the critical Rayleigh number  $R_c$  and wave number  $a_c$  increase dramatically when a strong magnetic field is present

$$R_{\rm c} \approx Q\pi^2, \quad a_{\rm c} \approx \left(\frac{\pi^4}{2}\right)^{1/6} Q^{1/6}, \quad \text{for } Q \gg 1$$
 (Eq. 7)

Comparison between Eqs. (6) and (7) indicates that the role of the magnetic force is strongly stabilizing: the presence of an intense magnetic field requires a much larger Rayleigh number to excite magnetoconvection.

#### Magnetoconvection with weak field, strong rotation

The Proudman-Taylor theorem states that infinitesimal, nonmagnetic steady flows in a rotating inviscid fluid are two-dimensional with respect to the direction of the rotation axis. It follows that the Proudman-Taylor constraint must be broken in order that convection can occur in rapidly rotating systems. In consequence, a large viscous force in association with small-scale convection cells is usually required. When the system rotates rapidly and the imposed magnetic field is weak, we obtain from Eq. (5)

$$R_{\rm c} \approx \frac{3}{2^{2/3}} \left(\pi^2 T_{\rm a}\right)^{2/3}, \quad a_{\rm c} \approx \left(\frac{\pi^2}{6}\right)^{1/6} T_{\rm a}^{1/6}, \quad \text{for } T_{\rm a} \gg 1 \qquad (\text{Eq. 8})$$

Comparison of Eqs. (6) and (8) indicates that the role of the Coriolis force is also strongly stabilizing: the effect of rapid rotation makes convection difficult.

## Magnetoconvection with magnetic and Coriolis forces in balance

When the rotational effect is predominant ( $T_a \gg 1$  and  $Q \ll 1$ ), magnetoconvection is ineffective, invoking large viscous effects in connection with the short horizontal length of the flow; when the effect of the magnetic field is dominant ( $Q \gg 1$  and  $T_a \ll 1$ ), magnetoconvection has similar features. However, when the two inhibiting effects, rotation and magnetic field, act simultaneously and have a comparable strength ( $Q \approx T_a^{1/2}$ ), magnetoconvection operates in the optimum state: both the critical Rayleigh number  $R_c$  and the critical wave number  $a_c$  reach an overall minimum. In other words, convection can be most readily excited when Lorentz and Coriolis forces are of comparable amplitude.

Several examples calculated from Eq. (5) are shown in Figure M147 for  $T_a^{1/2} = 0$ ,  $10^4$ ,  $10^6$ . The overall minimum for  $R_c$  and  $a_c$  can be explained by the fact that the effect of the magnetic field relaxes the

**Figure M147** The critical Rayleigh number  $R_c$  (*top panel*) and the corresponding wave number  $a_c$  (*lower panel*), calculated using Eq. (5), are shown as functions of the Chandrasekhar number Q for different values of  $\tau$ , where  $\tau = T_a^{1/2}$ .

Proudman-Taylor constraint, increases the length scale of the magnetoconvection cell and, hence, makes the system convect more readily and efficiently. This characteristic of magnetoconvection has led to an important suggestion that the dynamo of the Earth's core operates in the regime  $T_a^{1/2} \approx Q$  where the geodynamo as a thermal engine is most effective.

#### Magnetoconvection in spherical geometry

In rotating spherical geometry, magnetoconvection in the presence of an imposed azimuthal field whose strength is proportional to distance from the rotation axis has been extensively studied (for example, Fearn, 1979, 1998; Proctor, 1994). Spherical magnetoconvection exhibits similar features in a plane layer: the critical Rayleigh number  $R_c$ reaches an overall minimum as the magnetic field strength increases to  $Q = O(T_a^{1/2})$  at which the Lorentz and Coriolis forces are of comparable size. For larger values of Q, the effects of the magnetic field inhibit convection and thus  $R_c$  increases with growing Q; for smaller values of Q, the small scale of the convection cells resulting from the rotational constraint leads to extremely large  $R_c$ .

It should be pointed out, however, that spherical magnetoconvection in the presence of a more realistic magnetic field that satisfies electrically insulating boundary conditions shows a quite different behavior (Fearn and Proctor, 1983; Zhang, 1995). It was found that the twodimensionality of purely thermal convection survives under the influence of a strong Lorentz force and that there exist no optimum values of Q that can give rise to an overall minimum of the critical Rayleigh number (Zhang, 1995). The value of  $R_c$  is a monotonically, smoothly decreasing function of Q. This is because the more realistic magnetic field can become unstable when Q is sufficiently large (Zhang and Fearn, 1993).

## MAGNETOHYDRODYNAMIC WAVES

## Introduction

Magnetohydrodynamic waves are propagating disturbances found in electrically conducting fluids permeated by magnetic fields where magnetic tension provides a restoring force on fluid parcels moving across field lines. The role played by magnetohydrodynamic waves, transporting disturbances in the flow and magnetic field and connecting disparate regions of the fluid, is crucial to our understanding of hydromagnetic systems. Magnetohydrodynamic waves in the Earth's liquid iron outer core have been proposed as the origin of changes of the Earth's magnetic field taking place on timescales of decades to centuries, and are thus of interest to both geomagnetists and paleomagnetists.

In the Earth's outer core, in addition to the magnetic forces acting on the electrically conducting fluid, we must also consider Coriolis forces resulting from planetary rotation, buoyancy forces due to gravity acting on density gradients and the constraints placed on flow by spherical shell geometry. Magnetohydrodynamic waves could be excited by convection-driven instabilities (Braginsky, 1964), topographically as flow is forced over bumps at the core-mantle boundary (Hide, 1966), by instabilities of the background magnetic field (Acheson, 1972), or even tidally due to deviations of rotating core geometry from exact sphericity (Kerswell, 1994).

This article focuses on the likely properties of magnetohydrodynamic waves in the Earth's outer core and provides a review of attempts to observe them. After a brief account of the history of investigations into magnetohydrodynamic waves in the section "Historical Review," the physics underpinning their existence will be described in the section "Force Balance and Waves in Rapidly Rotating Hydromagnetic Fluids." In particular, attention will focus on the emergence of a new characteristic timescale associated with such waves in rotating magnetohydrodynamic systems. Dispersion relations for magnetohydrodynamic waves when magnetic, buoyancy (Archimedes), and Coriolis forces are of equal importance (MAC waves) will be derived and interesting properties are noted in the section "Dispersion Relations for MC/MAC Waves in the Absence of Diffusion." The influence of diffusion, spherical geometry, and nonlinear effects on the waves will be discussed in the sections "Effects of Diffusion on MC/MAC Waves," "Influence of Spherical Geometry on MC/MAC Waves," and "Nonlinear Magnetohydrodynamic Waves," respectively. In the section "Magnetohydrodynamic Waves in a Stratified Ocean at the Core Surface," the suggestion that a stratified layer may exist at the top of the Earth's outer core is described and the type of waves that could be present there will be discussed. Finally, in the section "Magnetohydrodynamic Waves as a Mechanism for Geomagnetic Secular Variation," attempts to identify the presence of magnetohydrodynamic waves in the Earth's outer core through observations of the Earth's magnetic field will be reviewed and suggestions made as to how the wave hypothesis of geomagnetic secular variation could be tested using a combination of dedicated modeling and rapidly improving high-resolution observations.

For further details, the interested reader should consult the overviews by Hide and Stewartson (1972) and Braginsky (1989) or look in the textbooks by Moffatt (1978) or Davidson (2001). More technical reviews of the subject include Roberts and Soward (1972), Acheson and Hide (1973), Eltayeb (1981), Proctor (1994), and Zhang and Schubert (2000).

## **Historical review**

Study of magnetohydrodynamic waves, especially with a focus on geophysical applications has a rich history and has captured the attention of some of the finest applied mathematicians and theoretical geophysicists over the past 50 years. Alfvén (1942) initiated the study of magnetohydrodynamic waves, investigating the simplest possible scenario where a balance of magnetic tension and inertia gives rise to waves, which became known as Alfvén waves in his honor (see Alfvén Hannes and Alfvén waves). Lehnert (1954) deduced that rapid rotation of the fluid system would lead to the splitting of plane Alfvén waves into two circularly polarized, transverse waves, one with period similar to inertial waves (a consequence of the intrinsic stability endowed to fluids by rotation) and a second with a much longer period. The latter represents a new, fundamental, timescale for rotating hydromagnetic systems which we shall refer to as the magnetic-Coriolis (MC) timescale. Chandrasekhar (1961) studied the effects of buoyancy on rotating magnetic systems, focusing primarily on axisymmetric motions invariant about the rotation axis. Braginsky (1964, 1967) realized the importance of nonaxisymmetric disturbances and showed that if magnetic, buoyancy, and Coriolis forces were equally important, fast inertial modes and slower magnetic modes would again result, but with periods also dependent on the strength of stratification. He christened these waves dependent on magnetic, buoyancy (Archimedes), and Coriolis forces as "MAC waves."

Hide (1966) was the first to consider the influence of spherical geometry on magnetohydromagnetic waves in a rotating fluid, studying the effects of the variation of Coriolis force with latitude. He showed that the resulting MC waves (commonly called MC Rossby waves) had the correct timescale to account for some parts of the geomagnetic secular variation, particularly its westward drift (see *Westward drift*). Malkus (1967) studied MC waves in a full sphere considering the special case when the background field increased in strength with distance from the rotation axis.

Elteyab (1972), Roberts and Stewartson (1974), Busse (1976), Roberts and Loper (1979), and Soward (1979) have demonstrated the importance of including magnetic and thermal diffusion in models of MAC waves, showing that the most unstable MAC waves in plane layer and annulus systems often occur on diffusive timescales. Elteyab and Kumar (1977) and Fearn (1979) carried out the first numerical studies of magnetohydrodynamic waves to include the effects of both buoyancy and diffusion in a rotating, spherical geometry. Fearn and Proctor (1983) went on to consider the effect of more geophysical physically plausible background magnetic fields and nonzero mean azimuthal flows. Most recently, Zhang and Gubbins (2002) have discussed the properties of convection-driven MAC and MC waves in a spherical shell geometry, studying a variety of background field configurations.

# Force balance and waves in rapidly rotating hydromagnetic fluids

A physical understanding of MC waves can be achieved through consideration of the force balance in a rotating, electrically conducting, inviscid fluid that involves inertia, magnetic tension resisting flow across field lines (see *Alfvén waves* and *Magnetohydrodynamics*), and Coriolis forces acting normal to flows and to the axis of rotation. Coriolis forces are well known for causing circulating eddies in the atmosphere (e.g., hurricanes) and arise because, in a rotating reference frame, inertial motions follow curved trajectories rather than straight lines. It is useful to think about rotation imparting vorticity to a fluid, in the same way that magnetic fields impart tension perpendicular to magnetic field lines; vorticity imparts tension perpendicular to vortex lines (which lie parallel to the rotation axis) leading to a restoring force when fluid flows across them. In this system, four possible force balances are conceivable. The first three require rapid fluid motions while the final is only possible for slow fluid motions. They are as follows:

- When magnetic forces are much stronger than Coriolis forces; magnetic tension alone balances inertia and disturbances are communicated by Alfvén waves (see *Alfvén waves*).
- When Coriolis forces are much stronger than magnetic forces; vortex tension balances inertia and disturbances are communicated by inertial waves.
- When magnetic and Coriolis forces are of similar strength; a combination of magnetic field tension and vortex tension balances inertia and disturbances are communicated by inertial magnetic Coriolis (inertial-MC) waves.
- 4. When fluid motions are slow so that inertia is unimportant in the leading order force balance but magnetic and Coriolis forces are of similar strength; in this scenario, magnetic and vortex tension are in balance and disturbances are communicated by MC waves.

Balance (4) thus permits the existence of a new class of slow wave in rotating hydromagnetic systems, which is absent in nonmagnetic and nonrotating systems. Time dependence in this case arises only through changes in the magnetic field that, via the Lorentz force, produces changes in the fluid flow.

An estimate of the MC timescale can be obtained by performing a scale analysis of the important terms in the equations for conservation of momentum and magnetic induction. In the momentum equation, Coriolis and magnetic (Lorentz) forces are in balance, so  $2\Omega U = B^2/\rho L_{\rm MC}$ , where  $\Omega$  is the angular rotation rate, U is a typical velocity scale, B is a typical magnetic field strength,  $L_{\rm MC}$  is a typical length scale over which changes associated with MC waves occur,  $\rho$  is the density of the fluid, and is the fluid's magnetic permeability. We also know that for a highly conducting fluid, changes in the magnetic field come primarily from advection, so scale analysis of the induction equation ignoring diffusion yields  $B/T_{MC} = UB/L_{MC}$ , where  $T_{\rm MC}$  is a typical timescale over which changes associated with MC waves occur. Substituting this expression for U into the force balance leads to the relation  $T_{\rm MC}=2\Omega L^2_{\rm MC} 
ho/B^2$ . The quantity  $v_{\rm A} = B/(\rho)^{1/2}$  has units of velocity and is the phase speed of Alfvén waves (see Alfvén waves). Estimates for these quantities in the Earth's core are  $\Omega = 7.3 \times 10^{-5} \text{ s}^{-1}$ ,  $\rho = 1 \times 10^4 \text{ kg}$ ,  $= 4\pi \times 10^{-7} T^2 \text{ m kg}^{-1} \text{ s}^2$ , so that  $T_{\text{MC}} = 10^{-6} L_{\text{MC}}^2 / B^2$ . Neither the magnetic field strength nor the length scale associated with its variation in the Earth's core is well known. Taking  $B = 5 \times 10^{-4}$ T as suggested by observations at the core surface and  $L_{\rm MC} = 3.5 \times 10^6$  m, the core radius, yields  $T_{\rm MC} \approx 1.5 \times 10^6$  y. Equally plausibly, if we are consider a wave with azimuthal wave number 8, and assume that the field inside the outer core is 10 times the observed core surface field strength we find  $T_{\rm MC} \approx 235$  years. The coincidence between the latter MC wave timescale and that of geomagnetic secular variation motivates attempts to link the two phenomena.

In the Earth's core, it is likely that buoyancy forces (either thermal or compositional) could also be important in the primary force balance (see *Core convection*). In the remainder of this article we shall therefore generalize our discussion to include buoyancy, which modifies the MC timescale to a MAC timescale because Archimedes forces are now present. In the next section we present an outline of the derivation of the dispersion relation for MAC waves.

## Dispersion relations for MC/MAC waves in the absence of diffusion

To focus the discussion, while keeping mathematics to a minimum, we shall consider a rather basic model of a rapidly rotating, electrically conducting, incompressible fluid in an infinite three-dimensional domain, where there are no dissipative processes (viscous, magnetic, or thermal diffusion) operating. Buoyancy forces are included via the Boussinesq model, with the degree of stratification depending on the magnitude of the background temperature gradient.

We shall work in Cartesian coordinates  $(\hat{x}, \hat{y}, \hat{z})$  with the axis of rotation along  $\hat{z}$ , a uniform background field  $B_0 = (B_{0x}\hat{x} + B_{0y}\hat{y} + B_{0z}\hat{z})$ and a uniform background temperature gradient of  $-\beta \hat{z}$ . If  $\alpha$  is the thermal expansivity of the fluid, then density is determined by the relation  $\rho = \rho_0(1 + \alpha\Theta)$  where  $\Theta$  is the perturbation from the background temperature field, so that in a gravity field of  $-g\hat{z}$  there will be a buoyancy force of magnitude  $g\alpha\Theta$  in the  $\hat{z}$  direction.

We shall consider small perturbations  $(\boldsymbol{u}, \boldsymbol{b}, \Theta)$  about a state of no motion (so the background velocity field is zero) and consider only slow motions so that inertial terms can be neglected and attention can focus on the MC force balance. The linearized equations governing the evolution of small perturbations are then the momentum equation

$$\underbrace{\underbrace{2\boldsymbol{\Omega}\times\boldsymbol{u}}_{\text{Coriolis}}}_{\text{acceleration}} = \underbrace{-\frac{1}{\rho}\nabla p}_{\text{acceleration}} + \underbrace{\frac{1}{\mu\rho}(\boldsymbol{B}_{0}\cdot\nabla)\boldsymbol{b}}_{\text{acceleration}} + \underbrace{\underline{g}\boldsymbol{\alpha}\Theta\hat{\boldsymbol{z}}}_{\text{buoyant}},$$

$$\underbrace{\text{due to pressure}}_{\text{gradient}} \operatorname{field tension}$$

(Eq. 1)

the induction equation

$$\frac{\partial \boldsymbol{b}}{\partial t} = (\boldsymbol{B}_0 \cdot \nabla)\boldsymbol{u}, \quad (\text{Eq. 2})$$
Change in the magnetic field Stretching of magnetic field by fluid motion

and temperature equation

$$\frac{\partial \Theta}{\partial t} = \underbrace{\beta(\hat{z} \cdot \boldsymbol{u})}_{\text{Change in the temperature field}} = \underbrace{\beta(\hat{z} \cdot \boldsymbol{u})}_{\text{advection of temperature field by fluid motion}}.$$
 (Eq. 3)

Taking  $\partial/\partial t(\nabla \times)$  the momentum equation (1) to eliminate pressure gives

$$2(\boldsymbol{\Omega}\cdot\nabla)\frac{\partial \boldsymbol{u}}{\partial t} = \frac{(\boldsymbol{B}_0\cdot\nabla)}{\rho}\frac{\partial}{\partial t}(\nabla\times\boldsymbol{b}) + g\alpha\frac{\partial}{\partial t}(\nabla\times\Theta\hat{\boldsymbol{z}}), \quad \text{(Eq. 4)}$$

while taking the curl  $(\nabla \times)$  of the induction equation (2) we find,

$$\frac{\partial}{\partial t} (\nabla \times \boldsymbol{b}) = (\boldsymbol{B}_0 \cdot \nabla) (\nabla \times \boldsymbol{u}).$$
 (Eq. 5)

Substituting from Eq. (5) into Eq. (4) for  $\partial/\partial t(\nabla \times \mathbf{b})$  gives a vorticity equation quantifying the MAC balance with terms arising from Coriolis forces on the left-hand side and terms arising from the magnetic and buoyancy forces on the right-hand side

$$2(\mathbf{\Omega}\cdot\nabla)\frac{\partial \boldsymbol{u}}{\partial t} = \frac{(\boldsymbol{B}_0\cdot\nabla)^2}{\rho}(\nabla\times\boldsymbol{u}) + g\alpha\frac{\partial}{\partial t}(\nabla\times\Theta\widehat{\boldsymbol{z}}). \quad (\text{Eq. 6})$$

Operating on Eq. (6) with  $((B_0 \cdot \nabla)^2 \nabla \times)/\rho$ , we can then eliminate  $((B_0 \cdot \nabla)^2 \nabla \times \boldsymbol{u})/\rho$  from the term on the left-hand side by using Eq. (6) once again. By utilizing the well-known relation for incompressible fluids that  $\nabla \times \nabla \times \boldsymbol{u} = -\nabla^2 \boldsymbol{u}$ , and then taking the dot product with  $\hat{\boldsymbol{z}}$  while noting that  $\hat{\boldsymbol{z}} \cdot (\nabla \times \Theta \hat{\boldsymbol{z}}) = 0$  and  $\hat{\boldsymbol{z}} \cdot (\nabla \times \nabla \times \Theta \hat{\boldsymbol{z}}) = -(\partial^2/\partial x^2 + \partial^2/\partial y^2)\Theta = -\nabla_H^2\Theta$  leaves

$$4(\mathbf{\Omega}\cdot\nabla)^2\frac{\partial^2}{\partial t^2}u_z = -\left[\frac{(\mathbf{B}_0\cdot\nabla)^2}{\rho}\right]^2\nabla^2 u_z - g\alpha\frac{(\mathbf{B}_0\cdot\nabla)^2}{\rho}\nabla_{\mathrm{H}}^2\frac{\partial\Theta}{\partial t}.$$

Finally, we make use of the temperature Eq. (3) to eliminate  $\partial \Theta / \partial t$ and obtain a sixth-order equation in  $u_z$ , which we shall refer to as the diffusionless MAC wave equation

$$\left(4(\mathbf{\Omega}\cdot\nabla)^2\frac{\partial^2}{\partial t^2} + \left[\frac{(\mathbf{B}_0\cdot\nabla)^2}{\rho}\right]^2\nabla^2 - g\alpha\beta\frac{(\mathbf{B}_0\cdot\nabla)^2}{\rho}\nabla_{\mathrm{H}}^2\right)u_z = 0.$$

Properties of diffusionless MAC waves can now be deduced by substitution of plane traveling wave solutions of the form  $u_z = \mathbf{Re}\{\hat{u_z}\mathbf{e}^{\mathbf{i}(k\cdot \mathbf{r}-\omega t)}\}$ , where  $\mathbf{k}$  is the wavevector and  $\omega$  is the angular frequency

$$4(\mathbf{\Omega}\cdot\mathbf{k})^{2}\omega^{2} - \left[\frac{(\mathbf{B}_{0}\cdot\mathbf{k})^{2}}{\rho}\right]^{2}k^{2} - \frac{(\mathbf{B}_{0}\cdot\mathbf{k})^{2}}{\rho}g\alpha\beta(k_{x}^{2}+k_{y}^{2}) = 0.$$
(Eq. 7)

This expression can be written more concisely by observing that terms in it correspond to characteristic natural frequencies for magnetic-inertial (Alfvén) waves, gravity waves, and inertial waves in rotating fluids, respectively

$$\omega_{\rm M}^2 = \frac{(B_0 \cdot k)^2}{\rho}, \quad \omega_{\rm A}^2 = \frac{g\alpha\beta(k_x^2 + k_y^2)}{k^2}, \quad \omega_{\rm C}^2 = \frac{4(\mathbf{\Omega} \cdot k)^2}{k^2},$$
(Eq. 8)

so Eq. (7) simplifies to

$$\omega_{\rm C}^2 \omega^2 - \omega_{\rm M}^4 - \omega_{\rm M}^2 \omega_{\rm A}^2 = 0. \tag{Eq. 9}$$

Solving for  $\omega$  gives the necessary condition (or dispersion relation) that must be satisfied by the angular frequency and wavevectors of plane MAC waves,

$$\omega = \pm \frac{\omega_{\rm M}^2}{\omega_{\rm C}} \left( 1 + \frac{\omega_{\rm A}^2}{\omega_{\rm M}^2} \right)^{1/2} = \pm \frac{k(\boldsymbol{B}_0 \cdot \boldsymbol{k})^2}{2\rho(\boldsymbol{\Omega} \cdot \boldsymbol{k})} \left( 1 + \frac{g\alpha\beta\rho(k_x^2 + k_y^2)}{k^2(\boldsymbol{B}_0 \cdot \boldsymbol{k})^2} \right)^{1/2}.$$
(Eq. 10)

Note that this is singular if  $B_0 \cdot k = 0$  or if  $\Omega \cdot k = 0$ , so diffusionless MAC waves cannot propagate normal to magnetic field lines or the rotation axis. Their frequency depends strongly on their wavelength (i.e., they are highly dispersive) and on their direction (i.e., they are anisotropic). In the special case when the background magnetic field and the direction of the rotation axis are parallel to the direction of wave propagation, and when buoyancy forces are absent ( $\alpha = 0$ ), the dispersion relation simplifies to  $\omega = B_0^2 k^2 / 2\Omega\rho$  or  $T_{\rm MC} = 2\Omega\rho L_{\rm MC}/B_0^2$  as was deduced from scaling arguments in the previous section. The phase speed of the waves is then  $c = \omega/k = B_0^2 k / 2\Omega\rho$  and it is seen that waves with shorter wavelengths travel faster.

## Effects of diffusion on MC/MAC waves

So far we have neglected the influence of any source of dissipation (viscous, magnetic, or thermal diffusion) on the system in order to simplify both the mathematical analysis and the physical picture. It is now necessary to consider their effects. Naively, we might expect the presence of dissipation should merely damp disturbances and irreversibly transform energy to an unusable form. Although such processes undoubtedly occur, they are not the only effects of the presence of diffusion. Perhaps more importantly, diffusion adds extra degrees of freedom to the system and facilitates the destabilization of waves that are stable in the absence of diffusion (see Roberts and Loper, 1979). This rather counterintuitive effect means that instability of MAC/MC waves can occur for smaller unstable density or magnetic field gradients than if no diffusion were present. In fact, such diffusive instability turns out to be possible, even in the presence of a stable density gradient.

The diffusive instability mechanism works most effectively when the oscillation frequency matches the rate of diffusion, so the timescale of the most unstable MC/MAC waves will be that of the diffusion process that is facilitating the instability. Diffusion thus introduces new preferred timescales into the MC/MAC wave problem.

To include diffusion in the mathematical description of MAC waves, we must replace the operator  $\partial/\partial t$  by  $(\partial/\partial t - v\nabla^2)$  in the momentum equation, by  $(\partial/\partial t - \eta\nabla^2)$  in the induction equation and by  $(\partial/\partial t - \kappa\nabla^2)$  in the heat equation. Retaining the acceleration term from the momentum equation and including the Laplacian (diffusion) terms before the substitution of plane wave solutions results in a more complicated dispersion relation for diffusive MAC waves

$$\begin{split} & \left(\omega_{\rm C}^2(\omega+i\eta k^2)^2 - \left[(\omega+i\nu k^2)(\omega+i\eta k^2) - \omega_{\rm M}^2\right]^2\right)(\omega+i\kappa k^2) \\ & + \omega_{\rm A}^2(\omega+i\eta k^2)\left[(\omega+i\nu k^2)(\omega+i\eta k^2) - \omega_{\rm M}^2\right] = 0. \end{split} \tag{Eq. 11}$$

Restricting ourselves to the conditions present in the Earth's outer core, where we expect ohmic diffusion to dominate viscous and thermal diffusion ( $\eta \gg v, \kappa$ ) and where we can again neglect inertial accelerations when considering slow oscillations, this expression simplifies to

$$\left(\omega_{\rm C}^2(\omega+i\eta k^2)^2-\omega_{\rm M}^4\right)\omega-\omega_{\rm M}^2\omega_{\rm A}^2(\omega+i\eta k^2)=0. \tag{Eq. 12}$$

The link to diffusionless MC waves becomes apparent if buoyancy forces are negligible ( $\omega_A = 0$ ) when Eq. (12) reduces to,

$$\omega = \frac{\omega_{\rm M}^2}{\omega_{\rm C}} - i\eta k^2. \tag{Eq. 13}$$

Here the classical damping role of magnetic diffusion is obvious, causing MC waves with shorter wavelengths to decay in amplitude more quickly than MC waves with longer wavelengths. More detail on diffusive MC waves and their consequences for on geodynamo simulations can be found in Walker *et al.* (1998).

## Influence of spherical geometry on MC/MAC waves

The Earth's outer core is not an infinite plane layer, but a thick spherical shell with an inner radius approximately one-third of its outer radius. How does spherical shell geometry influence propagation properties, stability, and the planform of magnetohydrodynamic waves? It appears that when the magnetic field is strong enough, and the Lorentz force dominates the force balance in the momentum equation, then the spherical boundaries play a secondary role. On the other hand, when the magnetic field is weak, the influence of the Coriolis force and its latitudinal variations caused by the spherical geometry are crucial. In the absence of any certain knowledge of the strength of the magnetic field in the Earth's core it is unclear if spherical shell geometry has a controlling influence on magnetohydrodynamic waves there, so the safest course is to use spherical geometry and study a variety of magnetic field strengths.

Hide (1966) was the first to appreciate the importance of the latitudinal dependence of the Coriolis force for waves in the Earth's core. He developed a simple analytical model of MC waves retaining only the linear variation of Coriolis force with latitude (this is known to meteorologists and oceanographers as a  $\beta$  plane model and is the necessary ingredient for the restoring force responsible for Rossby waves). We shall refer to Hide's waves as magnetic-Coriolis (MC) Rossby waves. He showed they would propagate westward in a thick spherical shell and could have a timescale similar to that of geomagnetic secular variation.

Eltayeb and Kumar (1977) and Fearn (1979) included both thermal buoyancy and diffusion and worked in spherical geometry. They were confronted by a rather complex scene, with several different mechanisms giving rise to different types of magnetohydrodynamic waves, any of which could potentially be important in the Earth's core. They identified four distinct regimes where different waves were favored. Only a brief overview of the four possible regimes is presented here.

## Type I: Magnetically modified, buoyancy-driven Rossby waves

When the magnetic field is very weak, wave motion is essentially that produced by convection in a rapidly rotating sphere (i.e., thermal Rossby waves or Busse rolls—see *Core convection*). The flow consists of columnar rolls parallel to the rotation axis, arranged on a cylindrical shell that intersects the outer boundary at midlatitudes. At the onset of convection and in the absence of any mean azimuthal flow these waves drift eastward on a thermal diffusion timescale. The planform of the waves is columnar because the Coriolis force promotes invariance along the rotation axis (see *Proudmann-Taylor theorem*). The magnetic field acts only as a small perturbation and actually stabilizes the system, increasing the critical Rayleigh number compared to the nonmagnetic systems. Instability is driven by the component of buoyancy perpendicular to the rotation axis and is balanced primarily by the Coriolis force (varying with latitude due to the spherical geometry) and viscous diffusion.

#### Type II: Buoyancy-driven magneto-Rossby waves

With stronger magnetic fields, buoyancy is balanced by the magnetic (Lorentz) force as well as the Coriolis force. The planform of Type II waves is similar to those of Type I waves and they too propagate on the thermal diffusion timescale. Both westward and eastward propagation of these waves is possible, depending on the relative magnitudes of magnetic and thermal diffusion. It should be noted that the magnetic field now plays a destabilizing roll, catalyzing the onset of convection. The dominant role of the uniform imposed magnetic field causes an increase in the length scale so that the number of waves fitting around a cylindrical shell decreases, while the latitude of the rolls moves toward where the magnetic field is strongest. Figure M148 shows the form of the radial magnetic field disturbance produced by a magneto-Rossby wave in spherical geometry when the imposed magnetic field increases linearly with distance from the rotation axis (the force-free field of Malkus, 1967). This figure is the result of an eigenvalue calculation (using the code of Jones et al., 2003) used to determine the most unstable wave in a regime when magnetic and Coriolis forces are approximately of equal magnitude.

## Type III: Buoyancy-driven MAC waves

When magnetic forces are much stronger than the Coriolis forces, boundary curvature associated with spherical geometry plays a less important role and the most unstable wave is of diffusive MAC-type, again propagating on the thermal diffusion timescale. The planform of the waves is no longer that of columnar rolls because the strong magnetic fields permit departures from z independence. Both westwardand eastward-propagating waves are possible in this regime.

**Figure M148** Anomalies in the radial magnetic field ( $B_r$ ) at  $r = 0.95r_0$  produced by a marginally critical, m = 5, buoyancy-driven magneto-Rossby wave. The imposed magnetic field is purely toroidal and increases linearly in magnitude with distance from the rotation axis. Units are arbitrary because no nonlinear saturation mechanisms are included in this model. Gray regions with solid contours indicate negative field anomalies, and white regions with dotted contours indicate positive field anomalies.

#### Type IV: Magnetically driven MAC waves

When the magnetic field becomes sufficiently strong or complex, then MC/MAC waves can be produced by either diffusive (resistive) or ideal instability of the background magnetic field. The resulting waves are of diffusive MC/MAC or diffusionless MC/MAC type and propagate on either the magnetic diffusion or on the MC/MAC timescale. They do not require the presence of buoyancy for their existence, and can even occur when the background density field is stable.

Fearn and Proctor (1983) have considered the additional effect of the presence of a background azimuthal flow (including shear) and found that this tends to stabilize diffusive MAC waves. They observed that such waves are localised at the extrema of the shear, moving with an azimuthal speed equal to the fluid velocity at that point. This indicates MC/MAC waves could perhaps be preferentially excited in zonal jets and would drift by advection rather than propagation, which could perhaps be of relevance at low latitudes in the Earth's outer core (see the section "Magnetohydrodynamic Waves as a Mechanism for Geomagnetic Secular Variation").

#### Nonlinear magnetohydrodynamic waves

All the magnetohydrodynamic waves discussed up to now have been linear in nature. This implies that (i) waves can simply be superposed without considering any mutual interaction and (ii) there is no feedback between the waves and the rest of the system. This scenario is unphysical because unstable waves can grow without limit, but is nonetheless useful for determining the types of waves most easily excited in a particular regime of interest. Early studies by Braginsky (1967) and Roberts and Soward (1972), though deriving linear equations for MAC waves riding on general background states, emphasized the importance of understanding nonlinear feedback processes. They noted that waves are determined by the background state, but the background state is itself altered by the waves. In seeking to interpret geophysical observations indicative of hydromagnetic waves in the Earth's core, we should remember that linear analysis is only formally valid for small perturbations to an artificial, steady background state and cannot tell us how waves will evolve, saturate, interact with each other, or what flow structures might result from nonlinear bifurcations of the waves. Attempts to understand such processes deserve a concerted theoretical and numerical modeling effort in the future.

Some progress in understanding nonlinear MAC waves has already been made. El Sawi and Eltayeb (1981) have derived higher order equations for MAC waves in a plane layer in the presence of a slowly varying background mean flow. Their equations describe the evolution of diffusionless MAC wave amplitude via the conservation of wave action (wave energy divided by wave frequency per unit volume). This conservation law tells us that wave energy increases, at the expense of the energy of the background state, whenever a wave moves into a region where its frequency is higher. More recently Ewen and Soward (1994) have derived equations describing the evolution of the amplitude of diffusive MAC waves in the limit of a weak magnetic field. They find that an azimuthal (geostrophic) mean flow is driven by magnetic forces resulting from the MAC waves and is linearly damped by viscous diffusion at the boundary.

A start has also been made at numerically investigating the nonlinear evolution of magnetohydrodynamic waves in rapidly rotating, convecting spherical shells. As the unstable density gradient is increased, it is observed that the system undergoes bifurcations from steadily traveling magnetohydrodynamic waves to vacillating wave motions for which both temporal and spatially symmetries have been broken (see *Magnetoconvection*).

Study of nonlinear MC and MAC waves is still in its infancy and may yet yield important and exciting insights that will help us to better understand how magnetohydrodynamic waves might manifest themselves in the Earth's core.

# Magnetohydrodynamic waves in a stratified ocean at the core surface?

There has been some debate over the possibility of a stratified layer or "inner ocean" at the top of the Earth's outer core and the MAC waves that would be supported there (Braginsky, 1999). This stratified layer has yet to be observed seismically, though its existence seems plausible on thermodynamic grounds with light fluid released during the solidification of the inner core expected to pond below the coremantle boundary. Oscillations of such a layer would be of shorter period than the MC/MAC waves expected in the body of the outer core due to the presence of an additional restoring force due to density stradification.

The dynamics of a stably stratified layer would be dominated by its thin spherical shell geometry. There would undoubtedly be many similarities with the water ocean on the Earth's surface, but with the additional complications caused by the presence of magnetic forces. In particular, MC Rossby waves, which rely on the change in the Coriolis force with latitude for their existence, are likely to be present within such an ocean. Braginsky has developed models of both axisymmetric and nonaxisymmetric disturbances of such a stably stratified layer and has suggested they could be responsible for short period geomagnetic secular variation.

Unfortunately, MAC waves and MC Rossby waves in a hidden ocean at the top of the outer core are not the only possible source of short period geomagnetic secular variation-torsional oscillations within the body of the core (see *Oscillations, torsional*) are an equally plausible explanation. Until the existence of the hidden ocean of the core can be confirmed, study of magnetohydrodynamic waves that may exist there will remain of primarily theoretical interest.

# Magnetohydrodynamic waves as a mechanism for geomagnetic secular variation

It has been common knowledge since the time of Halley that the Earth's magnetic field changes significantly over decades to centuries. Perhaps the most striking aspect of this geomagnetic secular variation is the westward motion of field features (see Westward drift). Several explanations have been proposed for this Westward drift, but today there are two widely accepted candidate mechanisms. The first involves bulk fluid motion at the surface of the outer core that advects magnetic field features. Bullard et al. (1950) originally envisaged this involving westward flow of all the fluid close to the core surface, but modern core flow inversions (see Core motions) have refined this suggestion-it now appears that a westward equatorial jet under the Atlantic hemisphere is sufficient to explain much of the westward drift of the geomagnetic field observed at the surface. The source of this proposed equatorial jet is still debated, but geodynamo models indicate that it could be produced by nonlinear inertial forces that are a by-product of columnar convection in a sphere, or by thermal winds due to an inhomogeneous heat flux into

the mantle (see *Inhomogeneous boundary conditions and the dynamo*). The second possible mechanism is that motivating the inclusion of this article in an *Encyclopedia of Geomagnetism and Paleomagnetism*— propagation of magnetohydrodynamic waves in the Earth's outer core. We shall henceforth refer to this mechanism as the wave hypothesis.

Hide (1966) and Braginsky (1967) proposed the wave hypothesis on theoretical grounds and each attempted to test it through the consideration of available records of the geomagnetic secular variation. It is informative to review these pioneering attempts before considering other possible ways to search for the presence of magnetohydrodynamic waves in the Earth's outer core.

Hide (1966) identified three major factors in favor of the wave hypothesis: (i) MC waves had periods comparable with the timescale of geomagnetic secular variation; (ii) MC waves had dispersion times comparable with the timescale of geomagnetic secular variation; and (iii) shorter wavelength MC waves had larger phase velocities and similarly higher order spherical harmonic components of the geomagnetic field drifted faster. His observational analysis was based on the mean westward drift rates of spherical harmonics up to degree 4, from seven previous publications, spanning 135 years from 1830 to 1965. Despite the failure of detailed comparisons between the predicted and observed drift rates for individual spherical harmonics, this study was instrumental in persuading many geophysicists that a wave origin for geomagnetic secular variation was worth serious consideration.

Braginsky (1967, 1972, 1974) sought to confirm the wave hypothesis by comparing his own theoretical predictions of the spectrum of diffusionless MAC waves to an observationally inferred spectrum of geomagnetic secular variation. Despite the poor quality of data available in the early

**Figure M149** Equatorial time-longitude plot of processed radial magnetic field  $B_r$  (with time-averaged axisymmetric field and field variations with timescales longer than 400 years removed) from the historical field model *gufm1*, (Jackson *et al.*, 2000). Field evolution in the azimuthal direction at the equator is shown and consists of spatially and temporally coherent wavelike anomalies, with dominant azimuthal wave number m = 5 and moving consistently westward. The contour lines are at intervals of  $5 \times 10^4$  nT. Gray regions with solid contours indicate negative field anomalies, and white regions with dotted contours indicate positive field anomalies.

**Figure M150** Snapshot from 1830 of the m = 5 radial magnetic field, core surface signal responsible for the wavelike pattern of field evolution observed at low latitudes in the historical geomagnetic field model *gufm1*. This snapshot was obtained by restricting the period of field variations to between 125 and 333 years and the wave number of field variations to m = 5 (i.e., FK filtering). The contour lines are at intervals of  $4 \times 10^3$  nT. Gray regions with solid contours indicate negative field anomalies, and white regions with dotted contours indicate positive field anomalies.

1970s, Braginsky's efforts were important in demonstrating that the wave hypothesis was at least compatible with observations.

In the last 20 years there have been significant advances in our observational knowledge of the Earth's magnetic field and its evolution. Using over 365000 historical observations from maritime records, observatories, surveys, and satellites, time-dependent models of the global magnetic field have now been constructed covering the past 400 years (see Time-dependent models of the geomagnetic field). Use of regularised inversion methods has enabled the construction of images of the magnetic field at the core surface allowing us to map its evolution at the edge of the source region. This technique has shown that the origin of the westward drift of magnetic field is not due to the whole field drifting westward but rather is due to the drift of small patches of intense magnetic field (see Westward drift), particularly at low latitudes in the Atlantic hemisphere. Advances have also been made in our understanding of field evolution over longer time intervals, notably through the use of archeomagnetic and lake sediment records to construct global field models for the past 3 ka (Korte and Constable, 2005). Although lacking the resolution of the historical models, these models offer the first glimpse of the long-term behavior of flux patches at the core surface and with the inclusion of more data hold great promise for the future.

Can recent observational advances help us in our attempts to evaluate the wave hypothesis by facilitating the identification of previously obscured signatures of magnetohydrodynamic waves? The existence of images of the evolution of the field at the core surface opens up fresh possibilities for comparing not only timescales of predicted wave motions, but also geographical features such as the latitude at which waves occur, their equatorial symmetry and their dispersive properties. Space-time analysis of geomagnetic field evolution, and particularly the use of time-longitude diagrams (as employed by oceanographers to study Rossby waves), can be carried out during the historical epoch (Finlay and Jackson, 2003). As shown in Figure M149, after the removal of the time-averaged axisymmetric field and those components of the field varying on timescales longer than 400 years, spatially and temporally coherent (wavelike) evolution of the radial magnetic field is observed at the equator. The clearest signal in the time-longitude plot has an azimuthal wave number of m = 5, a period of around 250 years and travels at  $\sim 17$  km yr<sup>-1</sup> westwards. Figure M150 shows the result of frequency-wave number filtering to recover the spatial structure of this wave at the core surface. The domination of aspects of geomagnetic secular variation by a single wave number disturbance suggests that a magnetohydrodynamic wave (perhaps

driven by an instability) might currently be present at low latitudes in Earth's outer core.

The major challenge for theoreticians is to keep pace with improving observations and construct models accurate enough to predict the structure of observable space-time features caused by magnetohydrodynamic waves in the core. Modeling of convection-driven magnetohydrodynamic waves (see *Magnetoconvection*) suggests these might propagate too slowly to account for observed azimuthal field motions. However, thermal and magnetic winds in the core (see *Thermal wind*) could advect wave patterns at the required speeds and produce spatially and temporally coherent patterns of field evolution consistent with observations.

The hypothesis that magnetohydrodynamic waves produce directly observable changes in the geomagnetic field cannot yet be conclusively confirmed or rejected. The difficulty in rigorously testing the hypothesis is twofold. Firstly, one requires robust predictions of observable signatures from theoretical wave models that take account of realistic background fields, diffusion, spherical geometry, and nonlinearity. Secondly, one requires self-consistent, high-fidelity observations over a long period of time to assess model predictions in a statistically significant way. Almost 40 years after the wave hypothesis was proposed this remains a tall order, but we are approaching the stage where such tests will be feasible.

## MAGNETOHYDRODYNAMICS

#### Introduction

Magnetohydrodynamics (MHD) is the study of the flow of electrically conducting fluids in the presence of magnetic fields. It has significant applications in technology and in the study of planets, stars, and galaxies. Here the main focus will be on its role in explaining the origin and properties of the geomagnetic field.

The interaction between fluid flow and magnetic field defines the subject of MHD and explains much of its fascination (and complexity). The magnetic field B influences the fluid motion V through the Lorentz force,  $\mathbf{J} \times \mathbf{B}$ . The electric current density  $\mathbf{J}$  is affected by the fluid motion through the electromotive force (emf),  $\mathbf{V} \times \mathbf{B}$ . The most famous offspring of this marriage of hydrodynamics to electromagnetism are the Alfvén waves, a phenomenon absent from the two subjects separately (see Alfvén waves). In fact, many consider the discovery of this wave by Hannes Alfvén in 1942 to mark the birth of MHD (see Alfvén, Hannes). Initially MHD was often known as hydromagnetics, but this term has largely fallen into disuse. Like MHD, it conveys the unfortunate impression that the working fluid is water. In reality, the electrical conductivity of water is so small that MHD effects are essentially absent. Moreover, many fluids used in MHD experiments are antipathetical to water. Even as fluid mechanics is now more widely employed than hydrodynamics, the terms magnetofluid mechanics or magnetofluid dynamics, which are already sometimes employed, may ultimately displace MHD.

Since electric and magnetic fields are on an equal footing in electromagnetism (EM), it may seem strange that the acronym EMHD is not preferred over MHD. In many systems, however, including the Earth's core, the application of EM theory in its full, unapproximated form would add complexity without compensating enlightenment. It suffices to apply the nonrelativistic version of EM theory that existed in the 19th century before Maxwell, by introducing displacement currents, cast the theory into its present-day form. In this pre-Maxwell theory, electric and magnetic fields are not on an equal footing; the magnetic field is the master and the electric field the slave. Consequently MHD is an appropriate acronym whereas EMHD is not. We exclude situations, such as those characteristic of electrohydrodynamics (EHD), in which an electric fields in MHD, which are created entirely by the emf  $\mathbf{V} \times \mathbf{B}$ .

The pre-Maxwell theory is described in the Section on Electrodynamics. It requires that the characteristic flow speed  $\mathcal{V}$  is small compared with the speed of light c, and that the characteristic timescale  $\mathcal{T}$ is large compared with  $\mathcal{L}/c$ , where  $\mathcal{L}$  is the characteristic length scale. The theory to be described also demands that  $\mathcal{L}$  is large compared with the Debye length, which is the distance over which the number densities of electrons and ions can differ substantially from one another.

To simplify the discussion below, some verbal abbreviations will usually be employed. In particular, velocity will mean fluid velocity, density will stand for the mass density, field will mean magnetic field, current will be short for electric current density, conductor will mean conductor of electricity, potential will signify electric potential, and core will refer to the Earth's core. Script letters  $\mathcal{L}$ ,  $\mathcal{T}$ ,  $\mathcal{V}$ ,  $\mathcal{B}$ ,  $\mathcal{J}$ ,  $\mathcal{E}$ , etc., will indicate typical magnitudes of length, time, velocity, field, current, electric field, etc. In the geophysical application, FOC means fluid outer core; SIC, solid inner core; CMB, core-mantle boundary; and ICB, inner core boundary.

#### Electrodynamics

Nonrelativistic electromagnetism

The pointwise form of the pre-Maxwell EM equations are, in SI units,

$$\nabla \times \mathbf{B} = \mathbf{J},\tag{Eq. 1}$$

$$\nabla \times \mathbf{E} = -\partial_t \mathbf{B},\tag{Eq. 2}$$

$$\nabla \cdot \mathbf{B} = 0, \tag{Eq. 3}$$

$$\nabla \cdot \mathbf{D} = \vartheta, \tag{Eq. 4}$$

where **D** is the electric displacement, **H** is the magnetizing force and  $\vartheta$  is the electric charge density; *t* is time and  $\partial_t = \partial/\partial t$ . Equations (1) and (2) are, respectively, Ampère's law and Faraday's law. The sources on the right-hand sides of Eqs. (1) and (4) must satisfy charge conservation and, in pre-Maxwell theory, this requires

$$\nabla \cdot \mathbf{J} = 0, \tag{Eq. 5}$$

which is consistent with Eq. (1). Equation (2) shows that, if Eq. (3) holds for any t, it holds for all t.

Equations (1)–(5) are invariant under the Galilean transformation:

$$\mathbf{x}' = \mathbf{x} - \mathbf{U}t,\tag{Eq. 6}$$

$$t' = t, (Eq. 7)$$

where  $\mathbf{x}$  is the position vector and  $\mathbf{U}$  is constant. The fields and sources transform as

$$\mathbf{B}' = \mathbf{B},\tag{Eq. 8}$$

$$\mathbf{E}' = \mathbf{E} + \mathbf{U} \times \mathbf{B},\tag{Eq. 9}$$

$$\mathbf{H}' = \mathbf{H},\tag{Eq. 10}$$

$$\mathbf{D}' = \mathbf{D} + \mathbf{U} \times \mathbf{H}/c^2, \tag{Eq. 11}$$

$$\mathbf{J}' = \mathbf{J},\tag{Eq. 12}$$

$$\vartheta' = \vartheta + \nabla \cdot (\mathbf{U} \times \mathbf{H})/c^2. \tag{Eq. 13}$$

According to (6) and (7), it follows that  $\partial'_t = \partial_t + \mathbf{U} \cdot \nabla$ , from which it is readily verified that the primed variables also obey Eqs. (1)–(5). The presence of the terms involving  $1/c^2$  in Eqs. (11) and (13) may seem anomalous in a theory based on  $c \gg \mathcal{L}/\mathcal{T}$ . However, since  $\mathbf{H/D} \sim c^2 \mathbf{B/E}$  (see the Section on Constitutive relations), it follows that all terms in Eq. (11) are of the same order, as are those in Eq. (13). Equation (13) has the curious consequence that the free charge density is frame-dependent.

We shall be interested in systems in which, on some surface *S*, the properties of the medium change abruptly. We exclude cases in which *S* separates the same material in different physical states and through which the material passes, changing its state as it does so, as for a shock discontinuity. The same integral laws that led to Eqs. (1)-(5) imply that

$$\llbracket \mathbf{n} \times \mathbf{H} \rrbracket = \mathbf{C}, \quad \text{on } S, \tag{Eq. 14}$$

$$\llbracket \mathbf{n} \times (\mathbf{E} + \mathbf{U} \times \mathbf{B}) \rrbracket = \mathbf{0}, \text{ on } S, \tag{Eq. 15}$$

$$\llbracket \mathbf{n} \cdot \mathbf{B} \rrbracket = 0, \quad \text{on } S, \tag{Eq. 16}$$

$$\llbracket \mathbf{n} \cdot \mathbf{D} \rrbracket = \Sigma, \quad \text{on } S, \tag{Eq. 17}$$

$$\llbracket \mathbf{n} \cdot \mathbf{J} \rrbracket = -\nabla_{\mathbf{S}} \cdot \mathbf{C}, \quad \text{on } S, \tag{Eq. 18}$$

where **C** and  $\Sigma$  are the surface current and the surface charge density on *S*;  $\nabla_S$  is the two-dimensional surface divergence on *S*;  $\llbracket Q \rrbracket = Q_1 - Q_2$  is the difference in the limiting values of any quantity *Q* at a point *P* of *S* from sides 1 and 2; the unit vector **n** to *S* is directed out of side 2 and into side 1; **U** is now the velocity of *P* although only the component of **U** along **n** is actively involved. The Galilean transformation, when supplemented by

$$\Sigma' = \Sigma + \mathbf{n} \cdot [\![\mathbf{U} \times \mathbf{H}]\!]/c^2, \qquad (\text{Eq. 19})$$

preserves Eqs. (14)-(18). Equations (13) and (19) may also be written as

$$\theta' = \vartheta - \mathbf{U} \cdot \mathbf{J}/c^2,$$
 (Eq. 20)

$$\Sigma' = \Sigma - \mathbf{U} \cdot \mathbf{C}/c^2. \tag{Eq. 21}$$

#### Constitutive relations

ΰ

The pre-Maxwell equations must be supplemented by relations that define the physical nature of the medium in which they are applied. We shall suppose that the medium is isotropic and homogeneous so that, at a point *P* within it and in a reference frame moving with the velocity  $\mathbf{U} = \mathbf{V}(\mathbf{x}_P)$  of *P*,

$$\mathbf{H}' = \mathbf{B}'/\mu,\tag{Eq. 22}$$

$$\mathbf{D}' = \epsilon \mathbf{E}',\tag{Eq. 23}$$

$$\mathbf{J}' = \sigma \mathbf{E}',\tag{Eq. 24}$$

where the proportionality variables are the permeability  $\mu$ , the permittivity  $\epsilon$ , and the electrical conductivity  $\sigma$ . Except in the crust, the temperature within the Earth everywhere exceeds the Curie point, at which permanent magnetism ceases to exist. We therefore assume that  $\mu$  is the permeability of free space  $\mu_0$ ; the permittivity of free space is  $\epsilon_0$  and  $c^2 = 1/\mu_0\epsilon_0$ . When translated back to the laboratory frame, (22)–(24) are, according to Eqs. (8), (10), and (12),

$$\mathbf{H} = \mathbf{B}/\mu_0,\tag{Eq. 25}$$

$$\mathbf{D} = \epsilon \mathbf{E} + (\epsilon - \epsilon_0) \mathbf{V} \times \mathbf{B}, \tag{Eq. 26}$$

$$\mathbf{J} = \sigma(\mathbf{E} + \mathbf{V} \times \mathbf{B}). \tag{Eq. 27}$$

Wherever **H** occurs, we shall now use Eq. (25) to remove it, in favor of **B**.

Equation (27) is the generalization of *Ohm's law* to a moving conductor, and is centrally important. It may be written equivalently as

$$\mathbf{E} = -\mathbf{V} \times \mathbf{B} + \eta \nabla \times \mathbf{B}, \tag{Eq. 28}$$

where  $\eta = 1/\sigma\mu_0$  is the *magnetic diffusivity*. This form provides a convenient way of removing **E** in favor of **B**; as mentioned in the Section Introduction, **E** plays a subsidiary role in MHD. Nevertheless, it is worth observing that, by Eqs. (3)–(5), (26), and (28),

$$\vartheta = -\epsilon_0 \nabla \cdot (\mathbf{V} \times \mathbf{B}). \tag{Eq. 29}$$

Unlike the case of a stationary conductor for which an initial  $\vartheta$  flows to the boundaries in a time of order  $\eta/c^2$  (i.e., instantaneously according to pre-Maxwell theory), the free charge density in a moving conductor is generally nonzero, and takes the value (29).

## EM energy conservation, ohmic dissipation, Lorentz force

It follows from Eqs. (1) and (2) that

$$\partial u_t^B + \nabla \cdot \mathbf{I}^B = -\mathbf{E} \cdot \mathbf{J},\tag{Eq. 30}$$

where  $u^{B}$  is the EM energy per unit volume and  $I^{B}$  is the EM energy flux (often called "the Poynting flux"):

$$u^B = B^2 / 2\mu_0, (Eq. 31)$$

$$\mathbf{I}^B = \mathbf{E} \times \mathbf{B}/\mu_0. \tag{Eq. 32}$$

When integrated over a small volume v surrounding a point P in the medium, Eq. (30) states that the rate of increase of magnetic energy in v is diminished by the outward flux of magnetic energy across its surface s and by the rate at which the EM field transfers its energy to the material contents of v, as determined from Eq. (28) as

$$-\mathbf{E} \cdot \mathbf{J} = -\mathbf{V} \cdot \mathbf{L} - Q^{J}, \tag{Eq. 33}$$

where

 $\mathbf{L} = \mathbf{J} \times \mathbf{B},\tag{Eq. 34}$ 

$$Q^J = J^2/\sigma \ge 0. \tag{Eq. 35}$$

Here **L**, the Lorentz force, is the force per unit volume exerted by the EM field on the medium, so that the net force and torque (about the origin of  $\mathbf{x}$ ) on the contents of a volume v are

$$\boldsymbol{f} = \int_{\boldsymbol{v}} \mathbf{L} d\boldsymbol{v} = \int_{\boldsymbol{v}} \mathbf{J} \times \mathbf{B} d\boldsymbol{v}, \qquad (\text{Eq. 36})$$

$$\boldsymbol{\Gamma} = \int_{\boldsymbol{\nu}} \mathbf{x} \times \mathbf{L} d\boldsymbol{\nu} = \int_{\boldsymbol{\nu}} \mathbf{x} \times (\mathbf{J} \times \mathbf{B}) d\boldsymbol{\nu}.$$
 (Eq. 37)

The work done by the Lorentz force diminishes  $u^B$  at the rate  $\mathbf{V} \cdot \mathbf{L}$ . When negative, this represents a transfer of kinetic energy to EM energy. The second term on the right-hand side of Eq. (33), which is necessarily nonnegative, gives the rate at which the EM field loses energy through ohmic heating, also called Joule losses.

By using Eqs. (1), (3), and (34) it is possible, and often useful, to replace the Lorentz force by an equivalent EM stress tensor:

$$L_i = \nabla_j \pi^B_{ij}, \tag{Eq. 38}$$

$$\pi_{ij}^{B} = \frac{B_{i}B_{j}}{\mu_{0}} - \frac{B^{2}}{2\mu_{0}}\delta_{ij}.$$
 (Eq. 39)

Through Eq. (38), **f** and  $\Gamma$  may be replaced by surface integrals:

$$f_i = \oint_s \pi_{ij}^B \mathrm{d}s_j, \tag{Eq. 40}$$

$$\Gamma_i = \oint_s \epsilon_{ijk} x_j \pi^B_{km} \mathrm{d} s_m, \qquad (\text{Eq. 41})$$

where, to obtain Eq. (41) the symmetry of  $\pi^{B}$  has been invoked. Alternate forms of Eqs. (40) and (41) are

$$\mathbf{f} = \oint_{s} \left[ \frac{\mathbf{B}(\mathbf{B} \cdot \mathbf{ds})}{\mu_{0}} - \frac{B^{2}}{2\mu_{0}} \mathbf{ds} \right], \tag{Eq. 42}$$

$$\mathbf{\Gamma} = \oint_{\mathbf{s}} \left[ \frac{\mathbf{x} \times \mathbf{B}}{\mu_0} \left( \mathbf{B} \cdot \mathbf{ds} \right) - \frac{B^2}{2\mu_0} \mathbf{x} \times \mathbf{ds} \right].$$
(Eq. 43)

The first term on the right-hand side of Eq. (42) represents a tension in the field lines; the second term contributes an isotropic magnetic pressure,  $P_{\rm m} = B^2/2\mu_0$ , which is about 4 atm for a field strength of 1 T. These interpretations will be useful in the Section on the perfect conductor below.

It is worth emphasizing that the magnetic field alone contributes to the EM force on the conductor, to the EM stresses, and to the EM energy. According to pre-Maxwell theory, the corresponding contributions made by the electric field are smaller by a factor of order  $(V/c)^2$ .

The induction equation; the magnetic Reynolds number On eliminating **E** between Eqs. (2) and (28), it is found that **B** obeys the *induction equation*,

$$\partial_t \mathbf{B} = \nabla \times (\mathbf{V} \times \mathbf{B}) - \nabla \times (\eta \nabla \times \mathbf{B}).$$
 (Eq. 44)

This equation is sometimes called "the dynamo equation." This is a misnomer, since Eq. (44) is applicable in many situations totally unrelated to dynamo theory.

When  $\eta$  is constant (the usual assumption), Eq. (3) shows that Eq. (44) can be written as

$$\partial_t \mathbf{B} = \nabla \times (\mathbf{V} \times \mathbf{B}) + \eta \nabla^2 \mathbf{B}.$$
 (Eq. 45)

This clearly exposes the evolution of **B** as a competition between EM induction (through  $\nabla \times (\mathbf{V} \times \mathbf{B})$ ) and ohmic diffusion (through  $\eta \nabla^2 \mathbf{B}$ ), and it is convenient to introduce a dimensionless measure of the relative importance of these effects:

$$R_{\rm m} = \mathcal{VL}/\eta = \mu_0 \sigma \mathcal{VL}. \tag{Eq. 46}$$

In analogy with the familiar (kinetic) Reynolds number  $R_k = \mathcal{VL}/\nu$ , used in fluid mechanics to quantify the effects of viscosity,  $R_m$  is called the *magnetic Reynolds number*. (Here  $\nu$  is kinematic viscosity.) An illuminating way of writing Eq. (45) is

$$d_t \mathbf{B} = \mathbf{B} \cdot \nabla \mathbf{V} - \mathbf{B} \nabla \cdot \mathbf{V} + \eta \nabla^2 \mathbf{B}, \qquad (\text{Eq. 47})$$

where  $d_t = \partial_t + \mathbf{V} \cdot \nabla$  is the motional derivative, the derivative following the fluid motion. This shows that, unless there is velocity shear  $(\nabla \mathbf{V} \neq \mathbf{0})$ , the magnetic field will simply be advected by the motion  $(d_t \mathbf{B})$  while being continually diffused by electrical resistance (through  $\eta \nabla^2 \mathbf{B}$ ).

MHD processes in rotating bodies such as the core are usually most easily studied using a reference frame that rotates with the body (see the Section on Classical and Coriolis MHD). Even though **E** is then different from the electric field in the inertial frame, the induction equation is unchanged, provided  $\partial_t$ ,  $d_t$ , and **V** are defined relative to the rotating frame.

Solutions to the induction equation are subject to the boundary conditions (14)–(18). The first question to ask concerns the role of the surface current **C**. From a physical standpoint, it is clear that, when  $\eta \neq 0$ , an infinitely thin concentration of current, even if it could be set up initially, would be instantly diffused into a layer of large, but finite, **J**. This shows that **C** = 0 when  $\eta \neq 0$ . Nevertheless, when  $R_m \gg 1$ , it is found that, where material properties of the medium change abruptly, a thin "boundary layer" may arise, which, because **J** is so large, carries a finite total current **C**. When focusing on phenomena on scales  $\mathcal{L}$  large compared with the thickness,  $\delta_m$ , of the boundary layer, it may be convenient (even though  $\eta \neq 0$ ) to pretend that the boundary layer is infinitely thin, i.e., is a surface current **C** (see *Core, boundary layers*).

A good example is provided by a rotating solid sphere of radius *a* across which a uniform field,  $\mathbf{B}_0$ , is applied; the sphere rotates about an axis perpendicular to  $\mathbf{B}_0$  with angular velocity  $\mathbf{\Omega}$  (see also *Dynamo, Herzenberg*). The appropriate magnetic Reynolds number is  $R_m = \Omega a^2/\eta$ . To an observer on the surface *S* of the sphere and rotating with it, the applied field will seem to be oscillatory and, if  $R_m \gg 1$ , it will therefore penetrate only a short distance, of order  $\delta_m = R_m^{-1/2} a = (\eta/\Omega)^{1/2}$ , into the sphere. This phenomenon is well known in the EM of solid conductors and is called the "skin effect," because the induced currents are confined to a thin "skin" on *S*. In the limit  $R_m \to \infty$ , the skin becomes infinitely thin, i.e., a surface current **C**. This creates a dipolar magnetic field, **b** that completely excludes  $\mathbf{B}_0$  from the interior of the sphere:  $\mathbf{n} \cdot (\mathbf{b} + \mathbf{B}_0) = 0$  on *S*; Swirling motions in a fluid conductor can similarly expel flux from within them.

For the remainder of this subsection, we suppose that  $R_m = O(1)$  and **C** = **0**. Then, of Eqs. (14)–(18), only Eqs. (14)–(16) are significant:

$$\llbracket \mathbf{B} \rrbracket = 0, \quad \text{on } S, \tag{Eq. 48}$$

$$[\mathbf{n} \times \mathbf{E}] = 0, \quad \text{on } S. \tag{Eq. 49}$$

By Eq. (28), condition (49) can also be written as  $[\mathbf{n} \times (\mathbf{V} \times \mathbf{B} - \eta \nabla \times \mathbf{B})] = 0$ , hence removing all reference to **E** when solving Eq. (44) subject to Eqs. (48) and (49). This again highlights the unimportance of **E** relative to **B**. If there is any interest in finding **E**,  $\vartheta$ , and  $\Sigma$ , these can be determined after Eq. (44) has been solved, by applying Eqs. (28), (29), and (17).

Condition (18) is superfluous since, according to Eq. (1), it is satisfied when  $[\![\mathbf{n} \times \mathbf{B}]\!] = 0$  is. Similarly, when Eq. (49) is obeyed, so is  $[\![\mathbf{n} \cdot \mathbf{B}]\!] = 0$ , by Eq. (2). Thus, only four of the five scalar conditions (48) and (49) are independent. According to Eqs. (3) and (48),  $[\![\mathbf{n} \cdot \nabla(\mathbf{n} \cdot \mathbf{B})]\!] = 0$ , but, because  $[\![\eta]\!]$  is generally nonzero,  $[\![\mathbf{n} \times \mathbf{J}]\!] \neq 0$ , so that  $[\![\mathbf{n} \cdot \nabla(\mathbf{n} \times \mathbf{B})]\!] \neq 0$ . Conditions (48) and (49) apply at the ICB but usually the SIC is modeled as a solid of the same conductivity as the fluid core  $([\![\eta]\!] = 0)$ , and moving with it at the ICB  $([\![\nabla]\!] = 0)$ . Then, by Ohm's law  $[\![\mathbf{J}]\!] = 0$  and  $[\![\nabla \mathbf{B}]\!] = 0$ .

Geophysically, a more significant application of Eqs. (48) and (49) is when S is the CMB. Because the mantle is a relatively poor conductor compared with the core, it is often assumed that the entire region  $\hat{V}$  above the CMB is electrically insulating. Then, distinguishing variables in  $\hat{V}$  by a circumflex and setting  $\hat{J} \equiv 0$  in Eq. (1), we have

$$\nabla \times \mathbf{B} = 0, \tag{Eq. 50}$$

$$\nabla \cdot \widehat{\mathbf{B}} = 0. \tag{Eq. 51}$$

(This also ignores all permanent magnetism in the crust.) Equations (50) and (51) then show that  $\hat{\mathbf{B}}$  is a potential field:

$$\hat{\mathbf{B}} = -\nabla \hat{\mathbf{\Phi}},$$
 (Eq. 52)

where

Ê

$$\nabla^2 \widehat{\mathbf{\Phi}} = 0. \tag{Eq. 53}$$

This is the basis for the Gauss representation of the observed geomagnetic field. The general solution of Eq. (53) is a linear combination of spherical harmonics,  $r^n S_n(\theta, \phi)$  and  $r^{-n-1}S_n(\theta, \phi)$ , the sources of which are respectively outside the sphere of radius r and within it (see *Harmonics, spherical*). Here  $(r, \theta, \phi)$  are spherical coordinates, with origin at the geocenter O and  $\theta = 0$  as north polar axis; the function  $S_n(\theta, \phi)$  is a surface harmonic,  $(g_n^m \cos m\phi + h_n^m \sin m\phi)P_n^m(\theta)$ , where  $P_n^m(\theta)$  is the Legendre function. For the main geomagnetic field, the  $r^n S_n(\theta, \phi)$  terms are found to be negligibly small at the Earth's surface and, when we assume that the mantle contains no sources of field, this is also true at the core surface,  $r = R_1$ . The representation of  $\hat{\mathbf{B}}$ into a sum of  $r^{-n-1}S_n(\theta, \phi)$  terms then holds throughout  $r \ge R_1$ , and (since magnetic monopoles do not exist), it is dominated at large rby the first interior harmonic,  $r^{-2}S_1(\theta, \phi)$ , which corresponds to a magnetic dipole. This leads to the important condition,

$$\widehat{\Phi} = O(r^{-2}), \quad \text{as} \quad r \to \infty,$$
 (Eq. 54)

which expresses, in a succinct mathematical way, the fact that the source of the main geomagnetic field lies entirely beneath the core surface.

Conditions (48) and (49) hold on the CMB, but Eq. (49) does not restrict solutions of Eq. (44). To see this, let us represent **B** and **E** in a well-known way:

$$\mathbf{B} = \nabla \times \mathbf{A},\tag{Eq. 55}$$

$$\mathbf{E} = -\partial_t \mathbf{A} - \nabla \Psi. \tag{Eq. 56}$$

The Coulomb gauge is convenient in pre-Maxwell theory, so that

$$\nabla \cdot \mathbf{A} = \mathbf{0},\tag{Eq. 57}$$

$$\nabla^2 \Psi = -\vartheta/\epsilon, \tag{Eq. 58}$$

the second of which follows from Eqs. (4) and (23). Continuity of  $\mathbf{n} \cdot \mathbf{B}$ and  $\mathbf{n} \times \mathbf{E}$  imply that  $[\![\mathbf{n} \times \mathbf{A}]\!] = 0$  and  $[\![\Psi]\!] = 0$  on S. Free charge may be exist in  $\hat{V}$ , but it is reasonable to suppose that  $\hat{\vartheta}$ , and therefore  $\hat{\Psi}$  also, vanish as  $r \to \infty$ . The Poisson equation (58) then determines  $\hat{\Psi}$ . The resulting  $[\![\mathbf{n} \cdot \nabla \Psi]\!]$  is generally nonzero, and defines  $\Sigma$  on S (see Eq. (17)).

In short, Eq. (49) does no more than determine  $\widehat{\mathbf{E}}$  in  $\widehat{\mathbf{V}}$  and  $\Sigma$  on *S*; it places no restriction on **B**. The essential difference between Eqs. (48) and (49) is that surface layers of "magnetic charge," analogous to surface layers of electric charge, do not exist. This means that, while a potential field  $\widehat{\mathbf{\Phi}}$  can always be found that satisfies Eq. (54) together with either  $[\mathbf{n} \cdot \mathbf{B}] = 0$  or  $[\mathbf{n} \times \mathbf{B}] = 0$ , to demand that it satisfies both these conditions places a restriction on **B** on *S*. This restriction expresses the fact that all sources of **B** are currents flowing beneath *S*. It is sometimes called "the dynamo condition."

#### The kinematic dynamo

A self-excited dynamo is a device that maintains the magnetic field indefinitely. Here "indefinitely" means that  $\mathbf{B} \neq 0$  as  $t \to \infty$ ; "maintains" means that the only sources of  $\mathbf{B}$  are currents flowing in the conductor itself, i.e., there are no external current-carrying coils even at infinity. The magnetic field is a by-product of the current flow (see Eq. (1)), and in a self-excited dynamo, the motion creates from that field the electromotive force that produces the required current flow. There is no conflict with energy conservation. As seen in the Section on EM energy conservation, ohmic dissipation, Lorentz force, the field creates a Lorentz force and this in general opposes the motion and attempts to bring the fluid to rest, an example of Lenz's law. Some agency has to maintain the motion, and provide the energy necessary to make good the ohmic losses  $Q^J$ . The self-excited dynamo is, in principle, no different from generators of electricity in a power station.

Theorists distinguish two types of self-excited dynamo: the kinematic dynamo and the MHD dynamo. In a kinematic dynamo, the flow V maintaining B is specified; in an MHD dynamo the energy sources driving the flow are specified and B and V are determined simultaneously by solving the full MHD equations. These equations are nonlinear and therefore much harder to solve than the induction equation, which is linear in  $\mathbf{B}$  and is all that is needed (together with the matching to a source-free external field **B**) in studying the kinematic dynamo. Not surprisingly, much is now known about kinematic dynamos, and many solutions exist (see Dynamos, kinematic). In some kinematic models, the conductor fills all space (see Dynamo, Herzenberg and Dynamo, Ponomarenko). Because of applications of the dynamo theory to the Earth and other heavenly bodies, it is more usual to assume that the conductor occupies a simple, simply-connected body, V, such as a sphere, the exterior  $\hat{V}$  of which is electrically insulating. (See the Section on The induction equation; the magnetic Reynolds number and see Dynamo, Backus; Dynamo, Braginsky; Dynamo, Bullard-Gellman; and Dynamo, Gailitis. See also Dynamos, fast and Dynamos, periodic.)

Maintenance of **B** obviously implies maintenance of  $u^B$ . By assumption, external sources do not bring magnetic energy into a system from the outside so that, by Eqs. (30)–(33), the integral of **V**·**L** over *V* must be negative to offset the ohmic losses  $Q^I$ , which is nonnegative at all points in *V*. A necessary condition for dynamo action is therefore that **V** is "sufficiently large," i.e.,  $R_m$  is "big enough" (see *Antidynamo and bounding theorems*). For convenience, we shall later say that  $R_m \gtrsim 100$  in a functioning dynamo, but it has to be clearly understood that a condition such as that is far from sufficient to ensure dynamo action. There are a number of antidynamo theorems that define circumstances in which a dynamo will not work, no matter how large  $R_m$  is (see *Antidynamo and bounding theorems*). The most significant of these is a result due to Cowling (1933) (see *Cowling's theorem*). This states that

An axisymmetric magnetic field cannot be maintained by dynamo action.

In what follows, axisymmetric quantities will be distinguished by an overbar. More generally,  $\overline{Q}(r, \theta)$  will be the  $\phi$ -average of a scalar

quantity  $Q(r, \theta, \phi)$ ; the remaining asymmetric part, Q', of Q will be denoted by a prime:  $Q' = Q - \overline{Q}$ . An axisymmetric field consists of a zonal magnetic field,  $\overline{\mathbf{B}}_{\phi}$ , in the direction of increasing  $\phi$  and a meridional field,  $\overline{\mathbf{B}}_{\phi}$ , that has only r and  $\theta$  components  $\overline{B}_r$  and  $\overline{B}_{\theta}$ . The essence of Cowling's theorem is that, although motions can induce  $\overline{B}_{\phi}$  from  $\overline{\mathbf{B}}_{M}$  (see Section on the perfect conductor), they cannot do the reverse; asymmetric field and flow are required to produce an emf  $(\overline{\mathbf{V}' \times \mathbf{B}'})_{\phi}$  that creates the current,  $\overline{J}_{\phi}$ , necessary to maintain  $\overline{\mathbf{B}}_{M}$ . This means that "dynamo fields are necessarily three-dimensional," i.e., their components must depend on r,  $\theta$ , and  $\phi$ . (Axi-symmetric  $\mathbf{V}$  are not, however, excluded by the theorem; e.g., see *Dynamo, Ponomarenko.*)

Despite the antidynamo theorems, self-excited kinematic models have been constructed and have been modeled in the laboratory (see *Dynamos, experimental*). These successes and earlier work going back to Parker (1955) have highlighted the importance of symmetry-breaking; dynamos flourish if the motions lack mirror-symmetry (see *Geodynamo, symmetry properties*). A flow is mirror-symmetric if a mirror (z = 0, say) exists such that

$$V_x(x,y,-z) = V_x(x,y,z), V_y(x,y,-z) = V_y(x,y,z),$$
  

$$V_z(x,y,-z) = -V_z(x,y,z).$$
(Eq. 59)

The simplest manifestations of such symmetry-breaking are helical motions. Helicity is defined as  $\mathbf{V} \cdot \boldsymbol{\omega}$ , where  $\boldsymbol{\omega} = \nabla \times \mathbf{V}$  is the vorticity of the flow. It is a measure of how mirror-symmetric the flow is; like a common carpenter's screw, a helical flow does not look the same when viewed in a mirror. Helicity is created naturally in convecting systems that are rotating; the rising and falling motions created by buoyancy acquire vertical vorticity through the action of the Coriolis force. The word helicity is a term in general use to describe any quantity that is the scalar product of a vector with its curl, such as the magnetic helicity,  $\mathbf{A} \cdot \mathbf{B} (= \mathbf{A} \cdot \nabla \times \mathbf{A})$ , and the current helicity,  $\mathbf{B} \cdot \mathbf{J} (= \mathbf{B} \cdot \nabla \times \mathbf{B} / \mu_0)$ . Helical flows tend to produce helical fields, as measured by the magnetic and current helicities.

Although examples exist of kinematic dynamos that function even though the motions are nonhelical, there is little doubt that helical dynamos are more efficient, i.e., they function at smaller values of  $R_{\rm m}$ . The simplest manifestation of this is the *alpha-effect*, in which helical motions produce a mean emf  $\overline{\mathbf{V}' \times \mathbf{B}'}$  that is proportional to  $\overline{\mathbf{B}}$ and is usually written as  $\alpha \overline{\mathbf{B}}$ . This includes an emf  $\alpha \overline{B}_{\phi}$  in the  $\phi$ -direction that drives the  $\phi$ -component of  $\overline{\mathbf{J}}$  that creates the axisymmetric meridional part,  $\overline{\mathbf{B}}_{\rm M}$ , of  $\mathbf{B}$  needed to defeat Cowling's theorem (see above). This simple fact largely explains the popularity of mean field dynamos, where only the axisymmetric part of  $\mathbf{B}$  is sought, induction by the asymmetric parts being parameterized by an ansatz, such as the simple choice  $\overline{\mathbf{V}' \times \mathbf{B}'} = \alpha \overline{\mathbf{B}}$  just made (see *Dynamos, mean field*).

#### The perfect conductor

A perfect conductor is one that has infinite electrical conductivity  $(\eta = 0)$ . Since **J** must be finite even though  $\sigma = \infty$ , Ohm's law (27) implies that

$$\mathbf{E} = -\mathbf{V} \times \mathbf{B}.\tag{Eq. 60}$$

The induction equation becomes

$$\partial_t \mathbf{B} = \nabla \times (\mathbf{V} \times \mathbf{B}) \quad \text{when} \quad \eta = 0.$$
 (Eq. 61)

In a perfect conductor, the magnetic Reynolds number,  $R_m$ , is infinite; see Eq. (46). Although  $R_m \gg 1$  in many applications of MHD (including some considered here),  $R_m = \infty$  is an idealization that is never achieved. It is however an abstraction that is often useful. This is a consequence of Eq. (61) from which it follows that (see *Alfvén's theorem and the frozen flux approximation*). MAGNETOHYDRODYNAMICS

Magnetic flux tubes move with a perfect conductor as though "frozen" to it.

Frozen flux provides a useful way of picturing MHD processes when  $R_{\rm m}$  is large, one that employs some of the concepts of stress and energy of the Section on EM energy conservation, ohmic dissipation, Lorentz force. Consider the way in which fluid motions can exchange energy with the field. Imagine a straight flux tube, initially of crosssectional area  $A_0$ , lying in a compressible fluid. Suppose a motion compresses the tube uniformly, so that, while remaining straight, its crosssectional area is reduced to  $A(\langle A_0 \rangle)$ . The density of the fluid it contains increases from its initial value of  $\rho_0$  to  $\rho = \rho_0(A_0/A)$ . If the compression is performed fast enough, heat conduction is negligible. In such an adiabatic process, the internal energy of the tube increases, so that its temperature rises. According to Alfvén's theorem, the flux of the magnetic field in the tube cannot change, so that the field B<sub>0</sub> initially within the tube increases in strength to  $B = B_0 A_0 / A$ , i.e., by the same factor as the density; thus  $B/\rho$  remains at its initial value,  $B_0/\rho_0$ . The magnetic energy per unit length contained in the tube increases, however, from  $A_0(B_0^2/2\mu_0)$  to  $A(B^2/2\mu_0) = [A_0(B_0^2/2\mu_0)](A_0/A)$ . In short, the kinetic energy of the compressing motion has been transformed into internal energy and magnetic energy. The reverse happens if  $A > A_0$ ; the flux trapped in an intense tube tends to expand into surroundings where the field is weaker. For these reasons, sound traveling across a field moves faster than it would in the absence of the field; the magnetic pressure created by the field intensifies the restoring force in the compressions and rarefactions of the wave.

The transformation of kinetic energy into magnetic energy also occurs in an incompressible fluid when motions stretch field lines against their tension. The process may be likened to the storing of elastic energy in a stretched rubber band or to the energy transmitted to a violin string by plucking it. If the flux tube of cross-sectional area  $A_0$  containing field  $B_0$  is lengthened from  $L_0$  to L, its cross-section will decrease in the same proportion  $(A = A_0L_0/L)$  and the field within it will increase by the same factor  $(B = B_0L/L_0)$ . The magnetic energy it contains, which is proportional to  $B^2$ , is enhanced by a factor of  $(L/L_0)^2$  from  $(B_0^2/2\mu_0)L_0A_0$  to  $(B^2/2\mu_0)LA = (B^2/2\mu_0)L_0A_0 = [(B_0^2/2\mu_0)L_0A_0](L/L_0)^2$ . If  $L = L_0 + \delta$  where  $\delta \ll L_0$ , the increase in magnetic energy is  $(B_0^2/\mu_0)A_0\delta$ . This is the work done by the applied force in stretching the tube by  $\delta$  in opposition to the magnetic tension  $(B_0^2/\mu_0)A_0$  of the field lines.

It was mentioned in the Section on the induction equation; the magnetic Reynolds number that fluid motions can create  $\overline{B}_{\phi}$  from  $\overline{\mathbf{B}}_{\mathrm{M}}$ . Alfvén's theorem provides a picture of the process: a zonal shearing motion  $\overline{V}_{\phi}$  drags the lines of force of  $\mathbf{B}_{\mathrm{M}}$  out of their meridional planes, i.e., it gives them a  $\overline{B}_{\phi}$  component. Dating from a time when the zonal shear,  $\overline{V}_{\phi}/r\sin\theta$ , was frequently denoted by  $\omega$ , this is often called *the omega effect*. Taking Alfvén's theorem literally,  $\overline{V}_{\phi}$  will continue to wind the field lines around the symmetry axis for as long as the motion is maintained, and  $\overline{B}_{\phi}$  and  $u^{B}$  will increase monotonically. The magnetic stresses grow as the field lines become increasingly stretched in the  $\phi$ -direction until at last the agency that creates  $\overline{V}_{\phi}$  can no longer maintain it.

Alfvén's theorem leads to a new phenomenon, the *Alfvén wave*. Consider again the straight flux tube, of cross-sectional area A in an incompressible fluid, and imagine that a transverse displacement bends the tube, carrying its contents with it, in obedience to the theorem. The tension  $\tau = AB^2/\mu_0$  of the tube acts, as in a stretched string, to shorten the tube. A wave results, which moves in each direction along the tube with speed  $V_A = \sqrt{(\tau/M)}$ , where  $M = \rho A$  in the mass per unit length of the string. The wave velocity is therefore

$$\mathbf{V}_{\mathrm{A}} = \mathbf{B} / (\mu_0 \rho)^{1/2}, \qquad (\mathrm{Eq.}\ 62)$$

which is usually called the *Alfvén velocity*. It is the speed with which energy can be transmitted along the field lines. On taking B = 0.01 T and  $\rho = 10^4$  kg m<sup>-3</sup> as typical of the core, it is found that  $V_A \sim 0.1$  m s<sup>-1</sup>. The MHD or *Alfvénic timescale*,

$$\tau_{\rm A} = \mathcal{L}/\mathcal{V}_{\rm A},\tag{Eq. 63}$$

is often significant. It provides an estimate of how quickly an MHD system responds to changes in its state. Alfvén waves are the simplest example of a wider class of waves; see the Section on the CMHD for ideal fluids and *Magnetohydrodynamic waves*.

It was seen in the Section on the induction equation; the magnetic Reynolds number that **C** may be nonzero at a surface *S* of discontinuity when  $\eta = 0$  on one side of *S*. This surface current is subjected to a Lorentz force that is computed best through the EM stress tensor (39). The discontinuity in magnetic stress is then

$$\llbracket \pi_{ij}^{\mathcal{B}} n_j \rrbracket = \frac{1}{\mu_0} (\mathbf{n} \cdot \mathbf{B}) (\mathbf{C} \times \mathbf{n}) - \llbracket P_{\mathbf{m}} \rrbracket \mathbf{n}.$$
 (Eq. 64)

This can be written, in analogy with  $\mathbf{J} \times \mathbf{B}$ , as  $\mathbf{C} \times \frac{1}{2}(\mathbf{B}_1 + \mathbf{B}_2)$ . Other stresses must act to compensate for this discontinuity. For example, if  $\mathbf{n} \cdot \mathbf{B} = 0$ , the discontinuity in  $P_{\rm m} = B^2/2\mu_0$  can be compensated by a discontinuity in the kinetic pressure P that makes the total pressure,  $P_{\text{total}} = P + P_{\text{m}}$ , continuous. Even if a discontinuity in  $P_{\text{total}}$ could be set up initially, it would immediately be radiated away from S sonically. If  $\mathbf{n} \cdot \mathbf{B} \neq 0$ , the situation is more complicated but it is helpful to recall (See the Section on the induction equation; the magnetic Reynolds number) that the surface current is an idealization for  $R_{\rm m} \rightarrow \infty$  of a thin boundary layer in which other processes may be significant. For example, the surface force  $(\mathbf{n} \cdot \mathbf{B})(\mathbf{C} \times \mathbf{n})/\mu_0$  in Eq. (64) represents the limit of a volumetric force that would create a large velocity shear in the boundary layer; associated with this is a large viscous stress that may be able to balance the magnetic stress, as in the Hartmann layer (See the Section on the Classical MHD). In the absence of such effects, one must assume that  $\mathbf{C} = 0$  when  $\mathbf{n} \cdot \mathbf{B} \neq 0$ . Even if a surface current could be set up initially, it would immediately be Alfvénically radiated away from S.

#### The imperfect conductor, reconnection

Some caution has to be exercised in applying Alfvén's theorem. According to the theorem, the topology of field lines cannot change. Fluid lying on a field line always remains on that field line; reconnection of field lines is impossible. This makes the dynamo problem meaningless; the magnetic flux trapped in the conductor is never lost, and one cannot even find out how the conductor acquired that flux originally. Magnetic field is gained, retained, or lost only by its diffusion relative to the conductor, and diffusion happens only when  $\sigma$  and  $R_m$  are finite. Nevertheless, Alfvén's theorem is useful in picturing what happens when  $R_m$  is large. As the conductor moves, it loses flux on the *EM diffusion timescale*,  $\tau_\eta$ , but this may be replenished by a shearing processes (such as those considered above) on the *advective timescale*  $\tau_V$ ; here

$$\tau_{\eta} = \mathcal{L}^2 / \eta, \tag{Eq. 65}$$

$$\tau_V = \mathcal{L}/\mathcal{V}.\tag{Eq. 66}$$

For a dynamo to be successful, renewal of flux must balance or exceed its destruction, i.e.,  $\tau_V$  must be shorter than  $\tau_\eta$ , implying that  $R_{\rm m} = \tau_\eta / \tau_V \gtrsim O(1)$ . The westward drift velocity on the CMB of recognizable features of the geomagnetic field is of order  $3 \times 10^{-4}$  m s<sup>-1</sup>. It is likely however that part of this motion is due to diffusion of the features relative to the conductor. A magnetic feature of scale  $\mathcal{L}$  can diffuse relative to the conductor at a drift speed  $c_{\rm d}$  of order  $\eta / \mathcal{L}$ . We shall therefore assume that the actual fluid velocity is less

than  $3 \times 10^{-4} \text{ m s}^{-1}$  and estimate that  $\mathcal{V} = 10^{-4} \text{ m s}^{-1}$ . Taking  $\mathcal{L} \sim 2 \times 10^6 \text{ m}$  and  $\eta = 2 \text{ m}^2 \text{s}^{-1}$ , this gives  $R_{\text{m}} \sim 100$ .

Because of the small scale of laboratory apparatus, it is hard to achieve O(1) values of  $R_m$ . For the same reason, it is hard to demonstrate dynamo action using liquid metals (but see *Dynamos, experimental*). The frozen flux picture is of limited usefulness in describing MHD experiments with liquid metals. When  $R_m \ll 1$ , EM diffusion is rapid ( $\tau_\eta \ll \tau_V$ ) and, in the limit, instantaneous. The left-hand side of Eq. (44) is then negligible compared with  $\nabla \times (\eta \nabla \times \mathbf{B})$ , and, on uncurling this equation, we obtain the limiting form that is the antithesis of Eq. (60):

$$\mathbf{J} = \sigma(-\nabla \Psi + \mathbf{V} \times \mathbf{B}). \tag{Eq. 67}$$

This is equivalent to the statement that **E** is a potential field  $(\mathbf{E} = -\nabla \Psi)$ , the potential of which can be obtained by solving the Poisson equation that follows from Eq. (67):

$$\nabla^2 \Psi = \nabla \cdot (\mathbf{V} \times \mathbf{B}). \tag{Eq. 68}$$

The first term on the right-hand side of Eq. (67) is *nonlocal*, i.e., it depends on the form of **V** and **B** everywhere. The second term creates a current  $\sigma \mathbf{V} \times \mathbf{B}$  and a *local* Lorentz force  $\sigma (\mathbf{V} \times \mathbf{B}) \times \mathbf{B}$ , from the prevailing **V** and **B**. The latter may be written as  $-\mathbf{V}_{\perp}/\tau_{\rm m}$ , where  $\mathbf{V}_{\perp} = \mathbf{V} - (\mathbf{V} \cdot \mathbf{B})\mathbf{B}/B^2$  is the part of **V** that is perpendicular to **B**, and  $\tau_{\rm m}$  is the *magnetic damping time*:

$$\tau_{\rm m} = \rho / \sigma \mathcal{B}^2 = \eta / \mathcal{V}_{\rm A}^2. \tag{Eq. 69}$$

This shows that, when  $R_m \ll 1$ , the primary effect of a field is to damp-out motions across magnetic field lines, rather like an anisotropic friction (Davidson, 2001).

Because of the small scale of laboratory apparatus, it is also hard to demonstrate Alfvén waves in the laboratory. After the wave has traveled a distance  $\mathcal{V}_A \tau_\eta$ , the comoving induced currents have essentially diffused away. The condition that a wave can cross the system before disappearing is  $\mathcal{V}_A \tau_\eta \gtrsim \mathcal{L}$  or  $Lu \gtrsim 1$ , where Lu is the *Lundquist number*:

$$Lu = \mathcal{V}_{\mathrm{A}}\mathcal{L}/\eta = \sqrt{(\tau_n/\tau_{\mathrm{m}})}.$$
 (Eq. 70)

If  $\mathcal{B} = 0.1$  T is the strength of a field applied across a liquid sodium system of scale  $\mathcal{L} = 0.1$  m, we have  $\mathcal{V}_A \sim 3 \text{ m s}^{-1}$ ,  $\eta \sim 1 \text{ m}^2 \text{ s}^{-1}$ ,  $\tau_m \sim 0.1$  s,  $\tau_\eta \sim 0.01$  s, and  $Lu \sim 0.3$ .

#### Some effects of turbulence

Many fluid systems occurring in nature are turbulent. The fluid flow within them exists on length scales that range from  $\mathcal{L}_{\text{macro}},$  comparable with the dimensions  ${\cal L}$  of the system, to  ${\cal L}_{micro} \ll {\cal L}_{macro},$  where by macro is meant large scales and by micro small scales (though still much larger than intermolecular distances). The corresponding magnetic Reynolds numbers range from  $R_{m,macro} = \mathcal{V}_{macro} \mathcal{L}_{macro} / \eta \gtrsim O(1)$ to  $R_{m,micro} = V_{micro} \mathcal{L}_{micro} / \eta \ll R_{m,macro}$ . In a violently turbulent environment such as the solar convection zone, even  $R_{m,micro} \gtrsim 1$  so that these scales of motion can generate a small-scale field by themselves. From seeds planted by an epoch-making paper by Parker (1955), a new subject grew called mean field electrodynamics in which the concepts of mirror-symmetry and  $\alpha$ -effect were central (see, for example, Krause and Rädler, 1980). It was shown that the microscale field and motion not only generate a macroscale field by the  $\alpha$ -effect but also destroy it by an enhanced turbulent diffusivity,  $\eta_{T}$ , vastly greater than the molecular (or radiative) value,  $\eta$ . This was advanced as an explanation of why the solar field reverses its polarity on a timescale,  $\tau_{\eta,T} = \mathcal{L}^2/\eta_T$ , of 11 years even though  $\tau_{\eta} = \mathcal{L}^2/\eta$  is greater than the age of the Sun. During the 22-year cycle, sunspots are seen as markers for a large-scale field that drift equatorward relative to the fluid with a velocity of order  $c_{d,T} = \eta_T / \mathcal{L}$ .

If the Earth's core were as turbulent as the Sun, the timescales of the geomagnetic field would be similarly shortened. The paleomagnetic evidence indicates however that polarity reversals are completed in a time comparable with  $\tau_\eta = \mathcal{L}^2/\eta$  which, taking  $\mathcal{L} \sim 10^6 \mbox{ m}$  and  $\eta = 2 \text{ m}^2 \text{ s}^{-1}$ , is of order  $10^4$  years. This strongly suggests not only that turbulence in the core is much less violent than in the convection zone of the Sun (which is hardly surprising) but also that R<sub>m,micro</sub> in the core is too small for EM induction by small eddies to affect the large-scale field significantly. If this is the case, the concepts of mean field electrodynamics are not applicable to the core, the turbulent  $\alpha\text{-effect}$  is negligibly small, and  $\eta_{\rm T}$  does not dominate  $\eta.$  We shall therefore ignore  $\eta_{\rm T}$  in what follow. According to these arguments, the geodynamo operates on the macroscale, for which the concepts of mirror-symmetry, helicity, and  $\alpha$ -effect apply only in a global nonlocal sense, as for the waves to be mentioned in the Section CMHD for ideal fluids below.

The microscales are, nevertheless, significant in another way; they considerably enhance the energy requirements  $Q^{I}$  of the geodynamo. The current densities associated with the macro- and microscales are related to their respective field strengths,  $\mathcal{B}_{macro}$  and  $\mathcal{B}_{micro}$  by Eq. (1):

$$\mathcal{J}_{\text{macro}} \sim \mathcal{B}_{\text{macro}} / \mu_0 \mathcal{L}_{\text{macro}}, \qquad \mathcal{J}_{\text{micro}} \sim \mathcal{B}_{\text{micro}} / \mu_0 \mathcal{L}_{\text{micro}}.$$
(Eq. 71)

Although it may be true that  $\mathcal{B}_{\text{micro}} \ll \mathcal{B}_{\text{macro}}$ , it is also true that  $\mathcal{L}_{\text{micro}} \ll \mathcal{L}_{\text{macro}}$ . It follows that  $\mathcal{J}_{\text{micro}}$  may be comparable with  $\mathcal{J}_{\text{macro}}$ , and therefore its contribution to  $Q^J = J^2/\sigma$  may be of a similar size. As shown in the Section on The imperfect conductor, reconnection, the microscale fields for which  $R_{\text{m,micro}} \ll 1$  create a Lorentz force, of order  $-\rho \mathbf{V}_{\perp}/\tau_{\text{m}}$ , and this acts like an anisotropic friction. The energy expended working against this friction is dissipated ohmically (see also *Core turbulence*).

#### Fluid dynamics

#### Energy sources

It is clear that an energy source is needed to maintain fluid flow in the face of viscous friction; in addition, an MHD system must expend further energy ohmically. In laboratory systems, the required energy is frequently supplied by pumps that force fluid flow through pipes or channels, and the magnetic field is usually generated externally. In contrast, many naturally occurring fluid systems are forced into motion by buoyancy forces and, because of their vast dimensions  $\mathcal{L}$ , can easily satisfy the condition  $R_m \gtrsim 100$  necessary for dynamo action at quite modest flow speeds  $\mathcal{V}$ . Moreover, these systems are often rotating, and the convective motions may then lack the mirror-symmetry that is detrimental to dynamo action; in other words, they possess helicity (see the Section on The kinematic dynamo). Not surprisingly, therefore, they are often able to equip themselves with the magnetic field that transforms them into MHD systems.

Buoyancy is not the only way of creating fluid flow; laboratory motions are sometimes produced by moving the walls of the container; and, in a similar way, flows in planetary cores can be forced at their boundaries. For example, motions in the core are affected by the lunisolar precession. This causes the Earth's axis of rotation to describe a cone of semiangle  $23\frac{1}{2}^{\circ}$  about an axis perpendicular to the ecliptic in a period of about 26 ka. The associated motion of the CMB affects the fluid flow in the core and may even be the main mechanism driving it (see Tilgner, 2005, and *Precession and core dynamics*). So far, a definitive assessment of the geophysical importance of precession is lacking.

Because MHD turbulence is poorly understood, it is hard to estimate the total energy requirements of the motions and fields in the Earth's core. Because the core is a liquid metal, its kinematic viscosity  $v(\sim 10^{-6} \text{ m}^2 \text{ s}^{-1})$  is substantially less than its magnetic diffusivity  $\eta(\sim 2 \text{ m}^2 \text{ s}^{-1})$ , i.e., its magnetic Prandtl number,

$$P_{\rm m} = \nu/\eta, \tag{Eq. 72}$$

is very small ( $\sim 10^{-6}$ ). Assuming that the dissipation length scale for the viscous energy dissipation  $Q^{\nu}$  is not much smaller than that for the magnetic energy dissipation  $Q^J$ , it follows that  $Q^v \ll Q^J$  (except possibly in boundary layers). The total ohmic dissipation from the macroscales has been estimated to lie between 0.1 and 2 TW  $(1 \mbox{ TW} = 10^{12} \mbox{ W})$  with the microscales possibly contributing just as much (see Section on Some effects of turbulence). Although a definitive figure is so far unobtainable, the fact that the Earth has possessed a magnetic field for most, and perhaps all, of its existence proves that the necessary power requirements have been met throughout that time, though the source of that power is not completely certain (see Geodynamo, energy sources). This article will focus mainly on core convection, but only in a simplified way. Even though it is often argued that compositional buoyancy is as (or even more) important as thermal buoyancy in driving core motions, only the latter will be included here, as this will suffice to illustrate the salient points. For a geophysically more faithful treatment, see Braginsky and Roberts (1995, 2003) and Convection, chemical and Core convection (q.v.). For MHD models of the geodynamo, see Geodynamo and Geodynamo, numerical simulations (q.v.).

## **Basic** equations

The aim in much of the remainder of this article is to explore the roles of the Coriolis, Lorentz, and buoyancy forces. An attempt will be made to raise the level of complexity gradually and to start from a model that includes these forces as simply as possible by using the Boussinesq model (see *Anelastic and Boussinesq approximations*). Then

$$\nabla \cdot \mathbf{V} = \mathbf{0},\tag{Eq. 73}$$

$$\partial_t \mathbf{V} + \mathbf{V} \cdot \nabla \mathbf{V} + 2\mathbf{\Omega} \times \mathbf{V} = -\nabla \Pi - \alpha T \mathbf{g} + \mathbf{J} \times \mathbf{B} / \rho + \nu \nabla^2 \mathbf{V}.$$
(Eq. 74)

In this approximation, the density  $\rho$  of the fluid is uniform, so that mass conservation reduces to the condition (73) of incompressibility. Momentum conservation (74) is expressed in the reference frame that corotates with the mantle, at a constant angular velocity  $\Omega$ . The resulting Coriolis acceleration,  $2\Omega \times V$ , appears on the left-hand side of Eq. (74). The centrifugal acceleration,  $\Omega \times (\Omega \times \mathbf{x})$ , has been combined with the kinetic pressure, *P*, to form the reduced pressure,  $\Pi = P/\rho - \frac{1}{2}(\Omega \times \mathbf{x})^2$ . The last two terms in Eq. (74) represent the Lorentz and viscous forces per unit mass. The buoyancy force per unit mass is  $-\alpha T\mathbf{g}$ , where *T* is the temperature,  $\alpha$  is the thermal expansion coefficient, and  $\mathbf{g}$  is the gravitational acceleration, assumed constant in time.

The temperature is governed by an energy equation of the form

$$d_t T = \kappa \nabla^2 T + Q/\rho C_p, \qquad (\text{Eq. 75})$$

where  $\kappa$  is the thermal diffusivity and Q comprises the various sources of heat:  $Q = Q^{\nu} + Q^{I} + Q^{R}$ , where  $Q^{R}$  arises from internal sources, if any, such as dissolved radioactivity;  $C_{p}$  is the specific heat at constant pressure. We shall initially consider nonmagnetic systems, but, when later we generalize to MHD situations, Eqs. (73)–(75) must be solved in conjunction with Eq. (3) and the induction equation (45).

The boundary conditions for **B** developed in Section Electrodynamics must be supplemented by boundary conditions on **V** and *T*, such as

$$\mathbf{V} = \mathbf{0}, \quad \text{on the CMB},$$
 (Eq. 76)

$$T = T_{\text{CMB}}, \text{ on the CMB},$$
 (Eq. 77)

where  $T_{\text{CMB}}$  is constant. Equation (76) expresses the no-slip condition that, at their common interface, the fluid moves with the solid, which

has zero velocity in the chosen reference frame. The SIC contains only about 5% of the total mass of the core, and its low inertia makes its rotation rate susceptible to the torques (mainly gravitational and magnetic) to which it is subjected (see Eq. (43)). These feature in an equation of motion for its angular velocity  $\Omega_{SIC}$  (see *Inner core rotational dynamics*). For simplicity, we shall assume that

$$\mathbf{V} = \mathbf{0}$$
, on the ICB, (Eq. 78)

$$T = T_{\rm ICB}$$
, on the ICB, (Eq. 79)

where  $T_{ICB}$  is constant. When viscous forces are ignored, the differential order of Eq. (74) is reduced, and it is possible to satisfy only one condition on **V** at the boundaries; the first of Eqs. (76) and (78) are then replaced by

$$\mathbf{n} \cdot \mathbf{V} = 0$$
, on the CMB and ICB, for  $v = 0$ . (Eq. 80)

The relative importance of the various terms of Eqs. (73)–(75) is quantified by several dimensionless groupings, of which the (kinetic) Reynolds number  $R_k = \mathcal{VL}/v$  has already been defined. It quantifies the relative sizes of the inertial and viscous forces. Among the dimensionless parameters describing convection, special mention should be made of the *Rayleigh number*, *Ra* and the usual (thermal) *Prandtl number*, *P*<sub>t</sub>:

$$Ra = g\alpha\beta \mathcal{L}^4 / v\kappa, \tag{Eq. 81}$$

$$P_{\rm t} = v/\kappa, \tag{Eq. 82}$$

where  $\beta$  is, in the Boussinesq approximation, a typical measure of the temperature gradient, e.g., the difference  $\Delta T$  between the temperatures of the ICB and CMB divided by the depth of the fluid core. (In a layer as thick as the FOC, however, the compressibility of the fluid is significant. Convection is better described by the anelastic approximation and a better choice of  $\beta$  is then the difference between the actual temperature gradient and the adiabatic temperature gradient [see *Core, adiabatic gradient; Anelastic and Boussinesq approximations*].) The Rayleigh number is a measure of how effective the buoyancy force is in overcoming the diffusive processes that oppose convection.

A popular way to gain insight into convective processes, popular because the theory is relatively tractable, is to study the onset of convection. A motionless conductive state is defined in which heat is carried across the system by thermal conduction; the linear stability of this state is then analyzed. It is found that when the control parameter, Ra, reaches some critical or marginal value,  $Ra_c$ , the conduction solution becomes convectively unstable. The eigenfunction corresponding to  $Ra_c$  gives the structure of the marginal state of motion. In the absence of Coriolis and Lorentz forces,  $Ra_c$  is typically of order  $10^3$  and the marginal mode is a pattern of overturning convection cells, having about the same horizontal scale as the depth  $\mathcal{L}$  of the convecting layer.

Although studies of this type provide some insight into convective flows, they clearly have limited value. They predict that, when  $Ra > Ra_c$ , the convective motions increase without limit, though in reality feedback from nonlinearities, such as the inertial term  $\mathbf{V} \cdot \nabla \mathbf{V}$ in Eq. (74), prevents this. The enhanced amplitudes and modified structure of the convective motions as Ra is increased from  $Ra_c$  are topics that are beyond the competence of linear theory and are also beyond the scope of this article. Here we shall use the results of linear stability analyzes to obtain clues about how Coriolis and Lorentz forces affect thermal convection.

#### Classical theory of rotating fluids

In this section we shall suppose that  $\mathbf{B} \equiv 0$ ; initially, buoyancy is also excluded ( $\mathbf{g} \equiv 0$ ). We give a rudimentary account of relevant concepts

in the theory of rotating fluids. For a more complete treatment, see the classic text of Greenspan (1968).

Two dimensionless numbers quantify the importance of viscosity and inertia relative to the Coriolis force, the *Ekman number*, *E*, and the *Rossby number*, *Ro*:

$$E = \nu / \Omega \mathcal{L}^2, \tag{Eq. 83}$$

$$Ro = \mathcal{V}/\Omega \mathcal{L}.$$
 (Eq. 84)

The Ekman number may be called a *structural parameter*, since, like  $P_{\rm m}$  and  $P_{\rm t}$  its value is determined by the rotation and physical properties of the Earth, none of which relate to MHD processes in the core. In contrast, the *Ro* may be called a *response parameter* since its value, like  $R_{\rm m}$  and  $R_{\rm k}$ , depends on the response of the system to the physical state in which it finds itself. The molecular viscosity,  $v_{\rm M}$ , is uncertain but is commonly estimated to be about  $10^{-6}$  m<sup>2</sup> s<sup>-1</sup>. Using this for v in Eq. (83) and taking  $\mathcal{L} = 2 \times 10^6$  m as before, we obtain  $E \sim 10^{-15}$ . Such a small value suggests that large-scale momentum is transported more effectively by small turbulent eddies than by molecular processes, and that *E* should be estimated using a larger, turbulent viscosity,  $v_{\rm T}$ . A popular paradigm (see, for example, Braginsky and Meytlis, 1990) assumes that  $v_{\rm T} \sim \eta$ , but even then *E* does not exceed  $10^{-9}$ . Taking, as before,  $\mathcal{V} = 2 \times 10^{-4}$  m s<sup>-1</sup>, we have  $Ro \sim 10^{-5}$ .

From the estimates just made, we see that the FOC is a *rapidly rotating fluid*, defined as one for which

$$E \ll 1$$
, (Eq. 85)

$$Ro \ll 1.$$
 (Eq. 86)

The ratio  $Ro/E = \mathcal{VL}/\nu$  is the (kinetic) Reynolds number  $R_k$  and is large. For the geodynamo to exist,  $R_m = \mathcal{VL}/\eta$  must be of order  $10^2$  and, since  $P_m \ll 1$ , Eq. (85) follows from Eq. (86). The smallness of *Ro* means that we may discard one of the inertial terms,  $\mathbf{V} \cdot \nabla \mathbf{V}$ , from Eq. (74). Looking ahead to the Section on the Classical and Coriolis MHD, we shall recognize that the nonlinear feedback equilibrating the geodynamo is the Lorentz force rather than the inertial force.

The remaining inertial term,  $\partial_t \mathbf{V}$ , in Eq. (74) is responsible for *inertial waves*. These are most easily studied by abbreviating Eq. (74) to

$$\partial_t \mathbf{V} + 2\mathbf{\Omega} \times \mathbf{V} = -\nabla \Pi, \tag{Eq. 87}$$

and by solving this equation and Eq. (73) subject to Eq. (80). The waves are dispersive and are obtained by assuming that V is proportional to  $\exp(i\omega t)$ . The spectrum of possible  $\omega$  is discrete, with infinitely many possible eigenvalues  $\omega$ , all in the range  $|\omega| \leq 2\Omega$  (see Greenspan, 1968). The closer  $|\omega|$  is to zero, the denser the packing of eigenvalues and the more two-dimensional the eigenfunctions are with respect to  $\Omega$ , which we shall take to be in the z-direction. The extreme case,  $\omega = 0$ , gives a single, infinitely degenerate eigenfunction called the geostrophic mode. For this mode,  $\partial_t \mathbf{V} = \mathbf{0}$  and Eqs. (73) and (87) give

$$2\mathbf{\Omega} \cdot \nabla \mathbf{V} = \mathbf{0}. \tag{Eq. 88}$$

Stated in words (see Proudman-Taylor theorem):

The slow steady inviscid motion of a rotating inviscid fluid is two-dimensional with respect to the rotation axis.

Taking  $\mathbf{\Omega} = \mathbf{\Omega} \mathbf{1}_z$ , Eq. (88) gives

$$\mathbf{V} = \mathbf{V}(x, y). \tag{Eq. 89}$$

(Here and elsewhere  $\mathbf{1}_q$  is the unit vector in the direction of increasing coordinate q.) Since the CMB and ICB have been assumed to be

spherical (though the following result is equally valid for an axisymmetric boundary), Eqs. (80) and (89) imply that

$$\mathbf{V} = \overline{V}_{\mathbf{G}}(s)\mathbf{1}_{\phi},\tag{Eq. 90}$$

where  $(s, \phi, z)$  are cylindrical coordinates. The function  $\overline{V}_G(s)$  is arbitrary; this is the infinite degeneracy referred to above. The geostrophic flow is axisymmetric, zonal, and constant on *geostrophic cylinders*, C(s). These are cylinders of constant radius *s*. Figure M151 shows a typical geostrophic cylinder and also a particularly significant one,  $C_2 = C(R_2)$ , which touches the SIC on its equator and is therefore called the tangent cylinder, abbreviated here to "TC" (see *Inner core tangent cylinder*).

For further insight into the geostrophic mode, consider the effect of a buoyancy force produced by an axisymmetric temperature distribution  $\overline{T}$  that creates a density stratification frozen into the fluid ( $\kappa = 0$ ). Then Eq. (74) gives

$$2\mathbf{\Omega} \times \overline{\mathbf{V}} = -\nabla \Pi - \alpha \overline{T} \mathbf{g}. \tag{Eq. 91}$$

Since  $\nabla \times \mathbf{g} = \mathbf{0}$ , this implies, instead of Eq. (88), that

$$2\mathbf{\Omega} \cdot \nabla \overline{\mathbf{V}} = -\alpha \mathbf{g} \times \nabla \overline{T}.$$
 (Eq. 92)

Since  $\mathbf{g}(=-g\mathbf{1}_r)$  is radial, this reduces to

$$\partial_z \overline{V}_{\phi} = (g\alpha/2\Omega r)\partial_{\theta}\overline{T},$$
 (Eq. 93)

which when integrated gives

$$\overline{\mathbf{V}} = [\overline{V}_T(s, z) + \overline{V}_G(s)]\mathbf{1}_{\phi}.$$
(Eq. 94)

**Figure M151** A typical geostrophic cylinder *C* and a particularly significant geostrophic cylinder *C*<sub>2</sub> called the "tangent cylinder" that touches the inner core  $r = R_2$  at its equator. The cylinder of radius *s* meets the surface of the outer core,  $r = R_1$ , on the latitude circles  $z = z_1 \equiv \sqrt{(R_1^2 - s^2)}$  and  $z = z_2 \equiv -\sqrt{(R_1^2 - s^2)}$ . If  $s < R_2$ , there is a northern geostrophic cylinder meeting the inner core at  $z = \sqrt{(R_2^2 - s^2)}$  and a southern geostrophic cylinder meeting it at  $z = -\sqrt{(R_2^2 - s^2)}$ .

The flow  $\overline{V}_{\rm T}$  is called the "thermal wind" (see *Thermal wind*). Its magnitude is  $O(g\alpha\Delta T/\Omega)$  and, if this is comparable with our assumed characteristic velocity  $\mathcal{V} = 2 \times 10^{-4}$  m s<sup>-1</sup>, the pole-equator temperature difference  $\Delta T$  is, for  $\alpha \sim 10^{-5}$  K<sup>-1</sup>, of the order  $10^{-4}$  K. This may be regarded as typical of the temperature differences between rising and falling fluid throughout the core though, more precisely, when the compressibility of the core is properly allowed for, it is typical of the excess or deficit of the temperature relative to the adiabat. The state (94) may be subject to asymmetric *baroclinic instabilities*. These are studied by, for example, Gill (1982).

There is clearly some arbitrariness in Eq. (94), since all or any part of  $\overline{V}_G$  can be absorbed into  $\overline{V}_T$ . A convenient way of removing this arbitrariness is to introduce a *geostrophic average*. The geostrophic average of a scalar field  $Q(\mathbf{x}, t)$  is denoted by angle brackets and is defined for  $s > R_2$  by:

$$\langle Q \rangle(s,t) = \frac{1}{A(s)} \int_{\mathcal{C}(s)} Q(\mathbf{x},t) \mathrm{d}S = \frac{1}{2z_1} \int_{-z_1}^{z_1} \overline{Q}(s,z,t) \mathrm{d}z. \quad (\text{Eq. 95})$$

Here  $\pm z_1(s) = \pm \sqrt{(R_1^2 - s^2)}$  gives the *z*-coordinates of the latitude circles where the geostrophic cylinder C(s) meets the CMB (see Figure M151);  $A = 4\pi s z_1(s)$  is the area of the cylinder and  $dS = s d\phi dz$ . The *ageostrophic part* of  $Q(\mathbf{x}, t)$  is what is left over after the geostrophic part has been subtracted:  $\widetilde{Q}(\mathbf{x}, t) = Q(\mathbf{x}, t) - \langle Q \rangle(s, t)$ . The geostrophic part of a vector field  $\mathbf{Q}(\mathbf{x}, t)$  is defined by

$$\langle \mathbf{Q} \rangle(s,t) = \langle Q_{\phi} \rangle(s,t) \mathbf{1}_{\phi}.$$
 (Eq. 96)

It is particularly significant because all the angular momentum about Oz contained between the shells C(s) and C(s + ds) is accounted for by  $V_G(s)$ . The separation (94) is made unique by defining  $\overline{\mathbf{V}}_G = \langle \overline{\mathbf{V}} \rangle$ .

The definitions of  $\langle Q \rangle$  and  $\langle \mathbf{Q} \rangle$  just given apply only when  $s > R_2$ . Inside the TC, there is a geostrophic average for the fluid to the north of the inner core and another for the fluid to the south.

The thermal wind is illustrative of a more general situation: the response of a rotating fluid to forcing. We consider

$$\partial_t \mathbf{V} + 2\mathbf{\Omega} \times \mathbf{V} = -\nabla \Pi + \mathbf{F},$$
 (Eq. 97)

where  $\mathbf{F}(\mathbf{x}, t)$  is assigned and the response V is sought. There are interesting cases in which the forcing has a high frequency. For example, in the rotating frame, the precessionally driven flow considered earlier has the same timescale as the inertial waves. Also, diurnal frequencies may arise from core turbulence. But, on the timescale  $\mathcal{T}$  of large scale convection, the modified Rossby number,  $1/\Omega \mathcal{T}$ , is small. The response to F is then a combination of free inertial waves (the solution to the homogeneous problem (87) defined by Eq. (97)) and a particular solution that varies slowly, on the same timescale as F. This is the part of V of greatest interest; the free inertial waves are of lesser significance and can be filtered out by discarding the  $\partial_t V$  term in Eq. (97), so dispensing with the inertial force in its entirety.

Although discarding  $\partial_t \mathbf{V}$  is tempting, some caution should be exercised. The geostrophic average of Eq. (97) is

$$\partial_t \overline{V}_{\rm G} + 2\Omega \langle \overline{V}_{\rm S} \rangle = \langle F_{\phi} \rangle. \tag{Eq. 98}$$

The second term is proportional to the mass flux out of C, and is by Eqs. (73) and (80):

$$\langle \overline{V}_{\rm s} \rangle \equiv \frac{1}{A(s)} \int_{\mathcal{C}} \mathbf{V} \cdot \mathrm{d}\mathbf{S} = 0,$$
 (Eq. 99)

so that Eq. (98) becomes

$$\partial_t \overline{V}_{\rm G} = \langle F_{\phi} \rangle. \tag{Eq. 100}$$

If its left-hand side is omitted, there is no solution to Eq. (100) unless  $\langle F_{\phi} \rangle = 0$ . When **F** is the buoyancy force  $-\alpha T \mathbf{g}$  alone,  $\langle F_{\phi} \rangle = 0$  because **g** has no  $\phi$ -component. If **F** contains the Lorentz force, however, it is not necessarily true that  $\langle F_{\phi} \rangle = 0$ , a point to which we return in the Section on Classical and Coriolis MHD. Meanwhile we see that one way of evading the difficulty that arises when  $\langle F_{\phi} \rangle \neq 0$ , while at the same time removing the free inertial waves, is to retain only the geostrophic part of the inertial force, replacing Eq. (74) by

$$\partial_t \overline{\mathbf{V}}_{\mathrm{G}} + 2\mathbf{\Omega} \times \mathbf{V} = -\nabla \Pi - \alpha T \mathbf{g} + \mathbf{J} \times \mathbf{B} / \rho + \nu \nabla^2 \mathbf{V}.$$
(Eq. 101)

This is often employed in preference to Eq. (74).

We have so far ignored the effects of viscosity. The smallness (85) of E encourages an asymptotic approach to determining core flow. Conceptually, the core is divided into boundary layers, in which viscosity is significant, and the remaining mainstream in which viscosity does not act at leading order (see Eq. (97)). The most important boundary layers in rotating fluids are the Ekman layers, the thicknesses of which are of order  $\delta_v = (v/\Omega)^{1/2} = E^{1/2} \mathcal{L} \sim 0.1 \text{ m}$  (see Greenspan, 1968) and Core, boundary layers). The main task of the Ekman layers is to reconcile mainstream flows with the no-slip conditions (76) and (78). For example, the mainstream  $\overline{\mathbf{V}}$  obtained from Eq. (97) will not in general obey Eq. (76) at the latitude circle  $(s, z_1)$ , and an Ekman layer forms that smoothly joins  $\overline{\mathbf{V}}(s, z_1)$  to the angular velocity of the CMB (which is zero by choice of reference frame). Associated with the Ekman layer is a significant process called Ekman pumping. Although the solution of Eq. (97) had to satisfy Eq. (80) to leading order, mass conservation in the Ekman layer requires that, at the next order, a meridional mainstream flow  $\overline{\mathbf{V}}_{\mathcal{M}}(s,z)$  exists of order  $E^{1/2}\overline{\mathbf{V}}(s,z_1)$ .

This provides an alternative way of overcoming the difficulty encountered when  $\langle F_{\phi} \rangle \neq 0$ . The outward mass flux  $\langle V_s \rangle$  from C(s), represented by the second term in Eq. (98), can be balanced by an inward radial flux from the Ekman layers on the northern and southern radial caps,  $\mathcal{N}(s)$  and  $\mathcal{S}(s)$ , that form the ends of C(s); see Figure M152 where, for simplicity, complications from the rotation of the

**Figure M152** A typical geostrophic cylinder C(s) of radius *s* and the two spherical caps,  $\mathcal{N}(s)$  and  $\mathcal{S}(s)$ , at its ends. The flux of fluid out of C through the curved surface of radius *s* is equal to the pumping from the Ekman layers on the spherical caps (see text).

SIC have been evaded by ignoring its existence. Pumping through the caps vitiates Eq. (99) and leads to a modification of Eq. (100) in which a frictional term of order  $E^{1/2}\Omega \overline{V}_G$  is added to the left-hand side. This determines the spin-up timescale,  $\tau_{\rm spin}$  up, on which changes in the angular velocity of the mantle are transmitted to the fluid core. By comparing  $\partial_t \overline{V}_G$  with  $E^{1/2}\Omega \overline{V}_G$ , we see that  $\tau_{\rm spin} \mu_p \sim E^{-1/2}\Omega^{-1} \sim E^{1/2}\tau_\nu$ , or about  $10^5$  y. Here  $\tau_y$  is the viscous decay time:

$$\tau_v = \mathcal{L}^2 / v. \tag{Eq. 102}$$

For  $\mathcal{L} = 2 \times 10^6$  m and  $v_{\rm M} = 10^{-6}$  m<sup>2</sup> s<sup>-1</sup>, this is over  $10^{11}$  y; for  $v_{\rm T} \sim \eta$  it is  $O(\tau_n)$ .

The effects of viscosity are also felt in complicated shear layers that surround the TC whenever the SIC does not move with the mantle. For a discussion of these "Stewartson layers," see *Core, boundary layers*.

Viscosity also plays a crucial role in thermal convection. We shall consider only the case (85) of small E; for simplicity, we suppose that  $P_{\rm t} > 1$ . We ignore the SIC and suppose that heat sources are distributed uniformly throughout the core. If these sources are weak, they create only a spherically symmetric temperature distribution  $\overline{T}_{c}(r)$  that carries heat out of the core by thermal conduction. Although the associated density distribution is top-heavy, the diffusion of heat and momentum prevents convective instability; but, if the heat sources are gradually increased, weak convection occurs as soon as Ra exceeds a critical value,  $Ra_c$ . For  $Ra = Ra_c$ , the flow is asymmetric in structure, not axisymmetric. It takes the form of a "cartridge belt" of twodimensional cells, often called Taylor cells, regularly spaced round the axis of rotation and drifting in longitude about that axis (Roberts, 1968; Busse, 1970; Jones et al., 2000). Adjacent cells spin around their axes in opposite directions in a sequence of cyclonic and anticyclonic vortices, with vorticity respectively parallel and antiparallel to  $\Omega$ . (See Convection, nonmagnetic rotating.) Although, when Ra exceeds Ra<sub>c</sub>, nonlinear interactions create other flow components (including an easily excited geostrophic motion), the cartridge belt structure is maintained, provided Ra is not too large.
