# ENCYCLOPEDIA of GEOMAGNETISM AND PALEOMAGNETISM

Edited by David Gubbins and Emilio Herrero-Bervera ENCYCLOPEDIA of EARTH SCIENCES 3 ERIE 0

# ENCYCLOPEDIA of GEOMAGNETISM AND PALEOMAGNETISM

## **Encyclopedia of Earth Sciences Series**

#### ENCYCLOPEDIA OF GEOMAGNETISM AND PALEOMAGNETISM

#### **Volume Editors**

David Gubbins is Research Professor of Earth Sciences in the School of Earth and Environment, University of Leeds, UK. He did his PhD on geomagnetic dynamos in Cambridge, supervised by Sir Edward Bullard and has worked in the USA, and in Cambridge before moving to Leeds in 1989. His work has included dynamo theory and its connection with the Earth's thermal history, modeling the Earth's magnetic field from historical measurements, and recently the interpretation of paleomagnetic data. He is a fellow of the Royal Society and has been awarded the gold medal of the Royal Astronomical Society and the John Adam Fleming Medal of the American Geophysical Union for original research and leadership in geomagnetism.

Emilio Herrero-Bervera is Research Professor of Geophysics at the School of Ocean and Earth Science and Technology (SOEST) within the Hawaii Institute of Geophysics and Planetology (HIGP) of the University of Hawaii at Manoa, where he is the head of the Paleomagnetics and Petrofabrics Laboratory. During his career he has published over 90 papers in professional journals including Nature, JGR, EPSL, JVGR. He has worked in such diverse fields as volcanology, sedimentology, plate tectonics, and has done field work on five continents.

#### Aim of the Series

The *Encyclopedia of Earth Sciences Series* provides comprehensive and authoritative coverage of all the main areas in the earth sciences. Each volume comprises a focused and carefully chosen collection of contributions from leading names in the subject, with copious illustrations and reference lists.

These books represent one of the world's leading resources for the Earth sciences community. Previous volumes are being updated and new works published so that the volumes will continue to be essential reading for all professional Earth scientists, geologists, geophysicists, climatologists, and oceanographers as well as for teachers and students.

See the back of this volume for a current list of titles in the *Encyclopedia of Earth Sciences Series*. Go to http://www.springerlink.com/reference-works/ to visit the "Earth Sciences Series" on-line.

#### **About the Editors**

Professor Rhodes W. Fairbridge<sup>†</sup> has edited 24 encyclopedias in the Earth Sciences Series. During his career he has worked as a petroleum geologist in the Middle East, been a World War II intelligence officer in the SW Pacific, and led expeditions to the Sahara, Arctic Canada, Arctic Scandinavia, Brazil, and New Guinea. He was Emeritus Professor of Geology at Columbia University and was affiliated with the Goddard Institute for Space Studies.

Professor Michael Rampino has published more than 100 papers in professional journals including *Science, Nature*, and *Scientific American*. He has worked in such diverse fields as volcanology, planetary science, sedimentology, and climate studies, and has done field work on six continents. He is currently Associate Professor of Earth and Environmental Sciences at New York University and a consultant at NASA's Goddard Institute for Space Studies.

## Dedication

Jack A. Jacobs (1916-2003)

This encyclopedia is dedicated to the memory of Jack Jacobs. He made contributions across the whole spectrum of geomagnetism and paleomagnetism throughout a long and productive career. His books *Micropulsations, Geonomy, The Earth's Core and Geomagnetism, Reversals of the Earth's Magnetic Field*, and the four volumes of *Geomagnetism* intended to replace *Chapman & Bartels'* work of the same name, cover the field. For this encyclopedia he completed articles for both editors, on *disc dynamo* and *geomagnetic excursions*, and was working on *superchrons and changes in reversal frequency* at the end.

## Preface

Geomagnetism is the study of the earth's magnetic field: its measurement, variation in time and space, origins, and its use in helping us to understand more about our Earth. Paleomagnetism is the study of the record left in the rocks; it has contributed much to our understanding of the geomagnetic field's past behavior and many other aspects of geology and earth history. Both have applications, pure and applied: in navigation, in the search for minerals and hydrocarbons, in dating rock sequences, and in unraveling past geologic movements such as plate motions. The entire subject is a small subdiscipline of earth science, and our goal has been to cover it in fine detail at a level accessible to anyone with a general scientific education. We envisage the encyclopedia to be of greatest use to those starting in the subject and those needing to know something of the field for their own application, but the topic is broad and demanding—as we have become increasingly aware while editing the huge variety of contributionsand we also expect it to be of use to experts in geomagnetism or paleomagnetism who need to stray outside their own area of expertise, for nobody is an expert in the whole field

The scope of the encyclopedia is defined by the "GP" section of the American Geophysical Union: the magnetic field of internal origin. Over 25% of the membership of GP has contributed to this book. External sources of magnetic field are included insofar as they are used in solid earth geomagnetism—for example periodic external fields, because they induce electric currents in the earth that are useful in mapping deep electrically conducting regions—and articles are included on the ionosphere, magnetosphere, Sun, and planets. External geomagnetism as such is a separate discipline in most research establishments as well as the AGU, and is therefore not treated.

Geomagnetism is the oldest earth science, having its origins in simple human curiosity in the lodestone's ability to point north. It claims what most believe to be the first scientific treatise, William Gillbert's (q.v.) De Magnete published in 1601, the claim being founded on its use of deduction from experimental measurement. These innocent beginnings were soon to give way to the intensely practical business of finding one's way at sea, and during the European age of discovery understanding the geomagnetic field and using it for navigation became a burning challenge for early scientists. A century after the publication of De Magnete saw *Edmond Halley* (q.v.) in charge of a Royal Navy vessel making measurements throughout the Atlantic Ocean. Halley's plans to fix position more accurately by using the departures of magnetic north from geographic north were dashed by the geomagnetic field's rapid changes in time, and the longitude problem was of course finally solved by Harrison and his accurate clock, but the compass remains an essential aid to navigation to this day.

Almost a century after Halley's voyages James Cook was making even more accurate measurements throughout the oceans, and in the 19th century, *Alexander von Humboldt* (q.v.) and *Carl Friedrich Gauss* (q.v.) set up a network of magnetic observatories, the first example of international cooperation in a scientific endeavor. The data compilation continued throughout the 19th century, with typical Victorian tenacity, led by *Edward Sabine* (q.v.), and detailed magnetic measurements were made by James Clark Ross' expedition to the poles and the voyage of HMS Challenger. Impressive though these data collections were, with hindsight they yielded rather little in the way of pure scientific discovery or useful application. True, Sabine was to identify the source of magnetic storms with activity on the Sun and they left us a wonderful record of the geomagnetic field in the 19th century, laying the foundation for modern surveying, but the real prize of discovering the geomagnetic field's origin eluded them.

Developments in the early 20th century were to catapult geomagnetism into the limelight yet again, this time in the quest for minerals. Metal ores, base and noble, are concentrated in rocks rich in magnetites that are intensely magnetic. Geomagnetism provided a cheap and simple prospecting tool for exploration, and magnetic surveys proliferated on land as never before. Geomagnetism provides the cheapest geophysical exploration tool, and while it may lack the precision of seismic methods it continues to produce economic returns-a year's profit from one of the larger mines would probably pay for all the mapping in the last century. The discovery of electromagnetic induction provided yet another technique for exploring the earth's interior and even more significantly it changed prevailing views on the origin of geomagnetic fluctuations and the earth's main dipole field. The many theories for the origin proposed around the turn of the 20th century are reviewed here by David Stevenson (see Nondynamo theories). The only one to survive the test of time was Joseph Larmor's (q.v.) self-exciting dynamo theory, but even this was to suffer a half-century setback from Thomas Cowling's (q.v.) proof that no dynamo could sustain a magnetic field with symmetry about an axis, which the earth's dipole has to a good approximation.

Spectacular progress was being made at about this time by French physicists such as Bernard Brunhes and Motonori Matuyama (q.v.) from Japan trying to understand the magnetic properties of rocks. In founding the science of paleomagnetism they discovered they were able to determine the direction of the earth's magnetic field at the time of the rock's formation, and made the astonishing discovery that the magnetic field had reversed direction in the past. This discovery, like the dynamo theory, suffered a setback when, in the late 1950s, Seiva Uyeda and Takesi Nagata from Japan found that some minerals reverse spontaneously: this providing an alternative but rather mundane explanation that appealed to some in a skeptical scientific community. Evidence for polarity reversals mounted, thanks in great part to the efforts of Keith Runcorn (q.v.) and colleagues in England, but it required precise radiometric dating and access to a suite of rocks younger than 5 million years to establish a complete chronology and put the question beyond any doubt: this was finally achieved by Allan Cox (q.v.) and colleagues in the USA in 1960, on the eve of the plate tectonic revolution.

It is hard to comprehend the rapidity of scientific developments in earth science in the 1960s and impossible to underestimate the importance of the role played by paleomagnetism and geomagnetism in the development of plate tectonics. The establishment of polarity reversals came together with H. Hess' ideas on seafloor spreading and the discovery of magnetic stripes on the ocean floor to provide a means to map the age of the oceans (see *Vine-Matthews-Morley hypothesis*) and confirm once and for all Wegener's ancient ideas of continental drift. Even today, almost all our quantitative knowledge of plate movements in the geological past comes from paleomagnetism and geomagnetism and the development of a *reversal timescale* (*q.v.* see also Bill Lowrie's article *Geomagnetic polarity timescales*). 1958 saw at last the removal of Cowling's objection to the dynamo theory (see *Dynamo, Backus* and *Dynamo, Herzenberg*) and work done in Eastern Europe and the former Soviet Union provided the mathematical foundation and physical insight needed to understand how the geomagnetic field could be generated in the earth's liquid iron core (see *Dynamos, mean-field* and *Dynamo, Braginsky*). Improvements in instrumentation accelerated magnetic surveys: electromagnetic surveys became routine, proton magnetometers could be towed behind ships, and Sputnik ushered in the satellite era with a magnetometer on board.

So where does geomagnetism and paleomagnetism stand now? The dynamo theory of the origin of the main field still presents one of the most difficult challenges to classical physics, but computers are now fast enough to solve the equations of magnetohydrodynamics (q.v., seealso Geodynamo, numerical simulations) in sufficient complexity to reproduce many of the observed phenomena; we have just entered a decade of magnetic observation with two satellites operational at the time of writing and two more launches planned in the near future; there are more aircraft devoted to industrial magnetic surveying than ever before; electromagnetic methods have found application in the search for hydrocarbon reserves and have moved into the marine environment (see EM, marine controlled source). Paleomagnetists have begun to map details of the magnetic field during polarity transition (see Geomagnetic polarity reversals), discover many examples of excursions (aborted reversals), are mapping systematic departures from the simple dipole structure, and have automated laboratory techniques to the point where, in a single day, they can make more measurements of the absolute paleointensity of magnetic materials such as ceramics and basaltic rocks than pioneer Emile Thellier (q.v.) could do in a lifetime (see articles on Absolute paleointensity).

The subject divides naturally into the studies of magnetic fields with different origins—indeed these differences often make it difficult even for experts to understand other branches of their own subject! Those studying the permanent magnetization of the earth's crustal rocks deal

with magnetic fields that owe their origin to permanent magnetism at the molecular or crystal grain level; those in electromagnetic induction study magnetic fields caused by electric currents induced in solid rocks deep inside the Earth; while dynamo theorists deal with induction by a fluid, and have to deal with the additional complexity of advection by a moving conductor. Paleomagnetism naturally separates into studies of the magnetism of rocks, or rock magnetism (q.v.), laboratory methods for determining the ancient field, and the history of the ancient field itself. This classification dictated our choice of topics. Special effort has been made to represent the activities of the global network of permanent magnetic observatories. These rarely feature in scientific papers and most practicing scientists are unaware of the meticulous nature of the work and the dedication of those unsung heroes charged with maintaining standards over decades-a persistence rarely experienced in modern science. The observatory section represents, to our knowledge, the first attempt to draw together into one place this rather loosely connected international endeavor.

Our subject relates to many other disciplines, either because the geomagnetic field is a vital part of our environment and provides a surprising range of useful techniques to others, from stratigraphy through navigation to radio communication. Partly because of this, and partly in an effort to provide a self-contained volume, we have strayed outside the strict remit of GP. We have included articles on earth structure, particularly those esoteric regions (see for example articles on D") important for geomagnetism, and have covered the fascinating magnetic fields of other planets and satellites.

Our main thanks must go to our contributors, who have so willingly and energetically contributed to make this a truly community effort: we have received very few refusals to our requests to contribute. Alan Jones and Kathryn Whaler advised on electromagnetic induction, a difficult subject for both editors. Thanks go to Stella Gubbins for her unstinting work in organizing the geomagnetism articles and presenting them to the publishers in good order.

## A

#### AEROMAGNETIC SURVEYING

#### Introduction

Magnetic surveying is one of the earliest geophysical methods ever used, with a magnetic compass survey being used in Sweden in 1640 to detect magnetic iron ores. Once instruments were developed in the 1880s to measure the magnitude of the Earth's magnetic field, magnetic surveys applied to mineral exploration became widespread (Hanna, 1990). These early surveys, comprising magnetometer measurements taken on or close to the Earth's surface, were limited in extent and only small areas could be covered in any great detail. With the advent of an aircraft-mounted magnetometer system (Muffly, 1946), developed primarily for submarine detection during World War II, the number and areal coverage of magnetic surveys expanded rapidly. The first airborne magnetic or aeromagnetic survey for geological purposes was flown in 1945 in Alaska by the U.S. Geological Survey and the U.S. Navy. By the end of the 1940s, aeromagnetic surveys were being flown worldwide.

#### **Survey objectives**

Aeromagnetic surveys are flown for a variety of reasons: geologic mapping, mineral and oil exploration, and environmental and groundwater investigations. Since variations in the measured magnetic field reflect the distribution of magnetic minerals (mainly magnetite) in the Earth's crust and human-made objects, surveys can be used to detect, locate, and characterize these magnetic sources. Most surveys are flown to aid in surface geologic mapping, where the magnetic effects of geologic bodies and structures can be detected even in areas where rock outcrop is scarce or absent, and bedrock is covered by glacial overburden, bodies of water, sand, or vegetation. Magnetic surveys can also detect magnetic sources at great depth (tens of kilometers) within the Earth's crust, being limited only by the depth at which magnetic minerals reach their Curie point and cease to be ferrimagnetic. Broad correlations can be made between rock type and magnetic properties, but the relationship is often complicated by temperature, pressure, and chemical changes that rocks are exposed to (Grant, 1985). Nevertheless, determining the location, shape, and attitude of magnetic sources and combining this with available geologic information can result in a meaningful geological interpretation of a given area. Certain kinds of ore bodies may produce magnetic anomalies that are desirable targets for mineral exploration surveys. Although hydrocarbon reservoirs are not directly detectable by aeromagnetic surveys, magnetic data can be used to locate geologic structures that provide favorable conditions for oil/gas production and accumulation (Gibson and Millegan, 1998). Similarly, mapping the magnetic signatures of faults and fractures within water-bearing sedimentary rocks provides valuable constraints on the geometry of aquifers and the framework of groundwater systems.

#### Survey design

Aeromagnetic surveys are usually flown in a regular pattern of equally spaced parallel lines (flightlines). A series of control or tie-lines is also flown perpendicular to the flightline direction to assist in the processing of the magnetic field data set. The ratio of control to flightline spacing generally ranges from 3 to 10 depending on the desired data quality. Flightline spacing is dependent on the primary aim of the survey and governs the amount of detail in the measured magnetic field. For reconnaissance mapping of large regions (e.g., states, countries), where little or no knowledge of the magnetic field to be mapped is available, typical line spacings are 1.5 km in Australia and 0.8 km in Canada. Reconnaissance survey lines are usually oriented north-south or east-west. For smaller areas with similar financial resources available, these spacings can be reduced (e.g., 0.2 km in Sweden and Finland). For smaller regions, the line spacing is governed by the size of the target (geological structure, oil prospect, ore body) being investigated. For example, mineral exploration surveys generally have spacings in the range 50-200 m and are flown perpendicular to the dominant geologic strike direction, although directions no more than 45° from magnetic north are preferred because N-S wavelengths are shorter than E-W wavelengths at low and intermediate latitudes. For areas with distinct regions of differing geologic strike, costs may permit splitting the survey into several flight directions or a single compromise direction must be assigned.

The survey flying height is intimately related to flightline spacing with lower heights being more appropriate for closer line spacings. This is due to the rapid decrease in magnetic field intensity and increase in wavelength as a function of the distance from a magnetic source. Theoretical arguments suggest a line spacing to height ratio of 2 or less is desirable to accurately sample variations in the magnetic field (Reid, 1980). The majority of surveys, however, have ratios higher than this, i.e., 2.5 to 8. The minimum flight height is limited by government restrictions, safety considerations, and ruggedness of the terrain. Topographic variations also affect the mode of flying used in a survey. For geologic mapping and mineral exploration surveys, measurements are desirable at levels as close to the magnetic sources as possible, hence surveys are flown at a constant height (mean terrain clearance) above the ground surface. Prior to the availability of 2

real-time global positioning system (GPS) navigation, surveys over mountainous regions were flown at a constant altitude. Postsurvey processing of the collected magnetic field data could then be applied to artificially "drape" the measurements onto a surface at some specified mean terrain clearance. This can improve the resolution of magnetic anomalies that is degraded by flying at the higher constant altitude. However, current usage of more accurate navigational systems (GPS) now permits fixed-wing surveys to be flown along a preplanned artificial drape surface in regions of rugged topography. The drape surface is set to a constant height above ground level but is modified to take into consideration the climb and descent rate of the survey aircraft. Helicopters can also offer an alternative (usually costlier) to fixed-wing aircraft in mountainous areas.

#### Survey data acquisition

Along with measurements of the magnetic field, information relating to the accurate location and time of these recorded values is gathered. A modern data acquisition system (usually computer-based) records and archives magnetic, navigational, temporal, altitude, and perhaps aircraft attitude data. In addition, video recordings of the flight-path of the aircraft are made that may be used later to identify magnetic effects of human-made sources and to provide checks on navigation. Accurate synchronization of all the data streams is crucial for subsequent processing of the raw magnetometer data. Magnetometer measuring rates of 10 samples per second and navigational information at one sample per second are current norms.

#### Magnetometers

Compared to the first magnetometers used in the 1940s, the resolution and accuracy of magnetic field measurements have increased significantly. The early fluxgate magnetometers had resolutions of about 1 nT and noise envelopes of 2 nT (Horsfall, 1997). These instruments only produced relative measurements of the field and suffered from appreciable drift, possibly 10 nT/hr. Proton precession magnetometers followed with a resolution of 0.1 nT and noise envelope of 1 nT. These instruments measured the magnetic field intensity and had minimal drift. These have been superseded by the optically pumped, generally caesium-vapor magnetometers which have a resolution of 0.001 nT and a noise envelope of 0.005 nT. Such levels of measurement accuracy are not met in practice since errors arise through unremoved aircraft magnetic effects, navigation effects, and postsurvey data processing. Standard sampling rates of 10 samples per second coupled with aircraft speeds of 220-280 km/hr result in measurements at an interval of 6-8 meters.

Single magnetometer aircraft configurations simply produce measurements of the magnetic field intensity in the direction of the Earth's magnetic field. By adding extra sensors, various other quantities can be measured. Two vertically separated sensors can provide vertical magnetic gradient information while two wing-tip sensors allow measurement of the transverse horizontal magnetic gradient. Vertical gradient measurements have the advantage in effectively suppressing longer wavelength magnetic anomalies and providing a higher resolution definition of shorter wavelength features. This is crucial in surveys flown for mapping of near-surface geology where the longer wavelength effects of deep sources are of secondary interest. In theory, having two sensors also implies that a simple subtraction of the two measurements removes any temporal effects in the data. However, in practical applications, temporal effects may still be present in the data. Transverse (perpendicular to the flight path) gradient measurements are not generally used as a final interpretation product but can be exploited when the magnetic data are interpolated between the flight lines to produce a regular grid of magnetic field values (Hogg, 1989).

#### Aircraft noise

Magnetic noise caused by the survey aircraft arises from permanent and induced magnetization effects and from the flow of electrical currents. The permanent magnetization of the aircraft results in a heading error which is a function of the flightline direction. Induced magnetizations occur due to the motion of the aircraft in the Earth's magnetic field. These effects are partially reduced by mounting the magnetometer as far away as possible from the source of the noise, either on a boom mounted on the aircraft's tail or in a towed "bird" attached by a cable. Although the bird can be located several tens of meters below the aircraft, this may introduce orientation and positional errors if the sensor does not maintain a fixed location relative to the aircraft. For magnetometers mounted on the aircraft, a technique called compensation is needed to reduce remaining magnetic noise effects to an acceptable level. Modern aircraft are compensated by establishing and modeling the magnetic response of the aircraft to changes in its orientation. This is usually done prior to surveying by flying lines in each of the four local survey directions in an area of low magnetic field gradient and at high altitude, while carrying out several roll, pitch, and yaw maneuvers. The compensation may be done digitally in real time through the data acquisition system, or later as part of data processing. Information on the aircraft's orientation and direction is used to predict the resultant magnetic effect, which is then removed as the survey is flown, or later. The figure of merit, consisting of the sum of the absolute values of the magnetic effects of the roll, pitch, and yaw maneuvers for each of the four headings (12 values in all), can be as low as one nanotesla. Once a survey is started, the aircraft's noise level should be assessed repeatedly to ensure that the same level of data quality is maintained.

#### Positioning

No matter what accuracies are achieved in the magnetic field measurements, the value of the final survey data is dependent on accurate location of the measurement points. Traditional methods of navigation relied heavily on visual tracking using aerial photographs. The actual location of the flight path would be recovered manually by comparing these photographs with images from onboard video cameras. Synchronizing the data recording with the cameras would allow positioning of the magnetic field data. Electronic navigation systems were also used either to interpolate between visually located points or provide positioning information for offshore surveys. Positional errors of the order of hundreds of meters would not be unexpected. These techniques have been superseded by the introduction in the 1990s of GPS. Navigation using GPS relies on the information sent from an array of satellites whose locations are known precisely. Signals from a number of satellites are used to triangulate the position of the receiver in the aircraft so that its position is known for navigational purposes and to locate the magnetic field measurements. GPS systems also provide highly accurate time information that forms the basis for synchronizing each component of the data acquisition system. Positional accuracies of  $\pm 5$  m horizontally and  $\pm 10$  m vertically can be achieved with a single GPS receiver. These values can be improved upon by using another receiver and refining positions by making differential corrections. The added receiver is set up at the survey base and simultaneously collects data from the satellites as the survey is flown. Postsurvey processing of all the positional data reduces errors in information provided by the satellites and accuracies of  $\pm 2-4$  m can be achieved. Current surveys generally use real-time differential GPS navigation where the raw positional information is corrected as the data is being collected. The GPS location and altitude are also used to calculate (and subtract) the expected normal field for the location, as predicted by the International Geomagnetic Reference Field (IGRF). This generally removes an unhelpful regional component arising from the Earth's core field.

#### Temporal effects

Since the Earth's magnetic field varies temporally as well as spatially, time variations that occur over the period of surveying must be determined and removed from the raw measurements. The dominant effect

for airborne surveys is the diurnal variation, which generally has an amplitude of tens of nanotesla. Shorter time-period variations due to magnetic storms can be much larger (hundreds of nanotesla) and severe enough to prevent survey data collection. Data can also be degraded my micropulsations with short periods and amplitudes of several nanotesla. Monitoring of the Earth's field is an essential component of a survey in order to mitigate these time-varying effects. One or more base station magnetometers is used to track changes in the field during survey operations. When variations are unacceptably large, surveying is suspended and any flightlines recording during disturbed periods are reflown. The smoothly changing diurnal variation is removed from the data using tie-line leveling. Simply subtracting this variation from the measured data is not sufficient since diurnal changes may vary significantly over the survey area. Nonetheless, the recorded diurnal can be used as a guide in the leveling process. Tie-line leveling is based on the differences in the measured field at the intersection of flightlines and tie-lines. If the distance and hence the time taken to fly between these intersection points is small enough then it can be assumed that the diurnal varies approximately linearly and can be corrected for (Luyendyk, 1997).

#### Data display and interpretation

The final product resulting from an aeromagnetic survey is a set of leveled flightline data that are interpolated onto a regular grid of magnetic field intensity values covering the survey region. These values can be displayed in a variety of ways, the most common being a color map or image, where the magnetic field values, based on their magnitude, are assigned a specific color. Similarly, the values can be represented as a simple line contour map. Both kinds of representation can be used in a qualitative fashion to divide the survey area into subregions of high and low magnetizations. Since the data are available digitally, it is straightforward to use computer-based algorithms to modify and enhance the magnetic field image for the specific purpose of the survey. Transformation and filtering allows certain attributes of the data to be enhanced, such as the effects due to magnetic sources at shallow or deep levels, or occurring along a specified strike direction. More sophisticated methods may estimate the depths, locations, attitudes, and the magnetic properties of magnetic sources.

#### AGRICOLA, GEORGIUS (1494–1555)

Agricola, which seems to have been the classical academic pen-name for Georg Bauer, was born at Glauchau, Germany, on March 24, 1494 as the son of a dyer and draper. He studied at Leipzig University and trained as a doctor, and became Town Physician to the Saxon mining community of Chemnitz. His significance derives from his great treatise on metal mining, *De Re Metallica* (1556), or "On Things of Metal." This sumptuously illustrated work was a masterly study of all aspects of mining, including geology, stratigraphy, pictures of mineshafts, machinery, smelting foundries, and even the diseases suffered by miners.

Book III of *De Re Metallica* contains a description and details of how to use the miner's compass which, by 1556, seems to have been a well-established technical aid to the industry. Agricola drew a parallel between the miner's and the mariner's compass, saying that the direction cards of both were divided into equidistant divisions in accordance with a system of "winds." Agricola's compass is divided into four quadrants, with each quadrant subdivided into six: 24 equidistant divisions around the circle. And just as a mariner named the "quarters" of his compass from the prevailing winds, such as "Septentrio" for north and "Auster" for south, so the miner likewise named his underground metal veins, depending on the directions in which they ran.

Agricola also tells us that when prospecting for ore, a mining engineer would use his compass to detect the veins of metal underground and use it to plot their direction and the likely location of their strata across the landscape.

Agricola, it was said, always enjoyed robust health and vigor. He served as Burgomaster of Chemnitz on several occasions and worked tirelessly for the sick during the Bubonic Plague epidemic that ravaged Saxony during 1552–1553. Then, on November 21, 1555, he suddenly died from a "four days" fever.

#### ALFVÉN WAVES

#### Introduction and historical details

Alfvén waves are transverse magnetic tension waves that travel along magnetic field lines and can be excited in any electrically conducting fluid permeated by a magnetic field. *Hannes Alfvén* (q, v) deduced their existence from the equations of electromagnetism and hydrodynamics (Alfvén, 1942). Experimental confirmation of his prediction was found seven years later in studies of waves in liquid mercury (Lundquist, 1949). Alfvén waves are now known to be an important mechanism

4

for transporting energy and momentum in many geophysical and astrophysical hydromagnetic systems. They have been observed in Earth's magnetosphere (Voigt, 2002), in interplanetary plasmas (Tsurutani and Ho, 1999), and in the solar photosphere (Nakariakov et al., 1999). The ubiquitous nature of Alfvén waves and their role in communicating the effects of changes in electric currents and magnetic fields has ensured that they remain the focus of increasingly detailed laboratory investigations (Gekelman, 1999). In the context of geomagnetism, it has been suggested that Alfvén waves could be a crucial aspect of the dynamics of Earth's liquid outer core and they have been proposed as the origin of geomagnetic jerks (q.v.) (Bloxham et al., 2002). In this article a description is given of the Alfvén wave mechanism, the Alfvén wave equation is derived and the consequences of Alfvén waves for geomagnetic observations are discussed. Alternative introductory perspectives on Alfvén waves can be found in the books by Alfvén and Fälthammar (1963), Moffatt (1978), or Davidson (2001). More technical details concerning Alfvén waves in Earth's core can be found in the review article of Jault (2003).

#### The Alfvén wave mechanism

The restoring force responsible for Alfvén waves follows from two simple physical principles:

- Lenz's law applied to conducting fluids: "Electrical currents induced by the motion of a conducting fluid through a magnetic field give rise to electromagnetic forces acting to oppose that fluid motion."
- 2. Newton's second law for fluids: "A force applied to a fluid will result in a change in the momentum of the fluid proportional to the magnitude of the force and in the same direction."

The oscillation underlying Alfvén waves is best understood via a simple thought experiment (Davidson, 2001). Imagine a uniform magnetic field permeating a perfectly conducting fluid, with a uniform flow initially normal to the magnetic field lines. The fluid flow will distort the magnetic field lines (see Alfvén's theorem and the frozen flux approx*imation*) so they become curved as shown in Figure A1 (part (b)). The curvature of magnetic field lines produces a magnetic (Lorentz) force on the fluid, which opposes further curvature as predicted by Lenz's law. By Newton's second law, the Lorentz force changes the momentum of the fluid, pushing it (and consequently the magnetic field lines) in an attempt to minimize field line distortion and restore the system toward its equilibrium state. This restoring force provides the basis for transverse oscillations of magnetic fields in conducting fluids and therefore for Alfvén waves. As the curvature of the magnetic field lines increases, so does the strength of the restoring force. Eventually the Lorentz force becomes strong enough to reverse the direction of the fluid flow.

Magnetic field lines are pushed back to their undistorted configuration and the Lorentz force associated with their curvature weakens until the field lines become straight again. The sequence of flow causing field line distortion and field line distortion exerting a force on the fluid now repeats, but with the initial flow (a consequence of fluid inertia) now in the opposite direction. In the absence of dissipation this cycle will continue indefinitely. Figure A1 shows one complete cycle resulting from the push and pull between inertial acceleration and acceleration due to the Lorentz force.

Consideration of typical scales of physical quantities involved in this inertial-magnetic (Alfvén) oscillation shows that the strength of the magnetic field will determine the frequency of Alfvén waves. Balancing inertial accelerations and accelerations caused by magnetic field curvature, we find that  $U/T_A = B^2/L_A\rho\mu$  where U is a typical scale of the fluid velocity,  $T_A$  is the time scale of the inertial-magnetic (Alfvén) oscillation,  $L_A$  is the length scale associated with the oscillation, B is the scale of the magnetic field strength,  $\rho$  is the fluid density, and  $\mu$  is the magnetic permeability of the medium. For highly electrically conducting fluids, magnetic field changes occur primarily through advection (see Alfvén's theorem and the frozen flux approximation) so we have the additional constraint that  $B/T_A = UB/L_A$  or  $U = L_A/T_A$ . Consequently  $L_A^2/T_A^2 = B^2/\rho\mu$  or  $v_A = B/(\rho\mu)^{1/2}$ . This is a characteristic velocity scale associated with Alfvén waves and is referred to as the Alfvén velocity. The Alfvén velocity will be derived in a more rigorous manner and its implications discussed further in the next section.

Physical intuition concerning Alfvén waves can be obtained through an analogy between the response of a magnetic field line distorted by fluid flow across it and the response of an elastic string when plucked. Both rely on tension as a restoring force, elastic tension in the case of the string and magnetic tension in the case of the magnetic field line and both result in transverse waves propagating in directions perpendicular to their displacement. When visualizing Alfvén waves it can be helpful to think of a fluid being endowed with a pseudoelastic nature by the presence of a magnetic field, and consequently supporting transverse waves. Nonuniform magnetic fields have similar consequences for Alfvén waves as nonuniform elasticity of solids has for elastic shear waves.

#### The Alfvén wave equation

To determine the properties of Alfvén waves in a quantitative manner, we employ the classical technique of deriving a wave equation and then proceed to find the relationship between frequency and wavelength necessary for plane waves to be solutions. Consider a uniform, steady, magnetic field  $B_0$  in an infinite, homogeneous, incompressible, electrically conducting fluid of density  $\rho$ , kinematic viscosity v, and magnetic diffusivity  $\eta = 1/\sigma\mu$  where  $\sigma$  is the electrical conductivity.

**Figure A1** The Alfvén wave mechanism. In (a) an initial fluid velocity normal to the uniform field lines distorts them into the curved lines shown in (b) giving rise to a Lorentz force which retards and eventually reverses the fluid velocity, returning the field lines to their undisturbed position as shown in (c). The process of field line distortion is then reversed in (d) until the cycle is completed with the return to the initial configuration in (e).

We imagine that the fluid is perturbed by an infinitesimally small flow u inducing a perturbation magnetic field b. Ignoring terms that are quadratic in small quantities, the equations describing Newton's second law for fluids and the evolution of the magnetic fields encompassing Lenz's law are

$$\underbrace{\frac{\partial \boldsymbol{u}}{\partial t}}_{\text{acceleration}} = \underbrace{-\frac{1}{\rho} \nabla p}_{\substack{\text{Derived mechanical} \\ \text{and magnetic} \\ \text{pressure gradient}}} + \underbrace{\frac{1}{\rho \mu} (\boldsymbol{B}_{0} \cdot \nabla) \boldsymbol{b}}_{\text{Lorentz acceleration}} + \underbrace{\frac{v \nabla^{2} \boldsymbol{u}}{v_{\text{iscous}}}}_{\text{diffusion}},$$

$$\underbrace{\frac{\partial \boldsymbol{b}}{\partial t}}_{\text{Change in the magnetic field}} = \underbrace{(\boldsymbol{B}_{0} \cdot \nabla)\boldsymbol{u}}_{\text{Stretching of magnetic field by fluid motion}} + \underbrace{\eta \nabla^{2} \boldsymbol{b}}_{\text{Magnetic field by fluid motion}}$$
(Eq. 1)

Taking the curl  $(\nabla \times)$  of equation 1, we obtain an equation describing how the fluid vorticity  $\xi = \nabla \times \boldsymbol{u}$  evolves

$$\frac{\partial \xi}{\partial t} = \frac{1}{\rho \mu} (\boldsymbol{B}_{0} \cdot \nabla) (\nabla \times \boldsymbol{b}) + v \nabla^{2} \xi.$$
 (Eq. 3)

 $\nabla \times$  equation 2 gives

$$\nabla \times \frac{\partial \boldsymbol{b}}{\partial t} = (\boldsymbol{B}_0 \cdot \nabla) \boldsymbol{\xi} + \eta \nabla^2 (\nabla \times \boldsymbol{b}).$$
 (Eq. 4)

To find the wave equation, we take a further time derivative of equation 3 so that

$$\frac{\partial^2 \xi}{\partial t^2} = \frac{1}{\rho \mu} (\boldsymbol{B_0} \cdot \nabla) \left( \nabla \times \frac{\partial \boldsymbol{b}}{\partial t} \right) + \nu \left( \nabla^2 \frac{\partial \xi}{\partial t} \right), \quad (\text{Eq. 5})$$

and then eliminate **b** using an expression for  $\frac{1}{\rho\mu}(\mathbf{B_0} \cdot \nabla)(\nabla \times \partial \mathbf{b}/\partial t)$  in terms of  $\xi$  obtained by operating with  $\frac{1}{\rho\mu}(\mathbf{B_0} \cdot \nabla)$  on (4) and substituting for  $\frac{1}{\rho\mu}(\mathbf{B_0} \cdot \nabla)(\nabla \times \mathbf{b})$  from equation 3 which gives

$$\frac{1}{\rho\mu}(\boldsymbol{B}_{0}\cdot\nabla)\left(\nabla\times\frac{\partial\boldsymbol{b}}{\partial t}\right) = \frac{1}{\rho\mu}(\boldsymbol{B}_{0}\cdot\nabla)^{2}\boldsymbol{\xi} - \nu\eta\nabla^{4}\boldsymbol{\xi} + (\nu+\eta)\nabla^{2}\left(\frac{\partial\boldsymbol{\xi}}{\partial t}\right),$$
(Eq. 6)

which when substituted into equation 5 leaves the Alfvén wave equation

$$\frac{\partial^2 \xi}{\partial t^2} = \frac{1}{\rho \mu} (\boldsymbol{B_0} \cdot \nabla)^2 \xi - \nu \eta \nabla^4 \xi + (\nu + \eta) \nabla^2 \left(\frac{\partial \xi}{\partial t}\right).$$
 (Eq. 7)

The first term on the right hand side is the restoring force which arises from the stretching of magnetic field lines. The second term is the correction to the restoring force caused by the presence of viscous and ohmic diffusion, while the final term expresses the dissipation of energy from the system due to these finite diffusivities.

#### Dispersion relation and properties of Alfvén waves

Substituting a simple plane wave solution of the form  $\xi = Re\{\hat{\xi}e^{i(\mathbf{k}\cdot\mathbf{r}-\omega t)}\}\$ where  $\mathbf{k} = k_x \hat{\mathbf{x}} + k_y \hat{\mathbf{y}} + k_z \hat{\mathbf{z}}$  and  $\mathbf{r} = x \hat{\mathbf{x}} + y \hat{\mathbf{y}} + z \hat{\mathbf{z}}$  into the Alfvén wave equation 7, we find that valid solutions are possible provided that

$$\omega^2 = \left(\frac{B_0^2 (\boldsymbol{k} \cdot \hat{\boldsymbol{B}}_0)^2}{\rho \mu} - \nu \eta k^4\right) - i(\nu + \eta)k^2 \omega.$$
 (Eq. 8)

where  $\hat{B}_0 = B_0 / |B_0|$ .

$$\omega = \frac{-i(\nu+\eta)k^2}{2} \pm \sqrt{\frac{B_0^2(\mathbf{k}\cdot\hat{\mathbf{B}}_0)^2}{\rho\mu} - \frac{(\nu-\eta)^2k^4}{4}}.$$
 (Eq. 9)

In an idealized medium with  $v = \eta = 0$  there is no dissipation and the dispersion relation simplifies to

$$\omega = \pm v_{\rm A}(\boldsymbol{k} \cdot \hat{\boldsymbol{B}}_0), \tag{Eq. 10}$$

where  $v_A$  is the Alfvén velocity

$$v_{\rm A} = \frac{B_0}{\left(\rho\mu\right)^{1/2}}.$$
 (Eq. 11)

This derivation illustrates that the Alfvén velocity is the speed at which an Alfvén wave propagates along magnetic field lines. Alfvén waves are nondispersive because their angular frequency is independent of |k| and the phase velocity and the group velocity (at which energy and information are transported by the wave) are equal. Alfvén waves are however anisotropic, with their properties dependent on the angle between the applied magnetic field and the wave propagation direction.

An idea of Alfvén wave speeds in Earth's core can be obtained by inserting into equation 11 the seismologically determined density of the outer core fluid  $\rho = 1 \times 10^4$  kg, the magnetic permeability for a metal above its Curie temperature  $\mu = 4\pi \times 10^{-7}$  T<sup>2</sup> mkg<sup>-1</sup>s<sup>2</sup> and a plausible value for the strength of the magnetic field in the core (which we take to be the typical amplitude of the radial field strength observed at the core surface  $B_0 = 5 \times 10^{-4}$  T) giving an Alfvén velocity of  $v_A = 0.004$  m s<sup>-1</sup> or 140 km yr<sup>-1</sup>. The time taken for such a wave to travel a distance of order of the core radius is around 25 years. It should also be noted that Alfvén waves in the magnetosphere (where they also play an important role in dynamics) travel much faster because the density of the electrically conducting is very much smaller.

Considering Alfvén waves in Earth's core, Ohmic dissipation is expected to dominate viscous dissipation but for large scale waves will still be a small effect so that  $vk^2 \ll \eta k^2 \ll v_A^2$ . Given this assumption the dispersion relation reduces to

$$\omega = \frac{-i\eta k^2}{2} \pm v_{\rm A}(\mathbf{k} \cdot \hat{\mathbf{B}}_0) \tag{Eq. 12}$$

and the wave solutions have the form of simple Alfvén waves, damped on the Ohmic diffusion timescale of  $T_{\rm ohm} = 2/\eta k^2$ 

$$\xi = Re\left\{\hat{\xi}e^{i(\boldsymbol{k}\cdot\boldsymbol{r}\,\pm\,\nu_{\rm A}(\boldsymbol{k}\cdot\hat{\boldsymbol{B}}_{0})t)e^{-t/T_{\rm ohm}}}\right\}$$
(Eq. 13)

Smaller scale waves are rapidly damped out by Ohmic diffusion, while large scale waves will be the longer lived, so we expect these to have the most important impact on both dynamics of the core and the observable magnetic field.

## Observations of Alfvén waves and their relevance to geomagnetism

The theory of Alfvén waves outlined above is attractive in its simplicity, but can we really expect such waves to be present in Earth's core? In the outer core, rotation will have a strong influence on the fluid dynamics (see *Proudmann-Taylor theorem*). Alfvén waves cannot exist when the Coriolis force plays an important role in the force balance; in this case, more complex wave motions arise (see *Magnetohydrodynamic waves*). In addition convection is occurring (see *Core convection*) 6

and gives rise to a dynamo generated magnetic field (see *Geodynamo*), which is both time dependent and spatially nonuniform, while the boundary conditions imposed by the mantle are heterogeneous—these factors combine to produce a formidably complex system.

Braginsky (1970) recognized that, despite all these complications, a special class of Alfvén waves is likely to be the mechanism by which angular momentum is redistributed on short (decadal) timescales in Earth's core. He showed that when Coriolis forces are balanced by pressure forces, Alfvén waves involving only the component of the magnetic field normal to the rotation axis can exist. The fluid motions in this case consist of motions of cylindrical surfaces aligned with the rotation axis, with the Alfvén waves propagating along field lines threading these cylinders and being associated with east-west oscillations of the cylinders. Similarities to torsional motions familiar from classical mechanics led Braginsky to christen these geophysically important Alfvén waves torsional oscillations (see Oscillations, torsional). Although the simple Alfvén wave model captures the essence of torsional oscillations and leads to a correct order of magnitude estimate of their periods, coupling to the mantle and the nonaxisymmetry of the background magnetic field should be taken into account and lead to modifications of the dispersion relation given in equation 9. A detailed discussion of such refinements can be found in Jault (2003).

The last 15 years have seen a rapid accumulation of evidence suggesting that Alfvén waves in the form of torsional oscillations are indeed present in Earth's core. The transfer of angular momentum between the mantle and torsional oscillations in the outer core is capable of explaining decadal changes in the rotation rate of Earth (see Length of day variations, decadal). Furthermore, core flows determined from the inversion of global magnetic and secular variation data show oscillations in time of axisymmetric, equatorially symmetric flows which can be accounted for by a small number of spherical harmonic modes with periodic time dependence (Zatman and Bloxham, 1997). The superposition of such modes can produce abrupt changes in the second time derivative of the magnetic field observed at Earth's surface, similar to geomagnetic jerks (Bloxham et al., 2002). Interpreting axisymmetric, equatorially symmetric core motions with a periodic time dependence as the signature of torsional oscillations leads to the suggestion that geomagnetic jerks are caused by Alfvén waves in Earth's core. Further evidence for the wave-like nature of the redistribution of zonally averaged angular momentum derived from core flow inversions has been found by Hide et al. (2000), with disturbances propagating from the equator towards the poles. The mechanism exciting torsional oscillations in Earth's core is presently unknown, though one suggestion is that the time dependent, nonaxisymmetric magnetic field could give rise to a suitable fluctuating Lorentz torque on geostrophic cylinders (Dumberry and Bloxham, 2003).

Future progress in interpreting and understanding Alfvén waves in Earth's core will require the incorporation of more complete dynamical models of torsional oscillations (see, for example, Buffett and Mound, 2005) into the inversion of geomagnetic observations for core motions.

Alfvén's Theorem and the Frozen Flux Approximation Alfvén, Hannes Olof Gösta (1908–1995) Core Convection Geodynamo Length of Day Variations, Decadal Magnetohydrodynamic Waves Oscillations, Torsional Proudman-Taylor Theorem

#### ALFVÉN, HANNES OLOF GÖSTA (1908–1995)

Hannes Alfvén is best known in geomagnetism for the "frozen flux" theorem that bears his name and for the discovery of magnetohydrodynamic waves. He started research in the physics department at the University of Uppsala, where he studied radiation in triodes. His early work on electronics and instrumentation was sound grounding for his later discoveries in cosmic physics. When his book *Cosmical Electro-dynamics* (Alfvén, 1950) was published, the author was referred to by one of the reviewers—*T.G. Cowling* (*q.v.*)—as "an electrical engineer in Stockholm." All of Hannes Alfvén's scientific work reveals a profound physical insight and an intuition that allowed him to derive results of great generality from specific problems.

Hannes Alfvén is most widely known for his discovery (Alfvén, 1942) of a new kind of waves now generally referred to as *Alfvén waves* (*q.v.*). These are a transverse mode of magnetohydrodynamic waves, and propagate with the Alfvén velocity,  $B/(\mu_0 \rho)^{1/2}$ . In the Earth's core they occur as torsional oscillations as well as other Alfvén-type modes that are altered by the Coriolis force and have quite a different character (see *Magnetohydrodynamic waves*). Before Alfvén, electromagnetic theory and hydrodynamics were well developed but as separate

scientific disciplines. By combining them, Alfvén founded the new discipline of magnetohydrodynamics (q.v.). Magnetohydrodynamics is of fundamental importance for the physics of the fluid core of the Earth and other planets but has also much wider significance. It is indispensable in modern plasma physics and its applications, both in the laboratory (e.g., in fusion research) and in space (ionospheres, magnetospheres, the sun, stars, stellar winds and interstellar plasma). A famous theorem in magnetohydrodynamics, sometimes called the Alfvén theorem (q.v.), is that of frozen flux, which says that if the conductivity of a magnetized fluid is high enough, magnetic field and fluid motion are coupled in such a way that the fluid appears to be frozen to the magnetic field lines. This is a powerful tool in many applications, for example in studying motions in the Earth's core (see Core motions). The degree to which the frozen condition holds in a fluid is characterized by a dimensionless parameter called the Lundquist number,  $\mu_0 \sigma B \lambda / \rho^{1/2}$  (see Geodynamo, dimensional analysis and timescales). It was derived by Alfvén's student Stig Lundqvist (1952), who also was the first to prove the existence of magnetohydrodynamic waves experimentally in liquid metal (Lundqvist, 1949). In plasmas, especially space plasmas, there are important exceptions to the validity of the frozen field concept, and Alfvén himself vigorously warned against its uncritical use.

The second fundamental contribution by Alfvén was the guiding center theory, in which the average motion of a charged particle gyrating in a magnetic field is represented by the motion of its center of gyration. This theory dramatically simplified many plasma physics problems and laid the foundation of the adiabatic theory of charged particle motion.

Specific fields where Hannes Alfvén contributed were the theory of aurora and *magnetic storms* (q.v.) (Alfvén, 1939), evolution of the solar system, and cosmology (he was a vocal opponent to the Big Bang theory). His auroral theory was disputed, in particular by *S. Chapman* (q.v.), and was generally disregarded. But when direct measurements in space became possible, many of Hannes Alfvén's ideas, especially about the auroral acceleration process, were vindicated. A similar fate was shared by many of Hannes Alfvén's ideas. Even his discovery of the magnetohydrodynamic waves was not taken seriously until Enrico Fermi acknowledged the possibility of their existence. His early work in cosmic ray physics led Alfvén to predict the existence of a galactic magnetic field, but his prediction was universally rejected, and by the time the galactic field was discovered, his prediction was long forgotten.

Hannes Alfvén was active in public affairs throughout his life, particularly in opposition to nuclear proliferation. He was president of the Pugwash Conference from 1970 to 1975. He wrote several popular science books, including a work of science fiction under the pseudonym O. Johannesson. Further details of his life and a complete list of publications may be found in Pease and Lindqvist (1998); more details of his life are on http://public.lanl.gov/alp/plasma/people/alfven.html.

#### ALFVÉN'S THEOREM AND THE FROZEN FLUX APPROXIMATION

#### History

In 1942, *Hannes Alfvén* (q.v.) published a paper that announced the discovery of the wave that now bears his name (Alfvén, 1942; see *Alfvén waves*), and that is now often regarded as marking the birth of magneto-hydrodynamics or "MHD" for short (see *Magnetohydrodynamics*). In interpreting the waves in an associated paper (Alfvén, 1943, §4), he enunciated a result that has become known as "Alfvén's theorem":

Suppose that we have a homogeneous magnetic field in a perfectly conducting fluid.... In view of the infinite conductivity, every motion (perpendicular to the field) of the liquid in relation to the lines of force is forbidden because it would give infinite eddy currents. Thus the matter of the liquid is "fastened" to the lines of force...

Here, one understands "in relation" to mean "relative." Also the term "frozen" instead of "fastened" has been thought more appealing, and the theorem is frequently referred to as "the frozen flux theorem." It is now more often stated in terms such as

Magnetic flux tubes move with a perfectly conducting fluid as though frozen to it.

The reason why it is a little more accurate to refer to "magnetic flux tubes" rather than "magnetic field lines" will be explained in section "Formal demonstrations of the theorem."

According to Alfvén's theorem, a perfect conductor cannot gain or lose magnetic flux. The theorem therefore has no bearing on field generation by dynamo action although, to understand how the conductor initially acquired the magnetic flux threading it, one must recognize the imperfect conductivity of the fluid and reopen the dynamo question. Similarly, the theorem shows that it is impossible to change the topology of the field lines passing through the conductor in any way whatever and, to understand how a real fluid allows the field lines to sever and reconnect, one must recognize that its resistivity is finite.

#### Underlying physics

Although MHD phenomena usually require the coupled equations of fluid dynamics and electromagnetism (em) to be solved together, all that is needed to establish Alfvén's theorem is the "kinematic" part of the relationship; the fluid velocity  $\mathbf{V}$  is regarded as given and the magnetic field  $\mathbf{B}$  is found by solving

$$\nabla \cdot \mathbf{B} = 0 \tag{Eq. 1}$$

and the em induction equation:

$$\partial_t \mathbf{B} = \nabla \times (\mathbf{V} \times \mathbf{B}) + \eta \nabla^2 \mathbf{B}.$$
 (Eq. 2a)

Here

γ

$$\eta = 1/\mu_0 \sigma \tag{Eq. 2b}$$

is the "magnetic diffusivity" (assumed uniform),  $\sigma$  being the electrical conductivity, and  $\mu_0$  the permeability of free space: SI units are used here. In kinematic dynamo theory, V is sought for which (Eq. 2a) has self-sustaining solutions B (satisfying the appropriate boundary conditions). There is also considerable geophysical interest in the inverse problem of inferring V from the B observed at the Earth's surface; see section "The inverse problem."

Alfvén's theorem follows from (Eq. 2a) in the zero diffusion limit:

$$\partial_t \mathbf{B} = \nabla \times (\mathbf{V} \times \mathbf{B}) \quad \text{for} \quad \sigma = \infty$$
 (Eq. 3)

A solution to this equation can be regarded as the first term in an expansion of the field in inverse powers of a magnetic Reynolds number. Such an expansion is, in the parlance of perturbation theory, "singular" since the term  $\eta \nabla^2 \mathbf{B}$  involving the highest spatial derivatives of B has been ejected from (Eq. 2a). The highest derivatives reassert themselves in the structure of boundary layers; see Core, boundary layers and the section "The inverse problem".

Equation (3) has the same form as the equation that governs the vorticity  $\boldsymbol{\omega} = \nabla \times \mathbf{V}$  in an inviscid fluid of uniform density driven by conservative forces:

$$\partial_t \boldsymbol{\omega} = \nabla \times (\mathbf{V} \times \boldsymbol{\omega}).$$
 (Eq. 4)

Kelvin's theorem follows from (Eq. 4):

Vortex tubes move with an inviscid fluid of uniform density as though frozen to it.

Clearly, Alfvén's theorem is the MHD analog of Kelvin's theorem. There is however a significant difference: (Eq. 3) is a linear equation that determines the evolution of **B** from an initial state for given **V**; (Eq. 4) is a nonlinear relationship between  $\nabla \times \mathbf{V}$  and  $\mathbf{V}$ .

#### Formal demonstrations of the theorem

Some readers, with as firm a grasp of em theory as Alfvén, will find his explanation of the theorem, given in the section "History", sufficiently persuasive. Others, who have a grounding in classical fluid mechanics, may be satisfied by the analogy with Kelvin's theorem, although that theorem too requires proof. Yet others, with a more mathematical bent, may prefer a direct demonstration, such as the one given below.

Let  $\Gamma(t)$  be an arbitrary curve "frozen" to the fluid as it moves, and let ds(t) be an infinitesimal element of  $\Gamma$  whose ends are situated at  $\mathbf{s}(t)$  and  $\mathbf{s}(t) + \mathbf{ds}(t)$ . The fluid velocities at these points are  $\mathbf{V}(\mathbf{s}(t),t)$ and  $\mathbf{V}(\mathbf{s}(t) + \mathbf{ds}(t), t) = \mathbf{V}(\mathbf{s}(t), t) + \mathbf{ds}(t) \cdot \nabla \mathbf{V}(\mathbf{s}(t), t)$ . At a time dt later, the ends are therefore situated at s + Vdt and s + ds + ds $[\mathbf{V} + d\mathbf{s} \cdot \nabla \mathbf{V}] dt$ . It follows that

$$d_t(\mathbf{ds}) = \mathbf{ds} \cdot \nabla \mathbf{V},\tag{Eq. 5a}$$

where

$$d_t = \partial_t + \mathbf{V} \cdot \nabla \tag{Eq. 5b}$$

is the "motional" or "Lagrangian" derivative, i.e., the time derivative following the fluid motion.

In the first application of this kinematic result, we combine it with (Eq. 3), written in the form

$$d_t \mathbf{B} = \mathbf{B} \cdot \nabla \mathbf{V} - \mathbf{B} \nabla \cdot \mathbf{V}, \tag{Eq. 6a}$$

where we have used (Eq. 1) and a vector identity. The result is

$$d_t(\mathbf{B} \times \mathbf{ds}) = -(\mathbf{B} \times \mathbf{ds})_i \nabla V_i, \quad \text{for} \quad \sigma = \infty, \tag{Eq. 6b}$$

where the summation convention applies to the repeated suffix *j*. It follows that

$$\mathbf{B} \times \mathbf{ds} = \mathbf{0}$$
 at  $t = 0 \Rightarrow \mathbf{B} \times \mathbf{ds} = \mathbf{0}$  for all  $t$ .  
(Eq. 6c)

A magnetic field line is a curve every element ds of which is parallel to **B**. According to (Eq. 6c), if  $\Gamma$  is initially a field line, it is always a field line. This establishes that magnetic field lines move with a perfectly conducting fluid, the weak form of Alfvén's theorem. The conclusion would still follow if a source term parallel to B were added to the right-hand side of (Eq. 3). The absence of this term leads to the stronger form of the theorem given below.

For the second application of (Eq. 5a), let  $\Sigma(t)$  be an arbitrary (open) surface "frozen" to the fluid as it moves and let dS(t) be an infinitesimal element of  $\Sigma$  having the shape of a parallelogram, two adjacent sides being along curves  $\Gamma^{(1)}$  and  $\Gamma^{(2)}$ , so that

$$\mathbf{dS} = \mathbf{ds}^{(1)} \times \mathbf{ds}^{(2)},\tag{Eq. 7a}$$

where  $ds^{(1)}$  and  $ds^{(2)}$  are elements of  $\Gamma^{(1)}$  and  $\Gamma^{(2)}$  to which (Eq. 5a) applies, leading to the result

$$d_t(\mathbf{dS}) = \mathbf{dS}(\nabla \cdot \mathbf{V}) - \mathbf{dS}_j \nabla V_j.$$
 (Eq. 7b)

It follows from (Eq. 6a) and (Eq. 7b) that

$$d_t(\mathbf{B} \cdot \mathbf{dS}) = 0, \quad \text{for} \quad \sigma = \infty,$$
 (Eq. 8a)

and therefore

$$\mathbf{B} \cdot \mathbf{dS} = \mathbf{0}$$
 at  $t = 0 \Rightarrow \mathbf{B} \cdot \mathbf{dS} = \mathbf{0}$  for all  $t$ . (Eq. 8b)

A magnetic surface, M(t), is a surface composed of field lines, so that every surface element, dS, is perpendicular to B. According to (Eq. 8b), if M is initially a magnetic surface, it is always a magnetic surface. This conclusion also follows from (Eq. 6c).

To obtain the stronger result, let *M* be a *magnetic flux tube*. This is a bundle of magnetic field lines and is therefore bounded by a magnetic surface for all t. Let  $\Sigma(t)$  be a cross-section of the tube, i.e., a surface that cuts across every magnetic field line within the tube. The net magnetic flux through  $\Sigma$ ,

$$m = \int_{\Sigma(t)} \mathbf{B} \cdot \mathbf{dS},\tag{Eq. 9}$$

is called the "strength" of the tube. It is easily seen from (Eq. 1) that m is the same for every cross-section  $\Sigma$ . Equation (8b) shows further that *m* is time independent:

$$d_t \int_{\Sigma(t)} \mathbf{B} \cdot \mathbf{dS} = 0, \quad \text{for} \quad \sigma = \infty.$$
 (Eq. 10a)

This conservation of flux is the strong form of Alfvén's theorem.

It is worth observing that, according to Eqs. (1), (3), and Stokes' theorem, (Eq. 10a) may also be written in Eulerian terms as

$$\int_{\Sigma(t)} (\partial_t \mathbf{B}) \cdot \mathbf{dS} + \oint_{\Gamma(t)} \mathbf{B} \cdot (\mathbf{V} \times \mathbf{ds}) = 0, \quad \text{for} \quad \sigma = \infty,$$
(Eq. 10b)

9

where  $\Gamma(t)$  is the perimeter of  $\Sigma(t)$ . If  $\Sigma$  were fixed in space, the first term on the left-hand side of (Eq. 10b) would be the rate of increase of the flux through  $\Sigma$ . The  $\mathbf{V} \times \mathbf{ds}$  in the second term is the rate at which the vector area of  $\Sigma$  increases as  $\mathbf{ds}$ , on the perimeter  $\Gamma$  of  $\Sigma$ , is advected by the fluid motion  $\mathbf{V}$ . The associated rate at which  $\Sigma$  gains magnetic flux is therefore  $\mathbf{B} \cdot (\mathbf{V} \times \mathbf{ds})$ .

#### The inverse problem

Even though no material, apart from superconductors, can transmit electricity without ohmic loss, Alfvén's theorem is often useful in visualizing MHD processes. For example, in rapidly rotating convective systems such as the Earth's core, the Coriolis force deflects the rising and falling buoyant streams partially into the zonal directions, and creates zonal field. This " $\omega$ -effect" is readily pictured with the help of Alfvén's theorem: The field lines of the axisymmetric part of **B**, for example, are dragged along lines of latitude by the zonal shear, i.e., the shear adds a zonal component to **B**. Alfvén's theorem is also helpful in attacking the problem of inferring unobservable fluid motions from observed magnetic field behavior, and it is this application that will be considered now: **B** and  $\partial_t$ **B** will be assumed known and **V** will be sought.

The electrical conductivity of the mantle is so low that the toroidal electric currents induced in the mantle by the changing MHD state of the core are small. If they are neglected, the magnetic field created by the core is, everywhere in the mantle and above, a potential field that can be expressed as a sum of internal spherical harmonics with time-varying Gauss coefficients whose values are obtained by analyzing observatory and satellite data (see *Time-dependent models of the geomagnetic field*). This sum can be used to compute **B** at the coremantle boundary (CMB) but the larger the order *n* of the spherical harmonic the more rapidly it increases with depth into mantle. The energy spectrum, which is dominated by the dipolar components at the Earth's surface, is almost flat at the CMB (see *Geomagnetic spatial spectrum*). Clearly, small errors that arise in the large *n* coefficients when the data at the Earth's surface is analyzed can have serious consequences when **B** is extrapolated to the CMB.

Although **B** is continuous across the CMB, its radial derivative is not. Extrapolation cannot therefore provide information about  $\nabla^2 \mathbf{B}$ in the core, even at its surface. If the unknown  $\eta \nabla^2 \mathbf{B}$  in (Eq. 2a) is significant, it is impossible to learn anything about **V** from the observed **B**. If however  $\eta \nabla^2 \mathbf{B}$  is small enough, (Eq. 3) may be a good first approximation to (Eq. 2a), and the extrapolated **B** and  $\partial_t \mathbf{B}$  may yield information about **V** (Roberts and Scott, 1965).

The first task is to assess the importance of  $\eta \nabla^2 \mathbf{B}$  in (Eq. 2a), restricting attention to the large scales *L* of **B** corresponding to the Gauss coefficients ( $n \leq 12$ ) that are accessible. The three terms appearing in (Eq. 2a) are respectively of order *B*/*T*, *V<sub>S</sub>B*/*L*, and  $\eta B/L^2$ , where *T* is the timescale of the large-scale **B**. The third term is small compared with one or both of the other terms if

$$V_S > \eta/L \approx 5 \times 10^{-6} \,\mathrm{m \ s^{-1}}$$
 and/or  $T << L^2/\eta \approx 2 \times 10^3 \,\mathrm{yr},$   
(Eq. 11a, b)

where we have taken  $\eta = 2 \text{ m}^2 \text{ s}^{-1}$  and  $L = R_1/10$  as representative, where  $R_1$  is the core radius. Many scales of geophysical interest satisfy (Eq. 11), and the adoption of (Eq. 3) in place of (Eq. 2a) seems plausible for these scales. In geomagnetic data analysis this is known as "the frozen flux hypothesis" or "the frozen flux approximation."

The plethora of geodynamo simulations that have been performed over the past decade have afforded many opportunities of comparing different methods of solving the inverse problem, and in particular of testing the frozen flux hypothesis, without having to incur the inaccuracies of downward extrapolation. Roberts and Glatzmaier (2000) used one of their highly numerically resolved simulations to evaluate the unsigned flux,

$$U = \int_{\rm CMB} |B_r| dS, \tag{Eq. 12}$$

at three epochs separated by about 150 years; see also Glatzmaier and Roberts (1996). It follows from (Eq. 10a) that U should be constant. They found instead that U varied, though by less than 4% over the  $\sim$  300 years. In deriving this result, they pretended that, as for the real Earth, only the harmonics of degree n less than 13 were available in calculating U but, even when all harmonics for  $n \le 36$  were used, U changed by only about 8% over the 300 year interval. (The slightly increased variability is expected since (Eq. 11) are less well obeyed for smaller L, i.e., larger n.)

It was already noticed earlier that (Eq. 3) governs the leading (i.e., largest) term in a singular expansion of **B** in powers of parameters such as  $\eta/VL$  and  $\eta T/L^2$ , which are small according to (Eq. 11). In fluid mechanics, such expansions are often said to be "mainstream expansions," since they apply in the main body of the fluid, away from thin diffusive "boundary layers." The nature of the boundary layers was discussed by Roberts and Scott (1965) but more realistically by Backus (1968) and by Hide and Stewartson (1972) (see *Core, boundary layers*). See also Braginsky and Le Mouël (1993) and Gubbins (1996). The  $\eta \nabla^2 \mathbf{B}$  term in (Eq. 2a) is important in the boundary layers since it, and it alone, can adjust the mainstream **B** to conditions imposed by the mantle. The nature of the singular expansion of **B** becomes important in interpreting what is meant by "the core surface velocity."

In the most convenient frame of reference, the one used here that rotates with the mantle,  $\mathbf{V} = \mathbf{0}$  on the CMB (the no-slip condition). But both **V** and **B** change rapidly across the diffusive boundary layer at the CMB. This layer adjusts the (zero) **V** and the extrapolated **B** on the CMB to the mainstream **V** and **B** governed by core MHD. It is the velocity,  $\mathbf{V}_{S}$ , on the lower surface *S* of this boundary layer that is the core surface velocity sought. The thickness,  $\delta$ , of the boundary layer is small compared with the scales *L* of **B** that can be extracted from the geomagnetic data. The normal components of these large-scale **B** and **V** cannot change substantially within the distance  $\delta$ . This has two consequences. First, since  $V_r = 0$  on the CMB,

$$V_r = 0, \quad \text{on} \quad S. \tag{Eq. 13}$$

Second, by (Eq. 1), the  $B_r$  and  $\partial_t B_r$  extrapolated to the CMB are also the  $B_r$  and  $\partial_t B_r$  on S. These are related since, according to (Eq. 3),

$$\partial_t B_r + \nabla_{\mathrm{H}} \cdot (B_r \mathbf{V}_S) = 0, \text{ on } S \text{ for } \sigma = \infty,$$
 (Eq. 14)

where  $\nabla_{\rm H}$  is the horizontal gradient operator.

Once (Eq. 14) is accepted, instead of the corresponding equation derived from (Eq. 2a), questions of nonexistence and nonuniqueness arise. By (Eq. 10a)

$$d_t \int_{\Sigma(t)} B_r \, \mathrm{d}S = 0, \tag{Eq. 15a}$$

for every co-moving surface area  $\Sigma(t)$  on *S*. Lacking knowledge of  $V_s$ , it is impossible to test (Eq. 15a) for every  $\Sigma(t)$ , but a more limited objective can be reached. One may transform (Eq. 15a), as in (Eq. 10b), into

$$\int_{\Sigma(t)} (\partial_t B_r) \mathrm{d}S + \oint_{\Gamma(t)} B_r(\hat{\mathbf{n}} \cdot \mathbf{V}_S) \mathrm{d}s = 0, \quad \text{for } \sigma = \infty,$$
(Eq. 15b)

where  $\hat{\mathbf{n}}$  is the (horizontal) normal vector to  $\Gamma(t)$ , directed outwards along *S* from the interior of  $\Sigma(t)$ . [Equation (15b) also follows by integrating (Eq. 14) over  $\Sigma(t)$  and applying the two-dimensional divergence theorem.] Let  $\Gamma(t)$  be a *null flux curve* (NFC), which is a closed curve on *S* defined by

$$B_r = 0, \quad \text{on an NFC.} \tag{Eq. 16a}$$

Equation (15b) gives (Backus, 1968)

$$\int_{\Sigma(t)} (\partial_t B_r) \mathrm{d}S = 0, \quad \text{on an NFC.}$$
 (Eq. 16b)

This, in contrast to (Eq. 15a), can easily be tested for the given  $\partial_t B_r$ . By (Eq. 1), there is at least one NFC on *S*, the magnetic equator, which separates the southern magnetic "hemisphere," where most (or conceivable all) of the magnetic flux leaves the core, from the northern magnetic "hemisphere" where it re-enters the core. Other smaller NFC can, and apparently do exist within these hemispheres. Because their scale *L* is smaller, (Eq. 11a,b) and therefore (Eq. 16b) are less well satisfied.

One must expect that observations will be inconsistent with (Eq. 16b) for three reasons. First, the analysis of geomagnetic data into spherical harmonic components is not completely accurate; second, the downward extrapolation to the CMB introduces errors that increase with the spherical harmonic number n of the Gauss coefficients; third, because  $\sigma$  is not infinite in the core, the magnetic flux through  $\Sigma(t)$ is not perfectly conserved anyway! At first sight, the third reason might seem to be the most significant, in view of the current rapid decrease in the axial dipole moment of the Earth (about 8% over the last 150 years). One should not forget however that the frozen flux hypothesis implies Alfvén's theorem, according to which the secular variation is caused by the rearrangement of the existing field lines already entering and leaving the core. Such a rearrangement can easily accommodate such a rapid change in dipole moment without contradicting the hypothesis; see Bondi and Gold (1950). The possibility that the other two reasons are mainly responsible for violations of (Eq. 16b) remains open. This led Roberts and Scott (1965) to suggest that the frozen field constraint should be turned into an advantage. They proposed that future spherical harmonic analyses of the geomagnetic field should impose the constraint both to improve the spherical harmonic representation of **B** and to obtain a finite  $V_S$  as a by-product. For implementations of this idea, see Benton et al. (1987), Constable et al. (1993) and O'Brien et al. (1997); see also Benton E.R.

When (Eq. 16b) is satisfied, a finite  $V_S$  exists but it is not unique. This was noted by Roberts and Scott (1968) and is most easily seen from the Backus (1968) representation of  $V_S$ :

$$B_r \mathbf{V}_S = \nabla_{\mathbf{H}} \phi - \hat{\mathbf{r}} \times \nabla_S \psi, \qquad (\text{Eq. 17a})$$

where  $\hat{\mathbf{r}}$  is the radial unit vector. It follows from (Eq. 14) that

$$\nabla_{\rm H}^2 \phi = -\partial_t B_r, \tag{Eq. 17b}$$

from which  $\phi$  can be determined uniquely from the given  $\partial_t B_r$ , but  $\psi$  remains largely undetermined, though Backus (1968) showed how a little information about  $\psi$  might be extracted.

The possibility of using the horizontal components of **B** to obtain information about  $V_S$  was mooted by Roberts and Scott (1965) and was the subject of a penetrating analysis by Backus (1968). There is a fundamental difficulty: when integrated across the boundary layer at the CMB, the electric currents (density **J**), which are horizontal on the CMB, are equivalent to a surface current **I**, and

$$\mathbf{B}_{S} = \mathbf{B}_{\text{CMB}} + \mu_{0} \hat{\mathbf{r}} \times \mathbf{I}; \tag{Eq. 18}$$

(see *Core, boundary layers*). Evidently, it is impossible to determine  $B_S$  from  $B_{CMB}$  without knowledge of I. Nevertheless Barraclough *et al.* (1989), making use of an interpretation of Backus' analysis due to Moffatt, undertook a study that led them to believe that I is small enough to be neglected. The resulting  $V_S$  was, however, unrealistic.

It was mentioned above that the secular variation is, according to the frozen flux hypothesis, created by the rearrangement of preexisting magnetic flux to and from the core. The alternative process of "flux creation" relies on ohmic diffusion. The rapid decrease in the Earth's axial dipole has been attributed by Bloxham and Gubbins (1985) to flux creation, more specifically to growing reversed flux patches within the southern magnetic hemisphere. They proposed to model this process by determining **V** from (Eq. 2a) rather than (Eq. 3).

One mechanism that has attracted particular attention is conversion of the otherwise undetectable toroidal field in the core into poloidal field that escapes into the mantle. The idea is analogous to the ejection of the large subsurface zonal magnetic field in the sun into the solar atmosphere, with the creation of a sunspot pair on the solar surface. This can be modeled directly by Alfvén's theorem since the solar surface is a "free" surface on which  $V_r$  may be nonzero; after a flux tube erupts, the fluid within the tube can fall back under gravity to the solar surface, leaving the erupted field in the solar atmosphere. This is not possible for the Earth's core by (Eq. 13). The flux can be ejected only by diffusion, i.e., by violating Alfvén's theorem through finite  $\sigma$ . An upwelling crowds field lines close to the CMB, and the enhanced J that results promotes field diffusion between the CMB and mantle. This idea was modeled in several publications, starting with Coulomb (1955), Allen and Bullard (1958, 1966), Nagata and Rikitake (1961), Hide and Roberts (1961), and Rikitake (1967), and was more recently revived by Bloxham (1986) and Drew (1993). It was originally motivated first by the belief that the  $\omega$ -effect (see above) is so potent that the toroidal field dominates the poloidal field everywhere in the core (except at the CMB), and second by the thought that even the slow diffusion of a sufficiently strong toroidal field could create significant secular variation. Recent geodynamo simulations have suggested however that the Lorentz force so strongly opposes the  $\omega$ -effect that the toroidal and poloidal fields have similar magnitudes. This makes toroidal flux expulsion models less attractive.

#### ANELASTIC AND BOUSSINESQ APPROXIMATIONS

#### Introduction

#### Background

The anelastic and Boussinesq approximations are simplifications of the system of equations governing buoyantly driven flows. The Boussinesq equations were the first to appear in print. In an influential paper on thermal convection, Rayleigh (1916) attributed them, without reference, to Boussinesq and the name has stuck, even though they had previously been employed by Oberbeck (1888). Although variations in density are the very essence of buoyancy, they are neglected everywhere in the Boussinesq equations "except in so far as they modify the action of gravity" (Rayleigh, 1916), i.e., the density is assumed to be constant except in the buoyancy force. This retains the essential physics with a minimum of complexity. The Boussinesq approximation usually performs well in modeling convection in laboratory conditions in which variations in pressure scarcely affect the density of the fluid. It is, however, unsatisfactory for large systems like the Earth's core, the lower part of which is significantly compressed by the overlying material. The Boussinesq approximation may then introduce unacceptable errors. A pressure dependence of density was first incorporated into the thermal convection equations by Spiegel and Veronis (1960) and, for atmospheric convection, by Ogura and Phillips (1962) (see also Gough, 1969). Braginsky (1964) introduced the anelastic approximation (calling it "the inhomogeneous model") for studying convection in a two-component fluid modeling the Earth's core. In what follows, "AA" is frequently used as an abbreviation for the "anelastic approximation" (see the section "The anelastic approximation (AA)"), "BA" for the "Boussinesq approximation" (see the section "The Boussinesq approximation (BA)"), and "CA" as a general term to describe these "convective approximations" and others to be described below.

Although none of the CAs can be used if the convective velocities are comparable with the speed of sound, one or another is applicable to convection in the laboratory, the oceans, the atmosphere, and the Earth's mantle and fluid core (see *Core convection*).

The following sections aim to describe the essence of the CAs with a minimum of inessentials. There are several simplifications:

- a. Only a one-component fluid is considered. In many geophysical systems, this is too restrictive; convection is complicated by the effects of salinity in the ocean, water vapor in the atmosphere, phase transitions in the mantle, and light admixture in the core (see *Convection, chemical*).
- b. The system under consideration is supposed to be driven steadily, by constant heat sources within it and/or constant temperature differences between its upper and lower boundaries (both assumed horizontal and stationary); this does not imply that the convection is steady.
- c. Variations in the gravitational acceleration, **g**, created by the density differences associated with the convection are ignored; **g** is assumed to be time-independent and specified in terms of a potential U so that  $\mathbf{g} = -\nabla U$ . The more general self-gravitational case, in which **g** is created by the mass of the fluid itself and varies as the convection redistributes mass, is not treated here.
- d. The inertial frame is used; there are no Coriolis or centripetal accelerations. There are no magnetic fields and associated Lorentz forces. For more general cases, see *Convection, nonmagnetic rotating; Magnetoconvection; Magnetohydrodynamics; Geodynamo.*

For the Earth's core, restrictions (a)-(d) are applied in papers by Braginsky (1964) and Braginsky and Roberts (1995, 2003). In particular, the slow evolution of the Earth, which has significant implications for core dynamics, is allowed for by a minor extension of the methods presented here. For mantle convection, see Davis and Richards (1992) and Schubert *et al.* (2001); phase transitions are considered in Tackley (1997). For oceanic and atmospheric convection, see Kamenkovich (1977), Gill (1982), and Monin (1990). For astrophysical convection, see Lantz and Fan (1999).

#### Basic equations

In their primitive, unapproximated form, the laws governing conservation of mass, momentum, and energy may be written as (e.g., Landau and Lifshitz, 1987)

$$\partial_t \rho = -\nabla \cdot (\rho \mathbf{V}),\tag{Eq. 1}$$

$$\rho d_t \mathbf{V} = -\nabla P + \rho \mathbf{g} + \mathbf{F}^{\mathsf{v}},\tag{Eq. 2}$$

$$\rho d_t \mathcal{E}^{\mathbf{I}} + \nabla \cdot \mathbf{I}^q = -P \nabla \cdot \mathbf{V} + Q^{\mathbf{R}} + Q^{\mathbf{v}}, \qquad (\text{Eq. 3})$$

where  $\partial_t = \partial/\partial t$  and  $d_t = \partial_t + \mathbf{V} \cdot \nabla$  is the motional derivative;  $\rho$  is the density; *P* is the pressure; **V** is the fluid velocity,  $\mathbf{F}^{\mathbf{v}}$  is the viscous force per unit volume;  $\mathcal{E}^{\mathbf{I}}(\rho, S)$  is the internal energy per unit mass (i.e., the "specific" internal energy); *S* is the specific entropy;  $\mathbf{I}^q$  is
the heat flux;  $Q^{\mathsf{R}}$  is a constant heat production per unit volume from internal heat sources (such as dissolved radioactivity); and  $Q^{\vee}$  is the heating rate per unit volume through viscous friction. The first term on the right-hand side of (Eq. 3) represents reversible  $P \, d\rho^{-1}$  work that, for example, is exchanged between the kinetic and internal energy when fluid motions compress or decompress the fluid; from (Eq. 1),  $\nabla \cdot \mathbf{V} = -\rho d_t \rho^{-1}$ , where  $\rho^{-1}$  is the specific volume.

The first law of thermodynamics for a moving fluid is

$$\mathrm{d}\,\mathcal{E}^{\mathrm{I}} = -P\mathrm{d}\rho^{-1} + T\mathrm{d}S,\tag{Eq. 4}$$

where T is temperature. It therefore follows from Eqs. (1) and (3) that

$$\rho T d_t S + \nabla \cdot \mathbf{I}^q = Q^{\mathsf{R}} + Q^{\mathsf{v}}. \tag{Eq. 5}$$

This equation, which may be called the "heat equation," is sometimes more convenient than (Eq. 3). It may also be written as

$$\rho d_t S + \nabla \cdot \mathbf{I}^S = \sigma^S, \tag{Eq. 6}$$

and is then often called the "entropy equation" because it shows how entropy is transported and created. It is transported by the entropy flux,  $I^{S}$ , which is related to the heat flux,  $I^{q}$ , by

$$\mathbf{I}^{S} = \mathbf{I}^{q} / T. \tag{Eq. 7}$$

It is created at a rate  $\sigma^{S}$  per unit volume which, according to (Eq. 5), is

$$\sigma^{S} = \sigma^{\kappa} + \sigma^{\nu} + \sigma^{R}, \tag{Eq. 8}$$

the three contributions to which arise respectively from thermal conduction, viscosity, and the internal heat sources:

$$\sigma^{\kappa} = -T^{-1}\mathbf{I}^{S} \cdot \nabla T = \mathbf{I}^{q} \cdot \nabla T^{-1}, \quad \sigma^{\nu} = T^{-1}Q^{\nu}, \quad \sigma^{\mathsf{R}} = T^{-1}Q^{\mathsf{R}}.$$
(Eq. 9)

The second law of thermodynamics states that evolution is irreversible. This requires that

$$\sigma^S \ge 0. \tag{Eq. 10}$$

Since this must hold for all possible evolving V and T, the three contributions (Eq. 9) to  $\sigma^{S}$  must be individually nonnegative.

It follows from Eqs. (1) and (2) that the evolution of the specific kinetic energy density,  $\mathcal{E}^{K} = \frac{1}{2}V^{2}$ , is governed by

$$\rho d_t \mathcal{E}^{\mathsf{K}} = -\mathbf{V} \cdot \nabla P + \rho \mathbf{V} \cdot \mathbf{g} + \mathbf{V} \cdot \mathbf{F}^{\mathsf{v}}.$$
 (Eq. 11)

Conservation of the total energy density,

$$\partial_t u^{\text{total}} + \nabla \cdot \mathbf{I}^{\text{total}} = Q^{\mathsf{R}},$$
 (Eq. 12)

follows from (3) and (11). Here

$$u^{\text{total}} = \rho(\mathcal{E}^{K} + \mathcal{E}^{I} + U), \qquad (\text{Eq. 13})$$

$$\mathbf{I}^{\text{total}} = \rho(\mathcal{E}^{K} + \mathcal{E}^{H} + U)\mathbf{V} + \mathbf{I}^{q} + \mathbf{I}^{v}, \qquad (\text{Eq. 14})$$

are the total energy density per unit volume and the total energy flux,  $\mathcal{E}^{H} = \mathcal{E}^{I} + P/\rho$  is the specific enthalpy, and  $\mathbf{I}^{\vee}$  is the energy flux due to viscosity. The derivation of (Eq. 12) makes use of alternative expressions for the last two terms in (Eq. 11). First, from (Eq. 1) and the time independence of *U*, the rate of working of the buoyancy force is

$$\rho \mathbf{V} \cdot \mathbf{g} = -[\partial_t(\rho U) + \nabla \cdot (\rho U \mathbf{V})]. \tag{Eq. 15}$$

Second, the rate of working of the frictional force is

$$\mathbf{V} \cdot \mathbf{F}^{\mathsf{v}} = -\nabla \cdot \mathbf{I}^{\mathsf{v}} - Q^{\mathsf{v}}.$$
 (Eq. 16)

More explicitly, the viscous force is the divergence of the viscous stress tensor,  $\hat{\boldsymbol{\pi}}^{\nu}$ :

$$F_i^{\nu} = \nabla_j \pi_{ji}^{\nu}, \quad \text{where} \quad \pi_{ij}^{\nu} = \pi_{ji}^{\nu}, \tag{Eq. 17}$$

so that (Eq. 16) holds with

$$U_{i}^{\nu} = -V_{j}\pi_{ji}^{\nu}, \quad Q^{\nu} = \pi_{ij}^{\nu}\nabla_{j}V_{i}.$$
 (Eq. 18)

Fourier's law will be employed below, i.e.,

$$\mathbf{I}^q = -K^T \nabla T, \tag{Eq. 19}$$

$$\sigma^{\kappa} = K^T (\nabla T)^2 / T^2, \qquad (\text{Eq. 20})$$

where  $K^T (> 0)$  is the thermal conductivity.

For later convenience, (Eq. 4) is augmented here by further thermodynamic relations (e.g., Landau and Lifshitz, 1980):

$$\rho^{-1} \mathrm{d}\rho = (\rho v_T^2)^{-1} \mathrm{d}P - \alpha \mathrm{d}T, \qquad (\text{Eq. 21})$$

$$\rho^{-1} d\rho = (\rho v_S^2)^{-1} dP - \alpha^S dS,$$
 (Eq. 22)

$$TdS = C_p(dT - \alpha^S dP/\rho), \qquad (Eq. 23)$$

$$TdS = C_{\nu}(dT - \alpha^{S} v_{S}^{2} d\rho / \rho), \qquad (Eq. 24)$$

where  $v_T$  and  $v_S$  are the isothermal and adiabatic sound speeds,  $C_p$  and  $C_v$  are the specific heats at constant pressure and volume, and  $\alpha$  and  $\alpha^S$  are the thermal and entropic expansion coefficients:

$$v_T^2 = \left(\frac{\partial P}{\partial \rho}\right)_T, \ v_S^2 = \left(\frac{\partial P}{\partial \rho}\right)_S, \ C_p = T\left(\frac{\partial S}{\partial T}\right)_P, \ C_v = T\left(\frac{\partial S}{\partial T}\right)_\rho,$$
(Eq. 25)
$$\alpha = -\frac{1}{\rho}\left(\frac{\partial \rho}{\partial T}\right)_P = -\rho\left(\frac{\partial S}{\partial P}\right)_T, \ \alpha^S = -\frac{1}{\rho}\left(\frac{\partial \rho}{\partial S}\right)_P = \rho\left(\frac{\partial T}{\partial P}\right)_T = \frac{\alpha T}{C_T}.$$

The equivalence of the two expressions for  $\alpha$  follow from the Gibbs relation  $(\partial \rho^{-1}/\partial T)_P = -(\partial S/\partial P)_T$ . When written in Jacobian form as  $\partial (\rho^{-1}, P)/\partial (T, P) = -\partial (T, S)/\partial (T, P)$ , this relation also leads to a result that will be useful in section "A more general CA":

$$\frac{\partial(\rho^{-1}, P)}{\partial(S, T)} = 1.$$
 (Eq. 27)

In the same way, the Gibbs relation  $(\partial \rho^{-1}/\partial S)_P = (\partial T/\partial P)_S$  confirms (Eq. 27) and also establishes the equivalence of two expressions for  $\alpha^S$  in (Eq. 26). In what follows, the coefficients (Eq. 25) and (Eq. 26) are evaluated in reference states denoted by  $_{0, a}$  and  $_b$ ; to avoid a proliferation of suffixes, these suffixes will be omitted, and also from  $K^T$ , the thermal diffusivity  $\kappa = K^T / \rho C_p$ , and the kinematic viscosity v.

Other useful thermodynamic relations are

$$C_p/C_v = v_S^2/v_T^2, \quad C_p - C_v = C_v \alpha T \gamma, \quad v_S^2 - v_T^2 = v_T^2 \alpha T \gamma,$$
  
(Eq. 28)

where

$$\gamma = \frac{\rho}{T} \left( \frac{\partial T}{\partial \rho} \right)_{S} = \frac{\alpha v_{S}^{2}}{C_{p}}$$
(Eq. 29)

is the Grüneissen parameter which, in making numerical estimates below, we shall assume is O(1). We shall frequently need to distinguish between cases in which the working fluid is a liquid and in which it is a gas. For a liquid, it is usually true that  $\alpha T \ll 1$ ; then (Eq. 28) shows that  $C_v \approx C_p$  and  $v_T \approx v_S$ . For a gas,  $\alpha T$  is close to unity.

Finally, another consequence of (Eq. 4) will be needed later:

$$\mathrm{d}\mathcal{E}^H = \rho^{-1}\mathrm{d}P + T\mathrm{d}S. \tag{Eq. 30}$$

## The Boussinesq approximation (BA)

The governing equations Eqs. (1)–(5) describe a multitude of processes having widely different characteristic time scales,  $\tau$ , e.g., fast processes (acoustic/seismic) and slow processes, usually called "convective." In the case of the Earth, the short timescales range from seconds to hours and the long timescales from years to millions of years. To model convection, it is advantageous to "filter out" the fast processes; this is the goal of the CAs. These approximations regard a convecting fluid as being, from a thermodynamic point of view, a small departure from a suitably defined, time-independent "reference state." This allows thermodynamic relations to be linearized. There is, however, no suggestion that other nonlinearities, such as  $\rho \mathbf{V} \cdot \nabla \mathbf{V}$  in the inertial term of (Eq. 2), can be ignored.

The simplest form of CA is the Boussinesq approximation (BA), which was originally devised for liquid systems for which (i) the density  $\rho$  and temperature *T* have nearly constant values  $\rho_0$  and  $T_0$ , and (ii) the deviation  $\rho_1 = \rho - \rho_0$  is small compared with  $\rho_0$  and depends only on  $T_1 = T - T_0$ , its dependence on the pressure *P* being neglected. The BA is widely and unquestioningly used; see, for example, Chandrasekhar (1961). It is employed in most, but not all, simulations of core dynamics as, for instance, in the geodynamo model of Glatzmaier and Roberts (1995). The aim of this section is to provide a simple motivation for the BA; the section "The generalized Boussinesq approximation (GBA)" presents a less direct but more satisfactory alternative.

Define a uniform reference state in which all thermodynamic quantities have constant values, indicated by the suffix  $_0$ . (We omit  $_0$  from  $C_p, \alpha, v_s^2, \ldots$  to avoid a proliferation of suffixes). The small deviations from the reference values are denoted by the suffix  $_1$ :

$$\rho = \rho_0 + \rho_1, \quad T = T_0 + T_1,$$
  

$$P = P_0 + P_1 = P_0 - \rho_0 U + \rho_0 \Pi_1, \quad S = S_0 + S_1, \dots$$
(Eq. 31)

The variables carrying the suffix 1 have both static and time-varying parts. In particular,  $P_1$  contains the hydrostatic term  $-\rho_0 U$ , which plays no essential role in the convective process.

The condition for the applicability of the BA may be illustrated through values typical of laboratory experiments in a layer of water of depth  $H \sim 10$  cm:

$$\begin{split} \rho_0 &\approx 1 \ {\rm cm}^{-3} = 10^3 \ {\rm kg \ m}^{-3}, \quad T_0 \sim 300 \ {\rm K}, \quad P_0 = 1 \ {\rm atm}, \\ \nu_S &\approx \nu_T \approx 1.5 \ {\rm km \ s}^{-1}, \quad \alpha \sim 10^{-4} {\rm K}^{-1}, \\ \Delta T &\sim 10 \ {\rm K}, \quad g \approx 10 \ {\rm m \ s}^{-2}, \end{split}$$
(Eq. 32)

where  $\Delta T$  is typical of the temperature differences:  $T_1 \sim \Delta T$ . The derivation rests on "thermodynamic linearization" in which dT, dP,  $d\rho$ , ... are replaced by  $T_1$ ,  $P_1$ ,  $\rho_1$ , ... For example, (Eq. 21) gives

$$\rho_1 / \rho_0 = P_1 / \rho_0 v_T^2 - \alpha T_1.$$
 (Eq. 33)

The fractional change in  $\rho$  created by the temperature difference  $T_1 \sim \Delta T$  is of order

$$\varepsilon_{\rm c} \equiv (\Delta \rho / \rho)_T = \alpha \Delta T.$$
 (Eq. 34)

The main part of the fractional change in  $\rho$  created by the pressure difference  $P_1$  is generally due to the hydrostatic force  $-\rho_0 U$ ; this is usually much greater than the part due to the small correction  $\rho_0 \Pi_1$ associated with the convection, which is therefore neglected. According to (Eq. 33), it is quantified by  $\varepsilon_a \sim P_1 / \rho v_s^2$ , i.e.,

$$\varepsilon_{a} \equiv (\Delta \rho / \rho)_{P} = H / H_{\rho}, \text{ where } H_{\rho} = v_{S}^{2} / g$$
 (Eq. 35)

is the "density scale-height." [Despite (Eq. 33),  $\varepsilon_a$  is here defined, for later convenience, using  $v_S$  rather than  $v_T$ ; for liquids, the main concern of this section,  $v_S \approx v_T$ .] From (Eq. 32), we see that  $\varepsilon_c \sim 10^{-3} \ll 1$  and that  $H_\rho \sim 200$  km is very large, so that  $\varepsilon_a \sim 5 \times 10^{-7}$ . Therefore both conditions (i) and (ii) are well satisfied: the density change is small and the contribution made by the *P* variation is much smaller than that due to *T*:

$$\varepsilon_{a} \ll \varepsilon_{c} \ll 1.$$
 (Eq. 36)

In other words, "the BA always applies in a thin enough layer."

By (Eq. 26), the thermodynamically linearized Eqs. (23) and (4) are

$$T_0 S_1 = C_p T_1 - \alpha T_0 P_1 / \rho_0, \quad \mathcal{E}_1^1 = T_0 S_1 + (P_0 / \rho_0^2) \rho_1.$$
 (Eq. 37)

By Eqs. (35) and (29),  $P_1/\rho_0 \sim \epsilon_a v_S^2 \sim \epsilon_a (\gamma C_p/\alpha)$ , so that  $T_0S_1 = C_P T_1[1 + \alpha T_0 O(\epsilon_a/\epsilon_c)]$ . i.e.,  $T_0S_1$  may be replaced by  $C_p T_1$  with an error that is even smaller than  $\epsilon_a/\epsilon_c$  because  $\alpha T_0$  is small for a liquid. In terms of the "height of an equivalent column,"  $H_P = P_0/\rho_0 g$ , the second of (Eq. 37) gives  $\mathcal{E}_1^1 = C_p T_1[1 + \gamma H_P/H_\rho]$ , where we have substituted  $\alpha T_1$  for  $\rho_1/\rho_0$ . According to (Eq. 32),  $H_P \sim 10$  m, and hence  $H_P/H_\rho \sim 5 \times 10^{-5} \ll 1$ . Therefore, when conditions (Eq. 36) are satisfied, the thermodynamics gives, to high accuracy,

$$\rho_1/\rho_0 = \alpha T_1, \tag{Eq. 38}$$

$$T_0 S_1 = C_p T_1,$$
 (Eq. 39)

$$\mathcal{E}_1^{\mathrm{I}} = C_p T_1. \tag{Eq. 40}$$

With these simplifications, Eqs. (1), (2), and (3) or (5) give the BA:

$$\nabla \cdot \mathbf{V} = \mathbf{0},\tag{Eq. 41}$$

$$d_t \mathbf{V} = -\nabla \Pi_1 - \alpha T_1 \mathbf{g} + \mathbf{F}^{\mathbf{v}} / \rho_0, \qquad (\text{Eq. 42})$$

$$d_t T_1 = \kappa \nabla^2 T_1 + (Q^{\mathbb{R}} + Q^{\mathbb{V}}) / \rho_0 C_p.$$
 (Eq. 43)

It may be seen that every term in Eqs. (1)–(5) has been evaluated on the assumption that  $\rho = \rho_0$ , apart from the buoyancy force, where  $\rho$  has been replaced by  $\rho_0(1 - \alpha T_1)$ .

A steadily convecting system may be thought of as a heat engine that does no useful work (though useful work would be done if a "windmill" were inserted into the fluid, driven by the convection). It does no useful work because, though thermal energy is converted into a higher form (kinetic energy), this returns as thermal energy through the viscous dissipation  $Q^{v}$ . The Boussinesq layer is a heat engine of very low efficiency, defined here as the ratio of the rate of working of the buoyancy forces to the rate at which the internal energy changes through convection:

$$\alpha T_1 \mathbf{V} \cdot \mathbf{g} / C_p d_t T_1 \sim \alpha g H / C_p = \gamma \varepsilon_a \ll 1.$$
 (Eq. 44)

Here  $d_i T_1$  has been estimated as  $T_1/\tau_c \sim T_1 V/H$ , where V and  $\tau_c$  are velocity and timescales typical of the convection,  $\tau_c$  being the timescale of convective overturning.

In the BA, the kinetic energy density,  $\mathcal{E}^{K} = \frac{1}{2}V^2$ , is an insignificant part of the total energy density,  $\mathcal{E}^{\text{total}}$ . The heat balance Eq. (43) is in fact a first, and rather good, approximation to the total energy balance Eq. (12). But, because the (small) rate of working of the buoyancy force,  $-\rho_0 \alpha T_1 \mathbf{V} \cdot \mathbf{g}$ , has no equal but opposite term in Eq. (43) to remove it from the total energy balance, the illusion is created that the gravitational field provides the energy necessary to drive the convection. In reality, the mean gravitational energy of a steadily convecting system does not change; the gravitational field on average does no work.

The dimensionless parameter that appears in virtually all convection studies is the Rayleigh number,

$$Ra = g\alpha \Delta T H^3 / \nu \kappa. \tag{Eq. 45}$$

For buoyancy to be influential, *Ra* must typically be greater than O(1). The Rayleigh number is the product of two nondimensional numbers,  $\varepsilon_c$ , and  $gH^3/\nu\kappa$ . Unless  $\varepsilon_c \ll 1$  and  $gH^3/\nu\kappa \gg 1$ , it is not obvious that the BA is useful. Stated another way, although Eq. (36) should hold, the product  $\varepsilon_a \varepsilon_c$  must be much larger than  $\nu\kappa/(H\nu_S)^2$ , which in the case of (32) is of order  $10^{-12}$ .

Returning to convection in the Earth's fluid core, and taking  $\alpha = 10^{-5} \text{K}^{-1}$ ,  $\nu = 10^{-6} \text{ m}^2 \text{ s}^{-1}$ ,  $\kappa = 3 \times 10^{-5} \text{ m}^2 \text{ s}^{-1}$ ,  $H^3 = 10^{19} \text{ m}^3$ , and  $\Delta T = 1500 \text{ K}$  as typical, it is seen that *Ra* is enormously large (*Ra* ~ 10<sup>29</sup>). This strongly indicates that a fresh approach is needed for this geophysical application. This will be provided in the next section, where it is shown that, by taking  $\Delta T$  to be the temperature difference between the inner core boundary (ICB) and the core-mantle boundary (CMB), as was done above, *Ra* is overestimated by a factor of order  $10^8$ .

#### The adiabatic (isentropic) reference state

In the section "The Boussinesq approximation (BA)," the basic state was uniform; its density, pressure, and all other thermodynamic variables were constant in space and time. This is appropriate only for a thin layer for which  $\varepsilon_a \ll 1$ . More generally the thermodynamic variables in the reference state depend on position, and here they will be distinguished by the suffix, *a*. An expansion like Eq. (31) is envisaged:

$$\rho = \rho_{a} + \rho_{c}, \quad P = P_{a} + P_{c}, \quad T = T_{a} + T_{c}, \quad S = S_{a} + S_{c}, \dots$$
(Eq. 46)

in which the suffix "c" distinguishes the convective parts of thermodynamic variables. As in the section "The Boussinesq approximation (BA)," it is unnecessary to add a suffix to V since  $V_a = 0$ . Also, since by assumption the reference state is steady,  $\partial_t f_a = 0$  for all adiabatic variables,  $f_a$ .

For the convective motions to be slow, it is necessary that the reference state be in "quasiequilibrium," i.e., it must be a steady state in which the dominant terms in the mechanical and thermal equations (2) and (6) balance. The mechanical quasiequilibrium is hydrostatic balance:

$$\nabla P_{a} = \rho_{a} \mathbf{g} = -\rho_{a} \nabla U. \tag{Eq. 47}$$

There is more than one way of enforcing thermal "quasiequilibrium"; see also "A more general CA." In this section we focus on one extreme, though extremely useful, choice that is particularly appropriate for a strongly convecting system: the *adiabatic reference state*. (This also motivated the choice <sub>a</sub> for reference state variables.)

Within a fluid parcel of dimensions  $\ell$ , entropy S is carried by heat conduction, at a speed of order  $\kappa/\ell$ . When the velocity V of the parcel is large compared with  $\kappa/\ell$ , i.e., when the Péclet number  $Pe = V\ell/\kappa$  is

large, *S* is transported far more effectively by convection. If, with the Earth's core in mind, we take  $\kappa \sim 10^{-5} \text{ m}^2 \text{ s}^{-1}$ ,  $V \sim 10^{-4} \text{ m} \text{ s}^{-1}$  and  $\ell \sim 10 \text{ km}$ , it is quickly seen that  $\kappa/\ell \sim 10^{-5} V$ , i.e.,  $Pe \sim 10^5$ . When  $Pe \gg 1$ , the entropy in the parcel is carried over a long distance, of order  $Pe \ell$ , virtually unchanged. This is confirmed by (Eq. 6) which for large *V* is approximately  $d_t S = 0$  though, over short distances, thermal diffusion smoothes out *S*. In this way, *S* is thoroughly homogenized by convection. The net result is a state that is nearly isentropic (except in boundary layers; see "Boundary conditions for CA"). It is therefore appropriate to complete the specification of the adiabatic reference state by supplementing (Eq. 47) with

$$\nabla S_{a} = \mathbf{0}. \tag{Eq. 48}$$

Trivially, all thermodynamic variables defined by Eqs. (47) and (48) are functions of U in the reference state.

It is well known that (Eq. 48) is the condition for the neutral stability of a compressible fluid; see e.g., Landau and Lifshitz (1987), "The anelastic approximation (AA)." A state in which  $\mathbf{g} \cdot \nabla S$  is large and positive would be top-heavy and would set up fast overturning motions; if  $\mathbf{g} \cdot \nabla S$  is large and negative, the state would be bottomheavy and overturning would be inhibited. It is only when  $\nabla S \approx \mathbf{0}$  that slow convective motions are possible, and the system is then close to a basic state for which  $\nabla S_a = \mathbf{0}$ .

As noted by Braginsky and Roberts (2003), Eqs. (30) and (48) imply that the hydrostatic balance (Eq. 47) can be re-expressed as:

$$\nabla(E_a^H + U) = \mathbf{0}.\tag{Eq. 49}$$

This parallels a similar statement ( $\mathcal{E}^G + U = \text{constant}$ , where  $\mathcal{E}^G = \mathcal{E}^H - TS$  is the specific Gibbs free energy) for hydrostatic equilibrium in an isothermal fluid; see, for example, Landau and Lifshitz (1987), "The adiabatic (isentropic) reference state."

Similar arguments apply to a chemically inhomogeneous fluid; the mass fractions of the constituents in the moving parcel are virtually unchanged during its displacement, but are smoothed out over short distances. We emphasize that zero gradients arise only for "miscible" quantities that, in the absence of diffusion, are advected without change by the flow. Prominent amongst quantities that do not become constant through mixing, are  $\rho_a$ ,  $T_a$ , and  $P_a$ . For example,  $P_a$  in the Earth's core varies from about 136 GPa at the CMB to 329 GPa at the ICB. This creates the nonzero "adiabatic gradients" in  $\rho_a$  and  $T_a$  that, by Eqs. (47), (48), (22) and (23), are

$$\nabla \rho_{a} = \left(\frac{\partial \rho}{\partial P}\right)_{S} \nabla P_{a} = \frac{\rho_{a}}{v_{S}^{2}} \mathbf{g}, \tag{Eq. 50}$$

$$\nabla T_{a} = \left(\frac{\partial T}{\partial P}\right)_{S} \nabla P_{a} = \alpha^{S} \mathbf{g}.$$
 (Eq. 51)

Equation (51) is often written as  $T_a^{-1}\nabla T_a = \gamma \mathbf{g}/v_S^2$ . As in (Eq. 35), we introduce

$$\varepsilon_{a} \equiv \Delta \rho_{a} / \rho_{a} = H / H_{\rho}, \text{ where } H_{\rho} = v_{S}^{2} / g.$$
 (Eq. 52)

This quantifies the fractional change in  $\rho_a$  across the fluid; for the Earth's core,  $H_\rho \sim 10^4$  km so that  $\varepsilon_a \sim 0.2$ . The fractional change,  $\Delta T_a/T_a$ , in temperature is of the same order, but the fractional change in  $P_a$  is much greater.

Often little error is made in assuming that large bodies like the Earth are spherically symmetric, and (Eq. 51) then gives

$$\Gamma \equiv -\frac{\mathrm{d}T_{\mathrm{a}}}{\mathrm{d}r} = \frac{g\alpha T_{\mathrm{a}}}{C_{p}} = g\alpha^{S}, \qquad (\mathrm{Eq.}\ 53)$$

where *r* is distance from the center of symmetry. In the Earth's core,  $\Gamma \sim 1 \text{ K km}^{-1}$ , so that the *adiabatic heat flux*,  $K^T \Gamma$ , is about 0.04 W m<sup>-2</sup> near the CMB, accounting for a heat loss to the mantle of order 6 TW.

The more vigorous the convection, the more appropriate is (Eq. 48) as choice of reference state. This is because the process of smoothing *S* becomes stronger. The precision of a result such as

$$\rho_{\rm c}/\rho_{\rm a} = P_{\rm c}/\rho_{\rm a}v_S^2 - \alpha^S S_{\rm c}, \qquad ({\rm Eq.~54})$$

obtained from (Eq. 22), can be assessed by comparing a force such as  $\rho_{ag}$  in the hydrostatic balance (Eq. 47) with a typical force appearing in the equations governing convection such as, in the case of Earth's core, the Coriolis force  $2\rho_{a}\Omega \times V$ . The ratio of these forces is

$$e_{\rm c} = 2\Omega V/g, \tag{Eq. 55}$$

which is about  $10^{-8}$ , if we assume, as is suggested by observations, that the typical flow speed, *V*, is at most  $10^{-3}$  m s<sup>-1</sup>. Since  $\rho_c \sim \varepsilon_c \rho_a$  and  $\varepsilon_c \ll 1$ , it follows not only that the terms discarded during thermodynamic linearization are negligible, but also that, whenever  $\rho$  appears, it can be safely replaced by  $\rho_a$ , except in the buoyancy force. (This parallels an analogous step in "The Boussinesq approximation (BA)," where  $\rho_1$  was neglected in comparison with  $\rho_0$  except in the buoyancy force.) The smallness of  $\varepsilon_c$  underscores the wisdom of using Eqs. (47) and (48) in defining the reference states for vigorously convecting systems; in the case of the Earth's core, the pressure gradient and buoyancy force in (Eq. 2) are greater than the remaining terms by a factor of order  $10^8$ , and by adopting (Eq. 47) they are "removed," so exposing the small terms that control convection.

#### The anelastic approximation (AA)

As emphasized in "The Boussinesq approximation (BA)," the prime aims of a CA are to "filter out" fast processes and to make use of thermodynamic linearization which, in the "anelastic approximation" or "AA," is linearization about the adiabatic state. The reduced forms of Eqs. (1), (2) and (6) are

$$\nabla \cdot (\rho_{\mathbf{a}} \mathbf{V}) = 0, \tag{Eq. 56}$$

$$d_t \mathbf{V} = -\nabla \Pi_{\rm c} - \alpha^S S_{\rm c} \mathbf{g} + \mathbf{F}^{\rm v} / \rho_{\rm a}, \qquad (\text{Eq. 57})$$

$$\rho_a d_t S_c + \nabla \cdot \mathbf{I}^S = \sigma^S, \tag{Eq. 58}$$

where  $\Pi_{\rm c} = P_{\rm c}/\rho_{\rm a}$  and

$$\mathbf{I}^{S} = T_{\mathbf{a}}^{-1}\mathbf{I}^{q}, \quad \mathbf{I}^{q} = \mathbf{I}_{\mathbf{a}}^{q} + \mathbf{I}_{\mathbf{c}}^{q}, \quad \sigma^{S} = T_{\mathbf{a}}^{-1}(Q^{\mathsf{R}} + Q^{\mathsf{v}}) - \mathbf{I}^{S} \cdot \nabla T_{\mathbf{a}}.$$
(Eq. 59)

It is sometimes useful to re-express  $\alpha^{S}S_{c}g$  in (Eq. 57) as  $S_{c}\nabla T_{a}$ ; see (Eq. 51).

The arguments leading to Eqs. (56)–(59) are now described. To filter out the fast time scales, the term  $\partial_t \rho_c$  on the left-hand side of (Eq. 1) must be omitted. When convection occurs, this term is of order  $\rho_c/\tau_c \sim \rho_c V/H$ . The right-hand side of (Eq. 1) is  $-\nabla \cdot (\rho \mathbf{V}) \sim \rho_a V/H$ . On the grounds (see above) that terms of order  $\rho_c = O(\varepsilon_c \rho_a) \ll \rho_a$  are tiny, we may therefore simplify (Eq. 1) as (Eq. 56), and we have also, for the same reason, taken the opportunity of replacing  $\nabla \cdot (\rho \mathbf{V})$  by  $\nabla \cdot (\rho_a \mathbf{V})$ . Equation (56) states that the curlfree part of the momentum flux,  $\rho_a \mathbf{V}$ , is negligible compared with its rotational part. Once the term  $\partial_t \rho$  has been omitted from (Eq. 1), the system loses all solutions of acoustic/seismic type that depend on the "elasticity" of the medium. This is the essence of the AA and gives it its name. The "filtering out" of the elastic waves is justified because their timescale is short compared with that of convective overturning. The elasticity of the medium is, however, responsible also for the nonuniform density of the basic state created by the pressure gradient, and this is recognized by the AA.

The replacement of  $\rho$  by  $\rho_a$  on the left-hand side of (Eq. 2) is similarly justified, but the two dominant terms on the right-hand side,  $-\nabla P_a$  and  $\rho_a \mathbf{g}$ , have already canceled out by (Eq. 47), so that (Eq. 2) becomes

$$\rho_{\mathbf{a}}d_t \mathbf{V} = -\nabla P_{\mathbf{c}} + \rho_{\mathbf{c}}\mathbf{g} + \mathbf{F}^{\mathbf{v}}.$$
 (Eq. 60)

A revealing simplification of (Eq. 60) was noticed by Braginsky and Roberts (1995, 2003). The density perturbation  $\rho_c$  resulting from  $P_c$ and  $S_c$  create, according to Eqs. (50) and (54), the buoyancy force

$$\rho_{\rm c}\mathbf{g} = (P_{\rm c}/\rho_{\rm a})\nabla\rho_{\rm a} - \rho_{\rm a}\alpha^{\rm S}S_{\rm c}\mathbf{g},\tag{Eq. 61}$$

so that the two first terms on the right-hand side of (60) are

$$-\nabla P_{\rm c} + \rho_{\rm c} \mathbf{g} = -\rho_{\rm a} \nabla (P_{\rm c}/\rho_{\rm a}) - \rho_{\rm a} \alpha^{\rm s} S_{\rm c} \mathbf{g}.$$
 (Eq. 62)

Equation (57) follows.

The resemblance of (Eq. 57) to the Boussinesq momentum equation (Eq. 42) is so striking that it is worth stressing that (Eq. 57) is a consequence of the assumption of an adiabatic, well-mixed reference state. It should also be emphasized that the density perturbation due to  $P_{\rm c}$  is fully taken into account in (Eq. 57). The "elastic" part of the density perturbation  $\rho_c$  has not been ignored in the AA; it has been absorbed into  $\Pi_c$  and therefore cannot supply the restoring force necessary for acoustic/seismic wave propagation (see above). Equation (57) shows clearly that the buoyancy force associated with deviations from a well-mixed adiabatic state is created only by the variations in entropy; the buoyancy force associated with pressure variations, though it may be just as large, does not contribute because, as for the BA, it is conservative and can be absorbed into the effective pressure to create a potential term, here  $\nabla \Pi_c$ . [Braginsky and Roberts (1995) show that these simplifications apply even when  $U(=U_{\rm a}+U_{\rm c})$  is created by the self-gravitation of the fluid mass and satisfies the appropriate Poisson equation.]

Because  $\rho_c \sim \varepsilon_c \rho_a \ll \rho_a$ ,  $T \sim \varepsilon_c T_a \ll T_a$  and  $d_t S_a = 0$ , the first term of the entropy equation (6) may be replaced by  $\rho_a d_t S_c$ , and (Eq. 58) results. Since  $\partial_t T_a = 0$ , (Eq. 58) may be re-written, with help from (Eq. 51), as the heat equation

$$\rho_{a}d_{t}(T_{a}S_{c}) + \nabla \cdot \mathbf{I}^{q} - \rho_{a}\alpha^{S}S_{c}\mathbf{V} \cdot \mathbf{g} = Q^{R} + Q^{v}.$$
 (Eq. 63)

On taking the scalar product of (57) with  $\rho_a V$  and using (Eq. 56) and (Eq. 16), it is found that the evolution of kinetic energy is governed by

$$\rho_a d_t E^K + \nabla \cdot (P_c \mathbf{V} + \mathbf{I}^{\vee}) + \rho_a \alpha^S S_c \mathbf{V} \cdot \mathbf{g} = -Q^{\vee}.$$
 (Eq. 64)

By combining (63) and (64), it follows that

$$\rho_{a}d_{t}(\mathcal{E}^{K}+T_{a}S_{c})+\nabla\cdot(\mathbf{I}^{q}+P_{c}\mathbf{V}+\mathbf{I}^{v})=Q^{R}.$$
(Eq. 65)

It may be particularly noted that the rate of working of the buoyancy force,  $-\rho_a x^S S_c \mathbf{V} \cdot \mathbf{g}$ , appearing in (Eq. 64) is canceled out by the same term with an opposite sign in (Eq. 63). To achieve this cancelation, it is necessary to use the fact that  $\nabla T_a = \alpha^S \mathbf{g}$ , a step that was impossible in "The Boussinesq approximation (BA)" since there  $\nabla T_0 = \mathbf{0}$ .

The total energy equation that follows from Eqs. (56) and (65) is

$$\partial_t u_{\rm c}^{\rm total} + \nabla \cdot \mathbf{I}_{\rm c}^{\rm total} = Q^{\rm R},$$
 (Eq. 66)

where

$$u_{\rm c}^{\rm total} = \rho_{\rm a}(\mathcal{E}^{\rm K} + T_{\rm a}S_{\rm c}), \tag{Eq. 67}$$

$$\mathbf{I}_{c}^{\text{total}} = \rho_{a}(\mathcal{E}^{K} + \mathcal{E}_{c}^{H})\mathbf{V} + \mathbf{I}_{a}^{q} + \mathbf{I}_{c}^{q} + \mathbf{I}^{v}, \quad \mathcal{E}_{c}^{H} = \rho_{a}^{-1}P_{c} + T_{a}S_{c}.$$
(Eq. 68)

Here  $E_c^H$  follows from (Eq. 30) by thermodynamic linearization.

The expressions Eqs. (67) and (68) for  $u_c^{\text{total}}$  and  $\mathbf{I}_c^{\text{total}}$  are different from Eqs. (13) and (14). To clarify, we shall temporarily call the latter  $\tilde{u}_c^{\text{total}}$  and  $\tilde{\mathbf{I}}_c^{\text{total}}$ , and introduce the next term in the  $\varepsilon_c$ -expansion of **V**, writing  $\mathbf{V} = \mathbf{V}_1 + \mathbf{V}_2 + \ldots$ , where  $\mathbf{V}_1$  has until now been written as **V**. Equation (1) gives

$$\nabla \cdot (\rho_{\mathbf{a}} \mathbf{V}_1) = \mathbf{0},\tag{Eq. 69}$$

$$\partial_t \rho_{\mathbf{c}} + \nabla \cdot (\rho_{\mathbf{c}} \mathbf{V}_1 + \rho_{\mathbf{a}} \mathbf{V}_2) = 0.$$
 (Eq. 70)

It can be readily shown from Eqs. (13) and (14) that

$$\tilde{u}_{c}^{\text{total}} = u_{c}^{\text{total}} + (E_{a}^{H} + U)\rho_{c}, \qquad (\text{Eq. 71})$$

$$\tilde{\mathbf{I}}_{c}^{\text{total}} = \mathbf{I}_{c}^{\text{total}} + (E_{a}^{H} + U)[\rho_{a}\mathbf{V}_{1} + (\rho_{c}\mathbf{V}_{1} + \rho_{a}\mathbf{V}_{2})].$$
(Eq. 72)

According to Eqs. (49), (69), and (70), the additional terms cancel out when (Eq. 71) is substituted into Eqs. (12), and (66)-(68) are recovered.

As was noted in "The adiabatic (isentropic) reference state," convection is driven by the superadiabatic temperature difference across the layer rather than by the full temperature difference (adiabatic plus superadiabatic), as was used in crudely estimating the Rayleigh number, Ra, for the Earth's core at the end of "The Boussinesq approximation (BA)." This means that a more realistic Ra is smaller by a factor of order  $\varepsilon_c$  so that  $Ra \sim 10^{21}$ . This is still so large that the core must be in a well mixed, turbulent state, and this confirms a posteriori the suitability of the AA in describing core motions. It might seem that when, thermodynamically, the convective state is a small perturbation away from the adiabatic state, the heat flux, must also be a small perturbation away from the adiabatic heat flux,  $I_a^q$ . This however is not necessarily the case. When Ra is large, the same motions that mix the fluid and lead to (Eq. 48) also transport a large amount of heat. Even with a small  $T_{c}$ , this may be of the same order as, or even larger than, the heat flux,  $K^T \Gamma$ , down the adiabat. This question and the role of turbulence is re-opened in the section "The role of turbulence."

The AA generalizes easily to convection in multicomponent fluids, such as the binary alloy often used to describe the dynamics of Earth's core. As for *S*, the mass fraction  $\xi(=\xi_a + \xi_c)$  of the light component of the alloy is almost homogenized by convection when *S* is, so that  $\nabla \xi_a = \mathbf{0}$  supplements (Eq. 48). Compositional differences create buoyancy forces, so that  $-\alpha^S S_c \mathbf{g}$  in (Eq. 57) is replaced by  $C\mathbf{g}$ , where  $C = -\alpha^S S_c - \alpha^\xi \xi_c$  is the *co-density* and  $\alpha^\xi = -\rho^{-1}(\partial \rho/\partial \xi)_{P,S}$ ; cf. (Eq. 26). Also,  $\xi_c$  is governed by an equation similar to (Eq. 58), although  $S_c$  obeys a different boundary condition. Full details of this generalized AA are given by Braginsky and Roberts (1995, 2003). It was basic in the geodynamo simulation of Glatzmaier and Roberts (1996).

# Alternative forms of the AA and BA

The temperature-based anelastic approximation (TAA)

The central thermodynamic variable describing convection in the AA is  $S_c$ ; see Eqs. (56)–(58). This is convenient when studying core convection, because the nonadiabatic heat flux,  $\mathbf{I}_c^q$ , is mainly due to turbulence and is therefore best expressed in terms of the inhomogeneities in the entropy (see "The role of turbulence."). For systems such as the Earth's mantle and oceans however, the temperature,  $T_c$ , is a more convenient variable to employ. One is then led to a "temperature-based anelastic approximation" or "TAA" in which  $S_c$  has been replaced by  $T_c$  in Eqs. (56), (57), and (63):

$$\nabla \cdot (\rho_{\mathbf{a}} \mathbf{V}) = \mathbf{0},\tag{Eq. 73}$$

$$d_t \mathbf{V} = -\nabla \Pi_{\mathbf{c}} - \alpha T_{\mathbf{c}} \mathbf{g} + \mathbf{F}^{\mathsf{v}} / \rho_{\mathsf{a}}, \qquad (\text{Eq. 74})$$

$$\rho_{a}d_{t}(C_{p}T_{c}) + \nabla \cdot \mathbf{I}^{q} - \rho_{a}\alpha T_{c}\mathbf{V} \cdot \mathbf{g} = Q^{R} + Q^{\nu}, \qquad (\text{Eq. 75})$$

where

$$\mathbf{I}^{q} = -K^{T} \nabla T_{a} - K^{T} \nabla T_{c}, \quad \text{and} \quad \Pi_{c} = P_{c} / \rho_{0}.$$
 (Eq. 76)

As before, the presence of  $\rho_a \alpha T_c \mathbf{V} \cdot \mathbf{g}$  in (Eq. 75) assures conservation of total energy.

The derivation of Eqs. (73)–(76) requires only

$$T_{\rm a}S_{\rm c} = C_p T_{\rm c} - (\alpha T_{\rm a}/\rho_{\rm a})P_{\rm c}, \qquad ({\rm Eq.}\ 77)$$

which follows from (Eq. 23) and thermodynamic linearization. If we use (Eq. 77) in full to remove reference to  $S_c$  in Eqs. (56)–(58), we obtain a theory in every way equivalent to the AA, though complicated by  $P_c$  terms from (Eq. 77). In order of magnitude, however,  $P_c/\rho_a H \sim \Pi_c/H \sim \alpha T_c g$ , so that (Eq. 77) implies

$$\alpha^{S}S_{c} = \alpha T_{c}[1 + O(\varepsilon_{a}\alpha T_{a}\gamma)], \qquad (Eq. 78)$$

$$T_{a}S_{c} = C_{p}T_{c}[1 + O(\varepsilon_{a}\alpha T_{a}\gamma)].$$
 (Eq. 79)

Whenever  $\alpha T_a \ll 1$ , as is the case for fluids and solids (but not for gases, where  $\alpha T_a \approx 1$ ), the product  $\varepsilon_a \alpha T_a \gamma$  in Eqs. (78) and (79) is negligibly small, even when  $\varepsilon_a \sim 1$ . We may then replace  $\alpha^S S_c \mathbf{g}$  in (Eq. 57) by  $\alpha T_c \mathbf{g}$  and  $d_t(T_a S_c)$  in (Eq. 63) by  $d_t(C_p T_c)$ . [Variations in  $C_p$  may be small, and  $d_t(C_p T_c)$  in (Eq. 75) may then be replaced simply by  $C_p d_t T_c$ , as is often done. We may also recall (see "Introduction") that, since  $\alpha T_a \ll 1$ , the differences between  $v_T$  and  $v_S$  and between  $C_v$  and  $C_p$  may be ignored.] Since the density change,  $\Delta \rho_a$ , across the system is not small when  $\varepsilon_a \sim 1$ , it is necessary to retain  $\rho_a$  within the divergence in (Eq. 73).

Slow, creeping motions occur in the Earth's mantle through a process called "subsolidus convection." This is well described by the basic equations of "Introduction," the viscosity defining  $\mathbf{F}^{v}$  being of order  $10^{21}$  Pa s ( $v \sim 2 \times 10^{17}$  m<sup>2</sup> s<sup>-1</sup>). The resulting motions are so slow ( $V \sim 1$  cm year<sup>-1</sup>) that the inertial term on the left-hand side of (Eq. 74) is utterly insignificant. Nevertheless,  $Ra \sim 10^7 - 10^8$  through much the mantle's vertical extent, in which therefore the temperature is close to an abiabat. The AA is then appropriate but, because  $\alpha T_a \sim 3 \times 10^{-2}$ , the approximate form Eqs. (73)–(75) of the AA applies almost equally well; see Schubert *et al.* (2001).

# The generalized Boussinesq approximation (GBA)

ρ

The approximation just described becomes even simpler when  $\varepsilon_a \equiv gH/v_s^2 \ll 1$ . For example, for the oceans,  $H \sim 5$  km and  $v_S \sim 1.5$  km s<sup>-1</sup>, gives  $\varepsilon_a \sim 2 \times 10^{-2}$ . In such a case, we may substitute

$$a_{a} = \rho_{0} + \rho_{a1}, \quad T_{a} = T_{0} + T_{a1}, \quad \dots$$
 (Eq. 80)

into Eqs. (73) to (76), where  $\rho_0, T_0, \ldots$  are constants. Because  $\rho_{\rm a1}/\rho_0 \sim T_{\rm a1}/T_0 \sim \varepsilon_{\rm a} \ll 1$ , we may omit  $\rho_{\rm a1}$  and  $T_{\rm a1}$  everywhere except where  $\nabla \rho_{\rm a}$  and  $\nabla T_{\rm a}$  are required, as in (Eq. 76). It follows that

$$\nabla \cdot \mathbf{V} = \mathbf{0},\tag{Eq. 81}$$

$$d_t \mathbf{V} = -\nabla \Pi_{\mathbf{c}} - \alpha T_{\mathbf{c}} \mathbf{g} + \mathbf{F}^{\mathsf{v}} / \rho_0, \qquad (\text{Eq. 82})$$

$$\rho_0 C_p d_t T_c + \nabla \cdot \mathbf{I}^q - \rho_0 \alpha T_c \mathbf{V} \cdot \mathbf{g} = Q^{\mathsf{R}} + Q^{\mathsf{v}}, \qquad (\text{Eq. 83})$$

where  $C_p$  and the other coefficients are assumed to be constants and

$$\mathbf{I}^q = -K^T \nabla T_a - K^T \nabla T_c$$
, and  $\Pi_c = P_c / \rho_0$ . (Eq. 84)

Since  $\varepsilon_a \ll 1$ , the term  $-\rho_0 \alpha T_c \mathbf{V} \cdot \mathbf{g}$  required to maintain energy conservation is small, but it has been retained in (Eq. 83), as it was for the AA and TAA.

Equations (81)–(84) define what Braginsky (1964) and Braginsky and Roberts (1995) termed the "homogeneous model." The density appearing in Eqs. (82) and (83) is the constant reference density  $\rho_0$ and, because of this similarity with the BA, we call the present theory the "generalized Boussinesq approximation" or "GBA," but often it is simply called the "Boussinesq approximation." As its name suggests, the GBA is more widely applicable than the BA. The BA requires that (Eq. 36) holds, but the GBA may be used when

$$\varepsilon_a \sim \varepsilon_c \ll 1.$$
 (Eq. 85)

This extension in the range of validity comes about because, whereas the BA involves the departure  $T_1$  from a constant reference temperature  $T_0$ , the GBA employs the deviation  $T_c$  from an adiabatic  $T_a$ .

The GBA is especially appropriate for the oceans. The fractional changes in density created by the pressure and temperature are of order  $\varepsilon_a$  and  $\varepsilon_c$ , respectively and, as in "The Boussinesq approximation (BA)," they are small. The pressure in the ocean changes from 1 atm at its surface to several times  $10^5$  atm at a depth of several kilometers. Hence  $P_1$  cannot be treated as a small correction to a constant  $P_0$ ; the changes in pressure and temperature are of the same order so that (Eq. 85) holds and not (Eq. 36). Nevertheless, as in the TAA above, it is only the temperature-created change in density,  $\rho_0 \alpha T_c \mathbf{g}$ , that drives convection. Although the GBA is relevant to oceanic convection, compositional buoyancy, arising from differences in salinity, is also a significant factor that requires Eqs. (81)–(84) to be appropriately generalized; see Kamenkovich (1977).

Despite the fact that  $\varepsilon_a \approx 0.2$  in the Earth's core, so that  $\rho_a \approx \rho_0$ and  $T_a \approx T_0$  are poor approximations, the GBA is often used in studying core convection. Since  $\alpha T_a \sim 5 \times 10^{-2}$  however, the approximations  $T_a S_c \approx C_p T_c$  and  $\alpha^S S_c \approx \alpha T_c$  are well satisfied, with an error only of order  $10^{-3}$ , so that the TAA is applicable.

#### The role of turbulence

It was observed in "The anelastic approximation (AA)" that, when *Ra* is large, there is every likelihood that the fluid motions are turbulent and therefore inaccessible to accurate numerical simulation either now or in the foreseeable future. This formidable difficulty besets the natural sciences. Progress can be made only by abandoning all hopes of describing  $\mathbf{V}, S_c, \ldots$  in detail, and by seeking instead the evolution of their averages,  $\overline{\mathbf{V}}, \overline{S_c}, \ldots$ ; these may be smooth enough to be numerically resolvable. The remaining "turbulent" fields,  $\mathbf{V}^t, S_c^t, \ldots$ , are often termed the "sub-grid scale" fields, and are numerically unobtainable. Since however small-scale motions may diffuse the mean fields far more effectively than the molecular diffusivities, their effect on the mean fields cannot be ignored. It is absolutely necessary to incorporate a description of the small-scale fields into the mean field theory.

The fields are separated into mean and turbulent parts:

$$\mathbf{V} = \overline{\mathbf{V}} + \mathbf{V}^t, \quad S_c = \overline{S}_c + S^t, \quad \dots \dots \quad (\text{Eq. 86})$$

(We omit the  $_c$  from  $S_c^t$  because turbulence automatically implies convection.) Consider first the transport of entropy. The ensemble average of the entropy equation, in the form (Eq. 58), is

$$\rho_{a}\overline{d}_{t}\overline{S}_{c} + \nabla \cdot \overline{\mathbf{I}}^{S} = \overline{\sigma}^{S}, \qquad (\text{Eq. 87})$$

where  $\overline{d}_t = \partial_t + \overline{\mathbf{V}} \cdot \nabla$  and

$$\mathbf{I}^{S} = \mathbf{I}_{a}^{S} + \overline{\mathbf{I}}_{c}^{Sm} + \overline{\mathbf{I}}^{St}, \quad \overline{\sigma}^{S} = T_{a}^{-1}(Q^{R} + \overline{Q}^{vm} + \overline{Q}^{vt}) - \mathbf{I}^{S} \cdot \nabla T_{a}.$$
(Eq. 88)

Here

$$\overline{\mathbf{I}}^{St} = \rho_{a} \overline{S' \mathbf{V}'} \tag{Eq. 89}$$

is the "turbulent entropy flux," from which the "turbulent heat flux,"  $\overline{\mathbf{I}}^{qt} = T_{a}\overline{\mathbf{I}}^{St}$  can be obtained. This may be comparable with the molecular heat flux down the adiabat,  $\mathbf{I}_{a}^{q} = -K^{T}\nabla T_{a}$ , and is large compared with  $\overline{\mathbf{I}}_{c}^{qm} = -K^{T}\nabla\overline{T}_{c}$ , which is of order  $\varepsilon_{c}\mathbf{I}_{a}^{q}$  where  $\varepsilon_{c} \ll 1$ ; the superfix *m* stands for "molecular." The viscous dissipation rate has a molecular part,  $\overline{Q}^{vm} = \overline{\pi}_{ij}^{vm}\nabla_{j}\overline{V}_{i}$ , and a turbulent part,  $\overline{Q}^{vt} = \overline{\pi}_{ij}^{vj}\nabla_{j}V_{i}^{t}$ , that is usually much larger.

Similar arguments apply to (Eq. 57), the average of which may be written as

$$\rho_{a}\overline{d}_{t}\overline{\mathbf{V}}-\overline{\mathbf{F}}^{vt}=\rho_{a}\nabla\overline{\Pi}_{c}-\rho_{a}\alpha^{S}\overline{S}_{c}\mathbf{g}+\overline{\mathbf{F}}^{vm}, \qquad (\text{Eq. 90})$$

where

$$\overline{\mathbf{F}}^{vt} = \nabla \cdot \frac{\Delta vt}{\overline{\boldsymbol{\pi}}}, \quad \text{and} \quad \overline{\pi}_{ij}^{vt} = -\rho_a \overline{V_i^t V_j^t}$$
(Eq. 91)

is the "Reynolds stress tensor";  $\overline{\mathbf{F}}^{VI}$  may be combined with the viscous force,  $\overline{\mathbf{F}}^{Vm}$ , of molecular origin created by  $\overline{\mathbf{V}}$ , previously denoted by  $\nabla \cdot \hat{\boldsymbol{\pi}}^{v}$ . It is however generally much greater (except perhaps, in the case of the Earth's core, in Ekman layers). The rate of working of the turbulent buoyancy force is

$$\overline{Q}^{t} = -\rho_{a} \alpha^{S} \overline{S^{t} \mathbf{V}^{t}} \cdot \mathbf{g} = -\overline{\mathbf{I}}^{S^{t}} \cdot \nabla T_{a}, \qquad (\text{Eq. 92})$$

and may be comparable with the rate of working,  $-\rho_a \alpha^{S} \overline{S_c} \nabla \cdot \mathbf{g}$ , of the mean buoyancy force. By using (Eq. 90) to remove the averaged fields from (Eq. 57), an equation governing  $\mathbf{V}^t$  is derived. Taking the scalar product of this with  $\rho_a \mathbf{V}^t$  and <u>averaging</u>, it is found that, in statistically steady turbulence  $(\mathcal{E}^{Kt} = \frac{1}{2}(V^t)^2 = \text{constant})$ ,

$$\overline{Q}' = \overline{Q}^{vt}, \tag{Eq. 93}$$

i.e., the buoyant energy released on the turbulent scales supplies on average the kinetic energy necessary to maintain the turbulent motions against viscous decay. It should be emphasized however that, in magnetohydrodynamic systems such as the Earth's core, the right-hand side of (Eq. 93) is replaced by the sum of the viscous and ohmic dissipations, and the ohmic dissipation may dominate; see Braginsky and Roberts (1995, 2003).

In summary, the mean fields are governed by

where  $\overline{\Pi}_c = \overline{P}_c / \rho_a$  and

$$\nabla \cdot (\rho_{\mathbf{a}} \overline{\mathbf{V}}) = 0, \tag{Eq. 94}$$

$$\overline{d}_t \overline{\mathbf{V}} = -\nabla \overline{\Pi}_c - \alpha^S \overline{S}_c \mathbf{g} + \overline{\mathbf{F}}^{\text{vtotal}} / \rho_a, \qquad (\text{Eq. 95})$$

$$\rho_{\mathrm{a}}T_{\mathrm{a}}\overline{d_{t}}\overline{S}_{\mathrm{c}} + \nabla \cdot \overline{\mathbf{I}}^{\mathrm{qtotal}} = Q^{\mathrm{R}} + \overline{Q}^{\mathrm{vtotal}}, \qquad (\mathrm{Eq.}\ 96)$$

 $\overline{\mathbf{F}}^{\text{vtotal}} = \overline{\mathbf{F}}^{\text{vm}} + \overline{\mathbf{F}}^{\text{vt}}, \quad \overline{Q}^{\text{vtotal}} = \overline{Q}^{\text{vm}} + \overline{Q}^{\text{vt}},$  $\overline{\mathbf{I}}^{\text{qtotal}} = \mathbf{I}_{a}^{q} + \overline{\mathbf{I}}_{a}^{qm} + \overline{\mathbf{I}}_{c}^{qt}.$ (Eq. 97)

Equations (94)–(96) have the same form as Eqs. (56)–(58), but involve mean quantities,  $\overline{F}^{vt}, \overline{Q}^{vt}, \overline{\pi}^{vt}$  and  $\overline{I}_c^{qt}$ , that have to be supplied by experimental measurement or by turbulence theory. Until this is done, the turbulent entropy and momentum fluxes must be parameterized.

"Local turbulence theory" provides one possible parameterization; this rests on the assumption of "scale separation," i.e., that the length and time scales on which the mean fields evolve are so widely separated from turbulent scales that the effects of the latter are, as far as the mean fields are concerned, only "local." The diffusive action of local turbulence on the averaged motion can be parameterized by turbulent diffusivities,  $K^t$  and  $v^t$ , that are much greater than their molecular counterparts, e.g.,  $\overline{\Gamma}^{St} = -K^t \nabla \overline{S}_c$ . [This parameterization is also commonly used in describing astrophysical convection.] Such forms are appropriate when the turbulence is isotropic but when, as for the Earth's core, this is probably not the case, anisotropic (tensor) diffusivities are more realistic, e.g.,  $\vec{\mathbf{I}}^{St} = -\vec{\mathbf{K}}^t \cdot \nabla \overline{S}_c$ . In either case, it is  $\nabla \overline{S}_{c}$  and not  $\nabla \overline{T}_{c}$ , that is significant. For this reason "the anelastic approximation (AA)" is more convenient for core convection than the alternative "temperature-based anelastic approximation (TAA)," even though the conditions required for the validity of the latter are fairly well satisfied. For the compositionally generalized AA of "the anelastic approximation (AA)," the turbulent flux  $\overline{\mathbf{I}}^{\zeta t} = \rho_{\overline{\mathbf{a}}} \overline{\xi^t \mathbf{V}^t}$  of  $\xi$  analogous to (Eq. 89) may be parameterized by  $\overline{\Gamma}^{\xi t} = -\overline{K}^t \cdot \nabla \overline{\xi}_c$ , with the same turbulent diffusivity  $\vec{\mathbf{K}}^t$  as in  $\vec{\mathbf{I}}^{St} = -\vec{\mathbf{K}}^t \cdot \nabla \overline{S}_c$ ; see Braginsky and Roberts (1995, 2003).

More detailed discussions about the role of turbulence may be found in Braginsky (1964), Braginsky and Meytlis (1990), and Braginsky and Roberts (1995, 2003). See also *Core turbulence*.

### **Final remarks**

#### An alternative expression of the BA

Formulations of the BA, different from "the Boussinesq approximation (BA)" and "the generalized Boussinesq approximation (GBA)," are often preferred; see for example Spiegel and Veronis (1960). In the convecting state, (Eq. 31) is replaced by

$$\rho = \rho_{\rm b} + \rho', \quad T = T_{\rm b} + T', \quad P = P_{\rm b} + P', \quad \dots, \quad (\text{Eq. 98})$$

where the primed variables arise from convection and variables carrying the suffix "b" refer to a "basic conductive state" that is in mechanical and thermal equilibrium:  $V_b = 0$ . Evidently, unlike "The Boussinesq approximation (BA)," the basic state is nonuniform. Mechanical equilibrium requires

$$\nabla P_{\mathbf{b}} = \rho_{\mathbf{b}} \mathbf{g} = -\rho_{\mathbf{b}} \nabla U. \tag{Eq. 99}$$

This implies that  $\rho_{\rm b}$ ,  $P_{\rm b}$ , and therefore  $T_{\rm b}$  are constant on equipotential surfaces, i.e., surfaces on which U is constant. Thermal equilibrium requires that  $T_{\rm b}$  satisfies the imposed thermal boundary conditions together with

$$\nabla \cdot (K^T \nabla T_{\mathbf{b}}) + Q^{\mathbf{R}} = 0, \tag{Eq. 100}$$

obtained from Eqs. (3) and (19).

According to Eqs. (46) and (98),  $T_c = T' + T_b - T_a$ . On substituting this into Eqs. (81)–(83) and assuming that  $T_c \sim T' \sim T_b - T_a \ll T_b$ , the equations governing the convective motions become

$$\nabla \cdot \mathbf{V} = \mathbf{0},\tag{Eq. 101}$$

$$d_t \mathbf{V} = -\nabla \Pi' - \alpha T' \mathbf{g} + \mathbf{F}^{\mathbf{v}} / \rho_0, \qquad (\text{Eq. 102})$$

$$d_t T' + \mathbf{V} \cdot \nabla (T_{\mathsf{b}} - T_{\mathsf{a}}) = [\nabla \cdot (K^T \nabla T') + Q^{\mathsf{v}}] / \rho_0 C_p. \quad \text{(Eq. 103)}$$

The term in (Eq. 103) that is proportional to the superadiabatic gradient is included implicitly in the GBA and is significant when  $\varepsilon_a \sim \varepsilon_c \ll 1$ ).

One of the disadvantages of the present formulation is apparent in the case of "free convection," in which boundary conditions prevent  $P_{\rm b}$  and  $T_{\rm b}$  from being constant on equipotential surfaces. Simultaneous solution of Eqs. (99) and (100) is then impossible, and the assumption  $V_{\rm b} = 0$  is untenable; convection occurs for all nonzero *Ra*. By adopting Eqs. (31) or (46) in preference to (Eq. 98), free convection motions do not have to be treated separately; they are on the same footing as convective instabilities and are included with them.

#### A more general CA

۲

In some contexts, convection is weak or nonexistent in some regions of the system but is strong in other regions. For example, consider the thermal boundary layer at a no-slip wall confining a strongly convecting system, or consider a transition layer via which convection in a superadiabatic region penetrates into an adjacent subadiabatic region. In such situations it is useful to select the basic state in a more general way than has so far been contemplated. The basic state (denoted by subscript "b") is again hydrostatic, but satisfies the heat equation (5) in the form

$$\rho_{\rm b} T_{\rm b} d_t S_{\rm b} + \nabla \cdot \mathbf{I}_{\rm b}^q = Q^{\rm R},\tag{Eq. 104}$$

which reduces to (Eq. 48) in a strongly convecting region but to (Eq. 100) in an adjacent weakly or nonconvecting region. Since  $d_t S_b (= \mathbf{V} \cdot \nabla S_b)$  involves **V**, (Eq. 104) imposes a consistency requirement on the solution of the convection equations. Despite this complication, the theory uses thermodynamic linearization and is therefore easier to apply than the full panoply of "Basic equations."

Denoting departures from the basic state by ', convection is governed by

$$7 \cdot (\rho_{\rm b} \mathbf{V}) = 0, \tag{Eq. 105}$$

$$d_t \mathbf{V} = -\nabla \Pi' + (T' \nabla S_b - S' \nabla T_b) + \mathbf{F}^{\nu} / \rho_b, \qquad (\text{Eq. 106})$$

$$\rho_{\mathsf{b}}d_t(T_{\mathsf{b}}S') - \rho_{\mathsf{b}}\mathbf{V} \cdot (S_{\mathsf{b}}\nabla T' - T_{\mathsf{b}}\nabla S') + \nabla \cdot \mathbf{I}_{\mathsf{b}}^q = Q^{\mathsf{v}}, \quad \text{(Eq. 107)}$$

where  $\Pi' = P'/\rho_b$ . In deriving (Eq. 106), the relations  $\nabla \rho_b = v_s^{-2} \nabla P_b - \rho_b \alpha^S \nabla S_b$  and  $\rho' = v_s^{-2} P' - \rho_b \alpha^S S'$  obtained from (Eq. 22) have been used. It follows from these that  $\rho' \nabla P_b - P' \nabla \rho_b = \rho_b^2 (T' \nabla S_b - S' \nabla T_b)$ , by (Eq. 27). The buoyancy term  $T' \nabla S_b - S' \nabla T_b$  in (Eq. 106) can also be written as  $-\alpha^S S' \mathbf{g} + \Pi' \alpha^S \nabla S_b$  or as  $-\alpha T' \mathbf{g} + \Pi' \alpha \nabla T_b$ ; cf. Eqs. (62) and (74).

A generalized CA of the type considered here has been developed by Rogers and Glatzmaier (2005).

#### Boundary conditions for CA

Boundary conditions are specific to the system under consideration and are imposed on the solutions of the basic equations of "Basic equations." They translate directly into corresponding conditions on solutions of the CA equations. Their application to the AA, however, raises questions that are briefly addressed here, using the Earth's core as an illustration.

The core and mantle form one, coupled system that must obey the correct thermal conditions at the CMB. The first of these is

$$T_{\rm Core} = T_{\rm Mantle}$$
, on the CMB, (Eq. 108)

where each side is the sum of adiabatic and convective parts, e.g.,  $T_{\text{Core}} = T_{\text{Core,a}} + T_{\text{Core,c}}$ . The second expresses continuity of the normal component of the heat flux

$$I_{\text{Core},n}^q = I_{\text{Mantle},n}^q$$
, on the CMB, (Eq. 109)

where each side is the sum of adiabatic and convective parts, e.g.,  $I_{\text{Core},n}^q = I_{\text{Core},a}^q + I_{\text{Core},n}^q$ . In the case of the core, these were denoted earlier simply by  $I_a^q = -K^T \partial_n T_a = K^T \Gamma$  and the normal component of  $\mathbf{I}_a^q$ .

It is clearly inconvenient to have to solve for core and mantle convection simultaneously but, because  $V_{\text{mantle}} \ll V_{\text{core}}$ , the two systems can be considered separately. Each of the four fluxes comprising (Eq. 109) are a few TW and, since  $I_{\text{Core},cn}^q \sim (\rho C_p V_n T_c)_{\text{Core}}$  and  $I_{\text{Mantle},cn}^q \sim (\rho C_p V_n T_c)_{\text{Mantle}}$ , it follows that  $T_{\text{Core},c} \ll T_{\text{Mantle},c}$ . To a very good approximation therefore, (Eq. 108) reduces to

$$T_{\text{Mantle}} = T_{\text{Core,a}}, \text{ on the CMB.}$$
 (Eq. 110)

This is the thermal condition to apply to mantle convection. It would be wrong from a physical point of view to assign  $T_{\rm CMB}$  when solving core convection. Having solved the mantle convection equations with the  $T_{\rm CMB}$  prescribed,  $I_{\rm Mantle,n}^q$  on the CMB becomes known (in principle), and this determines the right-hand side of (Eq. 109), which becomes the condition to be applied to core convection:

$$I_{\text{Core},cn}^q = I_{\text{CMB}}^q$$
, where  $I_{\text{CMB}}^q = (Nu - 1)I_{\text{Core},a}^q$ , on the CMB.  
(Eq. 111)

Here  $Nu = I_{\text{Mantle},n}^q / I_{\text{Core,a}}^q$  is the Nusselt number, a nondimensional measure of the importance of convective heat transport in the core relative to the conductive; in general it is a function of horizontal position on the CMB (see *Core-mantle coupling, thermal*).

In the bulk of the core, turbulent motions are responsible for the flux  $I_{qn}^{q}$  but  $V_n$ , falls to zero as the CMB is approached, so that thermal conduction must increasingly carry the necessary heat flux until, on the CMB itself,  $I_{qn}^{q} = -K^T \nabla_n T_c$ . Since  $I_{qn}^{q}$  is typically large,  $\nabla_n T$  must be large too, both at the CMB and in a thin, nonadiabatic, boundary layer abutting the CMB. We shall not discuss the structure of the boundary layer here (see *Core, boundary layers*).

#### A note on terminology

All CAs filter out elastic waves (seismic/acoustic) and they could therefore all be described as "anelastic," i.e., not elastic. Paradoxically, the AA and TAA are the only CAs that recognize elasticity at all, in the sense that they include the slow elastic response of the density to changes in pressure. If these are termed "anelastic," the BA is *totally* anelastic! A CA is commonly called "Boussinesq" if it uses  $\nabla \cdot \mathbf{V} = 0$  but "anelastic" if it uses  $\nabla \cdot (\rho_a \mathbf{V}) = 0$  instead.

ANISOTROPY, ELECTRICAL

# ANISOTROPY, ELECTRICAL

In the geosciences, the term "electrical anisotropy" describes the directional dependence of the electrical conductivity of Earth materials. In the case of intrinsic anisotropy, this directional dependence occurs on all scales, while in the case of macroscopic anisotropy composite media are formed from isotropic components in such a way that the bulk conductivity is anisotropic. Intrinsic anisotropy can be described with numerical modeling of the electromagnetic (see *EM*) induction process (e.g., Pek and Verner, 1997). An example of macroscopic anisotropy is presented in Figure A2.

#### Field observations: magnetotellurics

Fournier (1963) first realized that differences between amplitudes of orthogonal electromagnetic fields, measured with *magnetotellurics* (MT) (q.v.), can be associated with electrical anisotropy. In modern MT, anisotropic Earth models are derived from differences between the phases (phase lags between electric and magnetic fields) of two

**Figure A2** Isotropic and anisotropic MT Earth models and the corresponding transfer functions, displayed as apparent resistivity  $\rho_a$  (amplitude of the *E/B* transfer function) and phase  $\varphi$  (phase lag between the electric field *E* and the magnetic field *B*), as a function of period *T*. Due to the skin effect, electromagnetic fields with longer periods penetrate deeper into the Earth than shorter periods. The conductive (black) intermediate layer of the isotropic model generates a minimum in the apparent resistivity curve at intermediate periods as well as a variation in the phase curve, regardless of the polarization of the electromagnetic field,  $E_x/B_y$  or  $E_y/B_x$ . In the anisotropic model, this intermediate layer is conductive only in the *x* direction and therefore affects only the transfer function for the  $E_x/B_y$  and the  $E_y/B_x$  polarization in the intermediate period band.

polarizations of the electromagnetic field (Kellett *et al.*, 1992)—see Figure A2. In contrast, amplitude differences are rarely evaluated now due to *galvanic distortion* (q.v.) (Simpson and Bahr, 2005). Tests are available which allow to distinguish between anisotropic Earth models and models of conductivity anomalies that only generate anisotropic data (Bahr *et al.*, 2000). In these tests the phase differences obtained from many MT sites in a target area are compared, and anisotropic Earth models are considered if all sites have similar phase differences.

#### Laboratory measurements and scaling

The ratio between the highest and the lowest conductivity is referred to as anisotropy factor. The electrical anisotropy factors found in laboratory studies of crustal rocks (e.g., Rauen and Lastovickova, 1995) are smaller than those found in MT earth models, and this discrepancy has been explained with scaling techniques in composite media (Bahr, 1997) (Figure A3). In contrast, the anisotropy factor of hydrogen diffusity in olivine can be as large as 40 (Kohlstedt and Mackwell, 1998) and this can result in a large electrical anisotropy of "wet" olivine (Lizzaralde *et al.*, 1995).

#### Geodynamic implications

MT data from Northern Bavaria have been interpreted with electrical anisotropy in the middle crust with the direction of highest conductance (*electromagnetic strike*) aligned parallel to paleoterrane boundaries (Bahr *et al.*, 2000). Anisotropic conductive structures in the continental crust can therefore be fossil remainings of terrane accretion. Marine-controlled electromagnetic data from the Pacific show that the oceanic crust can be electrically anisotropic, with the direction of highest conductance aligned parallel to the fossil spreading direction (Everett and Constable, 1999). Strain-aligned mineralogical fabric with connected accumulations of trace conductors such as graphite or sulfides can account for this anisotropy. Graphite is also the most likely cause of electrical anisotropy in the North American lithosphere (Mareschal *et al.*, 1995).

With long period MT, electrical anisotropy has been found at the base of the Australian lithosphere with the direction of highest conductance rotated  $30^{\circ}$  relative to the direction of the present day absolute

**Figure A3** Electrical connectivity  $\gamma$  of a random resistor network representing a two-component medium as function of the fraction *p* of the high conductive component. At the percolation threshold, a small increase of this fraction results in a relatively large increase of the connectivity. Suppose the high conductive component is distributed in microcracks: If these cracks occur slightly more often in the *y* direction than in the *x* direction, then a large difference between the connectivities  $\gamma_y$  and  $\gamma_x$  in the *y* and *x* direction is created. This difference results in anisotropic bulk conductivity.

plate motion (APM) that is determined relative to the hotspot reference frame (Simpson, 2001). But the APM direction that is determined relative to a reference frame defined by requiring no net rotation of the lithosphere matches the electrical anisotropy direction better (Simpson, 2002). Mantle flow models suggest that shear of the mantle imparted by the drag of an overriding plate favors alignment of olivine [100] axes parallel to the direction of plate motion (McKenzie, 1979), and this has been confirmed by seismological studies with surface waves (e.g., Debayle and Kennett, 2000). Hydrogen diffusivities enhance the conductivity of olivine crystals anisotropically (e.g., Lizzaralde et al., 1995), providing a possible explanation for the MT anisotropy if hotspots are not stationary relative to the deep mantle (Simpson, 2002). However, electrical anisotropy has also been found below the European lithosphere where current plate motion is slow, and therefore paleoflow can also explain the electrical anisotropy of the sublithospheric mantle (Leibecker et al., 2002; Gatzemeier and Moorkamp, 2005).

Galvanic Distortion Induction Magnetotellurics Mantle, Electrical Conductivity, Mineralogy

# ANTIDYNAMO AND BOUNDING THEOREMS

Dynamos are devices that convert mechanical energy into electromagnetic energy. While technical dynamos depend on a suitable arrangement of multiply connected regions (usually wires) of high electrical conductivity within an insulating space, the generation of magnetic fields in planets and stars must occur in simply connected domains of essentially uniform finite conductivity. For a long time after Larmor (1919) (see Larmor, J.) first proposed this homogeneous dynamo process as the origin of magnetic fields in sunspots it has been doubtful whether it is possible. Mathematicians and geophysicists have proved antidynamo theorems in order to determine the conditions under which homogeneous dynamos are possible. The first and most famous theorem has been formulated and proved by Cowling (1934) (see Cowling, T.G.). He demonstrated that axisymmetric or two-dimensional magnetic fields cannot be generated by the homogeneous dynamo process (see Cowling's Theorem). Since the Earth's magnetic field is nearly axisymmetric the dynamo hypothesis of the origin of geomagnetism remained in doubt for a quarter of a century until Backus (1958) and Herzenberg (1958) could show in a mathematically convincing way that nonaxisymmetric fields could indeed be generated (see Dynamo, Herzenberg and Dynamo, Backus).

Antidynamo and bounding theorems can be divided into the following categories:

- Lower bounds on magnetic Reynolds numbers or related quantities that are necessary for amplifying magnetic fields
- 2. Structures and symmetries of velocity fields that cannot be dynamos (e.g., Toroidal theorem)
- 3. Structures and symmetries of magnetic fields that can not be generated by the dynamo process (e.g., Cowling's theorem)

#### Lower bounds for magnetic Reynolds numbers

Nearly all theorems that have appeared in the literature are based on the equation of magnetic induction for the magnetic flux density B,

$$\left(\frac{\partial}{\partial t} + \boldsymbol{v} \cdot \nabla\right) \boldsymbol{B} + \nabla \times (\lambda \nabla \times \boldsymbol{B}) = \boldsymbol{B} \cdot \nabla \boldsymbol{v}, \qquad (\text{Eq. 1})$$

which can be derived from Maxwell's equations in the magnetohydrodynamic approximation in which the displacement current is neglected and from Ohm's law for a moving conductor,

$$\lambda \nabla \times \boldsymbol{B} = \boldsymbol{v} \times \boldsymbol{B} + \boldsymbol{E} \tag{Eq. 2}$$

where *E* is the electric field, *v* is the velocity vector field, and  $\lambda$  is the magnetic diffusivity. The latter is defined as the inverse of the product of magnetic permeability and electrical conductivity,  $\lambda = (\sigma \cdot \mu)^{-1}$ . In writing equation 1, a solenoidal velocity field *v* has also been assumed.

Antidynamo theorems of type (i) can be obtained by multiplying equation 1 by **B** and integrating it over a finite domain V of finite conductivity

$$\frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}t}\int_{V+V'}|\boldsymbol{B}|^{2}\mathrm{d}^{3}V = \int_{V}\boldsymbol{B}\cdot(\boldsymbol{B}\cdot\nabla)v\mathrm{d}^{3}V - \int_{V}\lambda|\nabla\times\boldsymbol{B}|^{2}\mathrm{d}^{3}V$$
(Eq. 3)

Here the integral on the left hand side is extended over the entire space V + V' where the integral over the electrically insulating complement V' of *V* arises from the partial integration of the term  $\nabla \times (\lambda \nabla \times B)$  (for details see Backus, 1958). Using the maximum m(t) of the rate of strain tensor and the minimum decay rate  $s_d$ , which are defined by

$$m(t) = \max\left[\frac{1}{2}(\partial_i v_j + \partial_j v_i)\right], \quad s_{\rm d} \equiv \min\left(\frac{\int_V \lambda |\nabla \times \boldsymbol{B}|^2 {\rm d}^3 V}{\int_{V+V'} |\boldsymbol{B}|^2 {\rm d}^3 V}\right)$$
(Eq. 4)

the inequality

$$\frac{1}{2}\frac{d}{dt}\int_{V+V'}|\boldsymbol{B}|^{2}d^{3}V \leq (m(t)-s_{d})\int_{V+V'}|\boldsymbol{B}|^{2}d^{3}V$$
 (Eq. 5)

can be obtained (Backus, 1958). This relationship indicates the rate of stretching of the magnetic field by the velocity field must be sufficiently strong in order to overcome the effect of Ohmic dissipation. In the special case when V is a sphere of constant  $\lambda$  with radius  $r_0$  and when the velocity field is steady such that  $m(t) = v_0/r_0$  can be written with a constant  $v_0$  of the dimension of a velocity, inequality (Eq. 5) can be obtained in the form

$$\frac{1}{2}\frac{d}{dt}\int_{V+V'}|\boldsymbol{B}|^{2}d^{3}V \leq (Rm-\pi^{2})\frac{\lambda}{r_{0}^{2}}\int_{V+V'}|\boldsymbol{B}|^{2}d^{3}V$$
(Eq. 6)

where the magnetic Reynolds number  $Rm \equiv v_0 r_0/\lambda$  has been introduced and the expression  $s_d = \pi^2 \lambda/r_0^2$  for the smallest rate of decay of a magnetic field in a conducting motionless sphere has been used. This inequality states that unless the magnetic Reynolds number Rmexceeds the value  $\pi^2$  a dynamo cannot exist in a conducting sphere. Another version of this theorem was obtained by Childress (1969), which assumes the same form (Eq. 6) except that  $v_0$  in the definition of Rm denotes the maximum of |v|, which is the more common definition of the magnetic Reynolds number. For an improvement of Backus' bound, see Proctor (1977). A related criterion has been derived by Proctor (1979). It states for

$$\int_{V} |\nabla \boldsymbol{\nu}|^2 \mathrm{d}^3 V \le \frac{\lambda^2 \pi}{16r_0} \tag{Eq. 7}$$

no growing magnetic field can be obtained. The expression on the left hand side denotes, of course, the viscous dissipation of the velocity field v divided by the viscosity. It should be noted that all equations and derivations used in this article remain valid in a rotating system, which makes the results especially useful for geophysical and astrophysical applications.

#### Velocity fields that cannot act as dynamos

For the discussion of other dynamo theorems it is convenient to introduce the general representation for solenoidal vector fields such as **B** and  $\mathbf{v}$  (in the case when  $\nabla \cdot \mathbf{v} = 0$  can be assumed),

$$B = \nabla \times (\nabla h \times \mathbf{r}) + \nabla g \times \mathbf{r},$$
  

$$\mathbf{v} = \nabla \times (\nabla \Phi \times \mathbf{r}) + \nabla \Psi \times \mathbf{r} \equiv \mathbf{v}_{\text{pol}} + \mathbf{v}_{\text{tor}}$$
(Eq. 8)

where  $\mathbf{r}$  is the position vector. The poloidal scalar functions h and  $\Phi$  and the toroidal scalar functions g and  $\Psi$  are uniquely defined when the condition is imposed that their averages over surfaces  $|\mathbf{r}| = const$ . vanish (Backus, 1958). A famous theorem of type (ii) that was already known to Elsasser (1946) (see *Elsasser W*.) and been discussed in detail by Bullard and Gellman (1956) is the Toroidal theorem, which states that a purely toroidal velocity field for which  $\Phi \equiv 0$  holds cannot generate a magnetic field when  $\lambda = \lambda(r)$  is a function of the radius  $r = |\mathbf{r}|$  only. The validity of this theorem can easily be seen when equation 1, multiplied by  $\mathbf{r}$ ,

$$\left(\frac{\partial}{\partial t} + \boldsymbol{v} \cdot \nabla\right) \boldsymbol{B} \cdot \boldsymbol{r} - \lambda(r) \nabla^2 \boldsymbol{B} \cdot \boldsymbol{r} = \boldsymbol{B} \cdot \nabla \boldsymbol{v} \cdot \boldsymbol{r}$$
(Eq. 9)

is considered. Since the right hand side vanishes for a purely toroidal velocity field, equation 9 becomes the heat equation for the "temperature"  $B \cdot r$  without heat sources for which only decaying solutions exist. After the *r*-component of **B** has decayed it is easy to see that the other components must decay as well. The question could be raised whether a purely poloidal velocity field can generate a magnetic field. The answer is "yes." Gailitis (1970) provides an example in that he used an axisymmetric purely poloidal velocity field for his ring dynamo (see *Dynamo, Gailitis*).

Since a finite radial component of the velocity field is required for dynamo action according to the Toroidal theorem, it is of interest to see whether bounds on its magnitude can be obtained. The condition

$$\max|\mathbf{v}\cdot\mathbf{r}| \ge \lambda M_{\text{pol}}/M \tag{Eq. 10}$$

derived on the basis of equation 9 for a sphere of constant diffusivity  $\lambda$  provides a necessary condition for a dynamo (Busse, 1975). Here *M* denotes the total energy of the magnetic field, while  $M_{\rm pol}$  refers to the energy of its poloidal component.

A related criterion that is independent of magnetic energies has recently been derived by Proctor (2004). It states that the energies of poloidal and toroidal components of the magnetic field decay exponentially if

$$\frac{1}{2}|\mathbf{v}_{\rm pol}|_{\rm m}|\mathbf{v}_{\rm tor}|_{\rm m} + \sqrt{2}|\mathbf{v}_{\rm pol}|_{\rm m}\frac{\lambda}{r_0} < \frac{\lambda^2}{r_0^2}$$
(Eq. 11)

is satisfied where  $|\mathbf{v}_{pol}|_m$  and  $|\mathbf{v}_{tor}|_m$  indicate the maximum values of  $|\mathbf{v}_{pol}|$  and  $|\mathbf{v}_{tor}|$  in the conducting sphere of radius  $r_0$ . For  $|\mathbf{v}_{tor}|_m > \pi \lambda / r_0$  this criterion is more severe than Childress' criterion mentioned above in connection with relationship (Eq. 6).

Antidynamo theorems have also been derived for velocity fields with only a radial component (Namikawa and Matsushita, 1970) in which case the property  $\nabla \cdot \mathbf{v} = 0$  must be dropped, of course. For a discussion of antidynamo theorems for a combination of a toroidal velocity field and a purely radial velocity we refer to Ivers (1995) and earlier papers mentioned therein.

# Magnetic fields that cannot be generated by the dynamo process

We have already mentioned the fact that equation 1 does not permit growing axisymmetric magnetic fields as solutions as stated by Cowling's theorem. But it is also generally believed that neither a purely toroidal nor a purely poloidal magnetic field can be generated by the dynamo process in a sphere. The assumption of spherical symmetry is essential since the boundary conditions for poloidal and toroidal components separate on a spherical surface. The only other configuration with this property appears to be the planar layer, which may be regarded as the limit of a thin spherical shell. Proofs in the spherical and planar cases are thus essentially identical. A proof that any physically reasonable purely toroidal field must decay has been obtained by

Properties	Of magnetic field	Of velocity field	
Axisymmetry	No	Yes	
Purely toroidal	No	No	
Purely poloidal	No (?)	Yes	
Helical symmetry	Yes	Yes	

Table A1 Existence of homogeneous dynamos

Kaiser *et al.* (1994). In the poloidal case a proof depending on a physical plausibility argument has been given by Kaiser (1995).

#### Concluding remarks

The search for antidynamo theorems has led to some interesting mathematical theorems in the past decades. Just as important are the physical insights into the dynamo process that have been gained. The interactions of poloidal and toroidal components of the magnetic field are evidently essential for the operation of a dynamo. To summarize the main results of antidynamo theorems the Table A1 has been composed. In it we have included the case of helical symmetry, which is known to be dynamo friendly. Indeed Lortz (1968) was able to derive a dynamo with helical symmetry.

# ARCHEOLOGY, MAGNETIC METHODS

# Magnetism and archeology

# Introduction

Magnetic methods have become important tools for the scientific investigation of archeological sites, with magnetic prospection surveys and archeomagnetic dating being the most prominent ones. The principles behind these techniques were initially applied to larger and older features, for example prospecting for ore deposits (see Magnetic anomalies for geology and resources) or paleomagnetic dating (see Paleomagnetism). When these techniques were adapted for archeological targets it was soon established that very different methodologies were required. Archeological features are relatively small and buried at shallow depth and the required dating accuracy is in the order of tens of years. More importantly, the relationship between archeological features and magnetism is often difficult to predict and the planning of investigations can hence be complicated. Related is the problem of interpretation. Geophysical results on their own are only of limited use to resolve an archeological problem. It is the archeological interpretation of the results using all possible background information (site conditions, archeological background knowledge, results from other investigations, etc.), which provides useful new insights. If the relationship between magnetic properties and their archeological formation is unknown, such interpretation may become speculative.

All magnetic investigations depend on the contrast in a magnetic property between the feature of interest and its surrounding environment, for example the enclosing soil matrix. The most important magnetic properties for archeological studies are magnetization and magnetic susceptibility.

#### Remanent magnetism

Thermoremanent magnetization is probably the best understood magnetic effect caused by past human habitation. If materials that are rich in iron oxides are heated above their Curie temperature and then allowed to cool in the ambient Earth's magnetic field they have the potential to acquire a considerable thermoremanence that is fixed in the material until further heating. Typical archeological examples are kilns and furnaces, often built of clay, which during their heating cycles often exceed the Curie temperatures of magnetite (Fe<sub>3</sub>O<sub>4</sub>) and maghaemite (y-Fe<sub>2</sub>O<sub>3</sub>) (578°C and 578–675°C, respectively). Such iron oxides are commonly found in the clay deposits that were used for the construction of these features. Even if the clays only contained weakly magnetic haematite or goethite, the heating and cooling cycles may have converted these into ferrimagnetic iron oxides (see Magnetic mineralogy, changes due to heating). Similarly, fired bricks and pottery can exhibit thermoremanence but when the finished bricks are used as building material their individual vectors of magnetization will point into many different directions producing an overall weakened magnetic signature (Bevan, 1994). The same applies to heaps of pottery shards. The strong magnetic remanence of kilns led to their discovery with magnetometers in 1958 (Clark, 1990), which triggered the widespread use of archeological magnetometer surveys today.

Kilns also helped to establish the archeomagnetic dating technique as a new tool for chronological studies in archeology (Clark *et al.*, 1988).

Detrital remanence is caused when the Earth's magnetic field aligns magnetized particles that are suspended in solution and gradually settle (see *Magnetization, depositional remanent*). An example is stagnant water loaded with "magnetic sediments". The resulting deposits can exhibit a weak but noticeable remanence, which could be used for dating and prospection. It is suspected that similar effects have produced a small remanence and hence a noticeable positive signal in Egyptian mud-bricks, which were made from wet clay pushed into moulds and dried in the sun (Herbich, 2003). However, other magnetometer surveys over mud-brick structures (Becker and Fassbinder, 1999) have shown a negative magnetic contrast of these features against the surrounding soil. Although it is possible to consider burning events that could lead to such results during the demolition of buildings, it is more likely that these bricks were made from clay that has lower magnetic susceptibility than the soil on the building site.

#### Induced magnetism

Any material with a magnetic susceptibility will acquire an induced magnetization in the Earth's magnetic field (see Magnetic susceptibility). Hence, if past human habitation has led to enhanced levels of magnetic susceptibility in the soils, magnetic measurements can be used for their detection. The relationship between human activities and the enhancement of magnetic susceptibility was investigated by Le Borgne (1955, 1960), distinguishing thermal and bacterial enhancement. When soil is heated in the presence of organic material (for example during bush- or camp-fires), oxygen is excluded and the resulting reducing conditions lead to a conversion of the soil's hematite ( $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, antiferromagnetic) to magnetite (Fe<sub>3</sub>O<sub>4</sub>, ferrimagnetic) with a strong increase of magnetic susceptibility. On cooling in air, some of the magnetite may be reoxidized to maghemite ( $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>, ferrimagnetic), thereby preserving the elevated magnetic susceptibility. In contrast, the "fermentation effect" refers to the reduction of hematite to magnetite in the presence of anerobic bacteria that grew in decomposing organic material left by human habitation, either in the form of rubbish pits ("middens") or wooden building material. This latter effect requires further research but it is reported that changes in pH/Eh conditions as well as the bacteria's use of iron as electron source are responsible for the increase of magnetic susceptibility (Linford, 2004). The level of magnetic susceptibility that can be reached through anthropogenic enhancement also depends on the amount of iron oxides initially available in the soil for conversion. The level of enhancement can hence be quantified by relating a soil's current magnetic susceptibility to the maximum achievable value. This ratio is referred to as "fractional conversion" and is determined by heating a sample to about 700°C to enhance its magnetic susceptibility as far as possible (Crowther and Barker, 1995; Graham and Scollar, 1976). Whether the initial magnetic susceptibility was enhanced by pedogenic or anthropogenic effects can however not be distinguished with this method. It is also worth remembering that magnetite and maghemite have the highest magnetic susceptibility of the iron oxides commonly found in soils, and in the absence of elemental iron, a sample's magnetic susceptibility is hence a measure for the concentration of these two minerals.

More recent investigations have indicated additional avenues for the enhancement of magnetic susceptibility. One of the most interesting is a magnetotactic bacterium that thrives in organic material and grows magnetite crystals within its bodies (Fassbinder *et al.*, 1990) (see also *Biomagnetism*). Their accumulation in the decayed remains of wooden postholes led to measurable magnetic anomalies and is probably responsible for the detection of palisade walls in magnetometer surveys (Fassbinder and Irlinger, 1994). Other causes include the low-temperature thermal dehydration of lepidocrocite to maghemite (e.g., Özdemir and Banerjee, 1984) and the physical alteration of the constituent magnetic minerals, especially their grain size (Linford

and Canti, 2001; Weston, 2004). Magnetic susceptibility can also be enhanced by the creation of iron sulfides in perimarine environments with stagnant waters (Kattenberg and Aalbersberg, 2004). These may fill geomorphological features, like creeks, that were used for settlements and can therefore be indirect evidence for potential human activity.

# Archeological prospection

Archeological prospection refers to the noninvasive investigation of archeological sites and landscapes for the discovery of buried archeological features. To understand past societies it is of great importance to analyze the way people lived and interacted and the layout of archeological sites gives vital clues; for example the structure of a Roman villa's foundations or the location of an Iron-aged ditched enclosure within the wider landscape. Such information can often be revealed without excavation by magnetic surveys. These techniques have therefore become a vital part of site investigation strategies. Buried archeological features with magnetic contrast will produce small anomalies in measurements on the surface and detailed interpretation of recorded data can often lead to meaningful archeological interpretations. The techniques are not normally used to "treasure-hunt" for individual ferrous objects but rather for features like foundations, ditches, pits, or kilns (Sutherland and Schmidt, 2003).

#### Magnetic susceptibility surveys

Since human habitation can lead to increased magnetic susceptibility (see above), measurements of this soil property are used for the identification of areas of activity. Such surveys can either be carried out *in situ* (i.e., with nonintrusive field measurements) or by collecting soil samples for measurements in a laboratory. These two methods are often distinguished as being volume- and mass-specific, respectively, although such labeling only vaguely reflects the measured properties.

Most instruments available for the measurement of low field magnetic susceptibility internally measure the "total magnetic susceptibility" ( $k_t$  with units of m<sup>3</sup>), which is proportional to the amount of magnetic material within the sensitive volume of the detector: the more material there is, the higher will be the reading. For field measurements, the amount of investigated material is usually estimated by identifying a "volume of sensitivity" (V) for the employed sensor (e.g., a hemisphere with the sensor's diameter for the Bartington MS2D field coil). The "volume specific magnetic susceptibility" is then defined as  $\kappa = k_t/V$  (dimensionless). In contrast, laboratory measurements normally relate instrument readings to the weight of a sample (m), which can be determined more accurately. The "mass specific magnetic susceptibility" is then  $\chi = k_t/m$  (with units of m<sup>3</sup> kg<sup>-1</sup>). Accordingly, it is possible to calculate one of these quantities from the other using the material's bulk density ( $\rho$ ):  $\chi = \kappa/\rho$ .

The main difference between field and laboratory measurements, however, is the treatment of samples. It is common practice (Linford, 1994) to dry and sieve soil samples prior to measuring their magnetic susceptibility in the laboratory. Drying eliminates the dependency of mass specific magnetic susceptibility on moisture content, which affects the bulk density. Sieving removes coarse inclusions (e.g., pebbles) that are magnetically insignificant. In this way, laboratory measurements represent the magnetic susceptibility of a sample's soil component and can therefore be compared to standard tables. For field measurements, however, results can be influenced by nonsoil inclusions and the conversion of volume-specific measurements to mass-specific values is affected by changes in environmental factors (e.g., soil moisture content).

The measured magnetic susceptibility depends on the amount of iron oxides available prior to its alteration by humans (mostly related to a soil's parent geology), and also on the extent of conversion due to the anthropogenic influences. As a consequence, the absolute value of magnetic susceptibility can vary widely between different sites and "enhancement" can only be identified as a contrast between areas of higher susceptibility compared to background measurements. There is no predetermined threshold for this contrast and it is therefore justifiable to use the more qualitative measurements of field-based magnetic volume susceptibility (see above) for archeological prospection.

The instrument most commonly used for field measurements of volume specific magnetic susceptibility is the Bartington MS2D field coil consisting of a 0.2 m diameter "loop," which derives 95% of its signal from the top 0.1 m of soil (Schmidt *et al.*, 2005). Since most archeological features are buried deeper than this sensitivity range, the method relies on the mixing of soil throughout the profile, mostly by ploughing.

Magnetic susceptibility surveys, either performed as in situ field measurements or as laboratory measurements of soil samples, can be used in three different ways: (i) as primary prospection method to obtain information about individual buried features, (ii) to complement magnetometer surveys and help with their interpretation by providing data on underlying magnetic susceptibility variations, or (iii) for a quick and coarse "reconnaissance" survey using large sampling intervals to indicate areas of enhancement instead of outlining individual features. Figure A4a shows the magnetic susceptibility survey (MS2D) of a medieval charcoal burning area. Since a detailed study of this feature was required, the data were recorded with a spatial resolution of 1 m in both x- and y-directions. Corresponding magnetometer data (FM36) are displayed in Figure A4b. The magnetic susceptibility results outline the burnt area more clearly and are on this site well suited for the delineation of features. On former settlement sites where ploughing has brought magnetically enhanced material to the surface and spread it across the area, magnetic susceptibility measurements at coarse intervals of 5, 10, or 20 m can be used to identify areas of enhancement that can later be investigated with more detailed sampling, for example with a magnetometer (see below). Even where ploughing has mixed the soil, magnetic susceptibility measurements can vary considerably over short distances of about 2 m. It is hence not normally possible to interpolate coarsely sampled data and settlement sites can only be identified if several adjacent measurements have consistently high levels compared to the surrounding area. Figure A5 shows data from a survey at Kirkby Overblow, North Yorkshire, in search for a lost medieval village. The dots mark the individual measurements and their size represents the strength of the magnetic susceptibility, highlighting the singularity of each measurement. Nevertheless, areas of overall enhancement can be identified and these were later investigated with magnetometer surveys. The gray shading in this diagram visualizes the data in a contiguous way, coloring the Voronoi cell around each individual measurement according to its magnetic susceptibility. The limitations of such diagrams for widely separated measurements should be considered carefully.

#### Magnetometer surveys

In contrast to surveys that measure magnetic susceptibility directly, magnetometer surveys record the magnetic fields produced by a contrast in magnetization, whether it is induced as a result of a magnetic susceptibility contrast, or remanent, for example from thermoremanent magnetization. If the shape and magnetic properties of a buried archeological feature were known, the resulting magnetic anomaly could be calculated (Schmidt, 2001) (see also Magnetic anomalies, modeling). The inverse process, however, of reconstructing the archeological feature from its measured anomaly, is usually not possible due to the nonuniqueness of the magnetic problem and the complex shape and heterogeneous composition of such features. Some successful inversions were achieved when archeologically informed assumptions were made about the expected feature shapes (e.g., the steepness of ditches) and magnetic soil properties (for example from similar sites) (Neubauer and Eder-Hinterleitner, 1997; Herwanger et al., 2000). If surveys are conducted with sufficiently high spatial resolution, the mapped data often already provide very clear outlines of the buried features (Figure A6), allowing their archeological interpretation even without data inversion. However, when interpreting measured data directly, the typical characteristics of magnetic anomalies have to be taken into consideration. For example, in the northern hemisphere

**Figure A4** Medieval charcoal production site in Eskdale, Cumbria. (a) Magnetic susceptibility survey with Bartington MS2D field coil. (b) Fluxgate gradiometer survey with Geoscan FM36. Both surveys were conducted over an area of 40 m  $\times$  40 m with a spatial resolution of 1 m  $\times$  1 m.

Magnetic Susceptibility Readings [10E-5]

**Figure A5** Kirkby Overblow, North Yorkshire. To search for a deserted medieval village, a magnetic susceptibility survey was undertaken with the Bartington MS2D field coil. The measurements are represented as scaled dots and as shaded Voronoi cells. Basemap from 1st edition Ordnance Survey data.

anomalies created by soil features with induced magnetization have a negative trough to the north of the archeological structure and a slight shift of the positive magnetic peak to the south of its center (Figure A7).

To estimate the strength of a typical archeological response it is possible to approximate the anomaly with a simplified dipole field:  $B = \mu_0 m/r^3 = \Delta \kappa V B_{\text{Earth}}/r^3$ , where  $\mu_0$  is the magnetic permeability of free space ( $4\pi \times 10^{-7} \text{ Tm A}^{-1}$ ), *m* is the total magnetic moment of the feature, r the distance between measurement position and sample,  $\Delta \kappa$ its volume-specific magnetic susceptibility contrast, V its volume, and  $B_{\text{Earth}}$  the Earth's magnetic flux density. For a buried pit, the following values can be used:  $\Delta \kappa = 10 \times 10^{-5}$ ,  $V = 1 \text{ m}^3$ ,  $B_{\text{Earth}} = 48,000 \text{ nT}$ , and r = 1 m. This yields an anomaly strength of only 4.8 nT, which is typical for archeological soil features (e.g., pits or ditches). Anomalies created by the magnetic enrichment of soils through magnetotactic bacteria, for example in palisade ditches, can be as low as 0.3 nT (Fassbinder and Irlinger, 1994) and are therefore only detectable with very sensitive instruments and on sites where the signals caused by small variations in the undisturbed soil's magnetic properties are very low (low "soil noise"). Peak values higher than approximately 50 nT are normally only measured over ferrous features with very high magnetic susceptibility, or over features with thermoremanent magnetization, like furnaces or kilns. As shown by the numerical approximation above, the anomaly strength depends both on the magnetization and the depth of a buried feature and can therefore not be used for the unambiguous characterization of that feature. More indicative is the spatial variation of an anomaly (see Figure A7) since deeper features tend to create broader anomalies.

Surveys are normally undertaken with magnetometers on a regular grid. The required spatial resolution obviously depends on the size of the investigated features, but since these are often unknown at the outset, a high resolution is advisable. Recommendations by English Heritage have suggested a minimum resolution of 0.25 m along lines with a traverse spacing of 1 m or less (0.25 m  $\times$  1 m) (David, 1995). However, to improve the definition of small magnetic anomalies even denser sampling is required. Such high-definition data can even show peaks and troughs of bipolar anomalies from small, shallowly buried iron debris (e.g., farm implements) and therefore help to distinguish these from archeological features with wider anomaly footprints. More recently, it has become possible to collect randomly sampled data with high accuracy (Schmidt, 2003) that can either be gridded to a predefined resolution or visualized directly with Delaunay triangulation (Sauerländer *et al.*, 1999).

Due to the often small anomaly strength caused by archeological features, very sensitive magnetometers are required for the surveys. The first investigations (Aitken *et al.*, 1958) were made with proton-free precession magnetometers (see also *Observatories, instrumentation*) but due to the slow speed of operation and their relative insensitivity, these are rarely used for modern surveys. In Britain, the most commonly used magnetometers use fluxgate sensors (see also *Observatories, instrumentation*), which can achieve noise levels as low as 0.3 nT if sensors and electronics

**Figure A6** Fluxgate gradiometer data from Ramagrama, Nepal. The outlines of a small Buddhist temple complex are clearly visible, including the outer and inner walls of the courtyard building (1). In addition, the foundations of a small shrine (2) within an enclosure wall (3) can be discerned.

are carefully adjusted. In Austria and Germany, some groups use cesium vapor sensors that are built to the highest possible specifications and have reported sensitivities of 0.001 nT (Becker, 1995). On loess soils, which produce very low magnetic background variations, the weak anomalies caused by magnetotactic bacteria in wood (see above) were detected with cesium magnetometers, revealing palisade trenches of Neolithic enclosures (Neubauer and Eder-Hinterleitner, 1997).

Magnetometer sensors measure the combination of the archeological anomaly and the Earth's magnetic field. Hence, to reveal the archeological anomalies, readings have to be corrected carefully for changes in the ambient field, caused by diurnal variations (see Geomagnetic secular variation) or magnetic storms (see Storms and substorms, magnetic). Proton free-precession instruments are often used in a differential arrangement ("variometer") by placing a reference sensor in a fixed location to monitor the Earth's magnetic field. The survey is then carried out with an additional sensor, which is affected by the same ambient field. Subtracting the data from both sensors cancels out the Earth's field. The same can be achieved with a gradiometer arrangement where the second sensor is usually rigidly mounted 0.5-1 m above the first so that both are carried together. Their measurements can be subtracted instantly to form the gradiometer reading. Despite the heavier weight of such an arrangement, it allows for improved instrument design. Especially for fluxgate sensors a signal feedback system, linked to the upper sensor, can be used to enhance the sensitivity of the instrument. Archeological features that can be detected with magnetometers are often buried at shallow depth and a gradiometer's sensor separation is then similar to the distance between the feature and the instrument. Therefore, the gradiometer reading is not an approximation for the field gradient and is better recorded as the difference in magnetic flux density (nT) between the sensors and not as a gradient (nT  $m^{-1}$ ). The magnetic field created by the feature of interest and the ambient magnetic field combine at the sensor and the recorded signal depends on the vector component measured with the particular instrument. For example, fluxgate sensors measure a single component of the magnetic field (usually the vertical component) and a gradiometer therefore records exactly this component of the archeological anomaly. In contrast, gradiometers built from field intensity sensors, like proton free-precession and cesium vapor sensors, measure the component of the anomaly in the direction of the ambient Earth's magnetic field, since this is much larger than the anomaly. Its direction governs the vector addition of the two contributions and the gradiometer reading can be approximated as  $|\mathbf{B}_{\text{Earth}} + \mathbf{B}_{\text{anomaly}}| - |\mathbf{B}_{\text{Earth}}| \approx \mathbf{B}_{\text{anomaly}} \cdot \mathbf{e}_{\text{Earth}}$  where  $\mathbf{e}_{\text{Earth}}$  is the unitvector in the direction of the Earth's magnetic field (Blakely, 1996). As a consequence, vertical fluxgate sensors record weaker signals in areas of low magnetic latitude (i.e., near the equator) and data from the two sensor types cannot be compared directly.

The "detection range" of archeological geophysical surveys depends on the magnetization and depth of the features (see above) as well as the sensitivity of the used magnetometers and can therefore not easily be specified. Based on practical experience with common instruments, it is estimated that typical soil features, like pits or ditches, can be detected at depths of up to 1-2 m, while ferrous and thermoremanent features can be identified even deeper. Weak responses were recorded from paleochannels that are buried by more than 3 m of alluvium (Kattenberg and Aalbersberg, 2004).

Prior to their final interpretation, magnetometer data often have to be treated with computer software for the improvement of survey deficiencies and the processing of resulting data maps (Schmidt, 2002). Data improvement can reduce some of the errors introduced during the course of a survey, such as stripes and shearing between adjacent survey lines. To reduce the time of an investigation, adjacent lines of a magnetometer survey are often recorded walking up and down a field ("zigzag" recording). However, since most magnetometers have at least a small heading error, a change in sensor alignment resulting from this data acquisition method can lead to slightly different offsets for adjacent lines, which are then visible as stripes in the resulting data (Figure A8a, middle). A common remedy for this effect is the subtraction of the individual mean or median value from each survey line. This helps to balance the overall appearance but also removes anomalies running parallel to the survey lines. If the sensor positions for the forward and backward survey direction are systematically offset from the desired recording position (e.g., always 0.1 m "ahead") anomalies will be sheared and data will appear "staggered" (Figure A8a, left). If this defect is sufficiently consistent, it can be removed (Figure A8b) by fixed or adaptive shifting of every other data line (Ciminale and Loddo, 2001). Another common problem found with some instruments is the "drift" of their offset value, mostly due to temperature effects. If regular measurements are made over dedicated reference points the effects of drift can be reduced numerically. All these methods of data improvement require detailed survey information, for example about the length of each survey line, the direction of the lines, the size of data blocks between reference measurements, etc. It is hence essential that metadata are comprehensively recorded (see below). Once all data have been corrected for common problems and all survey blocks balanced against each other, they can be assembled into a larger unit (often referred to as "composite") and processed further. Typical processing steps may include low- and high-pass filtering and reduction-to-thepole. However, most processing can introduce new artifacts into the data (Schmidt, 2003) and should therefore only be used if the results help with the archeological interpretation.

Many archeological magnetometer surveys are commissioned to resolve a clearly defined question, for example to find archeological remains in a field prior to its development for housing. However, most data are also of potential benefit beyond their initial intended use and should therefore be archived. For example, the removal of

**Figure A7** Calculated shape of the magnetic anomaly caused by the induced magnetization of a buried cubic feature with 3 m side length. The anomaly is measured with a vertical fluxgate gradiometer (0.5 m sensor separation), 0.5 m above the cube's top surface. The strength of the anomaly was calculated for an inclination of 70° and a magnetic susceptibility contrast of  $\kappa = 1 \times 10^{-8}$ .

**Figure A8** Fluxgate gradiometer data from Adel Roman Fort, West Yorkshire. (a) Field measurements with staggered data (*left*) and stripes (*center*). (b) After their improvement the data clearly show a ditch (1) and the soldiers' barracks (2) to the north of the road through the Fort (3).

all archeological remains during the development of a building site may mean that the collected geophysical data are the most important record of an ancient settlement. It is therefore essential that data archiving is undertaken according to recognized standards. In particular, detailed information describing data collection procedures and the layout of site and survey is important. Such information is usually referred to as "metadata" (Schmidt, 2002) and complements the numerical instrument readings as well as processed results. Related to the archiving of data from geophysical surveys is the recommendation that at least a brief report should be provided and archived, whenever possible.

# Archeomagnetic dating

As with paleomagnetic dating (see Paleomagnetism), the magnetic remanence preserved in archeological structures can be used for their dating. Although some research has been undertaken on depositional ("detrital") remanence in sediments (Batt and Noel, 1991), archeomagnetic dating is mainly applied to thermoremanent magnetization. By firing archeological structures that are rich in iron oxides above their Curie temperature (ca 650-700°C) they become easily magnetized in the direction of the ambient field, which is usually the Earth's magnetic field. On subsequent cooling below the blocking temperature, this acquired magnetization will form a magnetic remanence. When archeological features that were exposed to such heating and cooling are excavated, oriented samples can be recovered and their thermoremanent magnetization measured. By comparing these data with an archeomagnetic calibration curve that charts the variation of magnetic parameters with time, a date can be determined for the last firing of the archeological feature.

Most archeomagnetic dating methods use two or three components of the remanent magnetization vector (inclination, declination, and sometimes intensity). It is therefore a pre-requisite that samples are collected from structures that have not changed their orientation since the last firing. Typical features include kilns, hearths, baked floors, and furnaces. Unfortunately, it is not always possible to assess whether an archeological feature is found undisturbed and in situ. For example, due to instabilities following the abandonment of a kiln, the walls may have moved slightly or the area around a fire place may have been disturbed by modern agricultural activities. Only the final statistical analysis (see below) can ascertain the validity of results. In recent years, advances in archeointensity dating have been made using only the magnitude of the magnetization for age determinations (see Shaw and microwave methods, absolute paleointensity determination). It is therefore possible to magnetically date materials that are no longer in their original position, like fired bricks that were used in buildings or even nonoriented pottery fragments (Shaw et al., 1999; Sternberg, 2001).

A variety of different sampling methods exist, which all have their respective benefits. Some groups extract samples with corers, others encase the selected samples in Plaster of Paris before lifting them together with the plaster block, and in Britain plastic disks are commonly glued to the samples before extraction. As it is important to accurately record the orientation of the sample while still in situ, plaster and disks are usually leveled horizontally and the north direction is marked with a compass (either conventional, digital, or sunbased). Determining the right sampling locations within a feature is important as the effect of magnetic refraction often causes magnetic field lines to follow the shape of heated features similar to the demagnetization effects observed in grains and elongated objects. Soffel (1991) reports an approximately sinusoidal dependence of both inclination and declination from the azimuthal angle in a hollow cylindrical feature while Abrahamsen et al. (2003) have found that sample declinations from a hemisphere of solid iron slag with 0.5 m diameter vary throughout 360°. It is therefore essential that several samples from different parts of a feature are compared to statistically assess whether a consistent magnetization vector can be determined.

After the last firing of an archeological structure, magnetically soft materials may have acquired a viscous remanent magnetization that gradually followed the changing direction of the Earth's magnetic field (see *Geomagnetic secular variation*). Its contribution to a sample's overall magnetization can lead to wrong estimates for the age, and it therefore has to be assessed with a Thellier experiment and then removed. This removal can either be accomplished through stepwise thermal demagnetization (see *Demagnetization*) or with stepwise alternating field (AF) demagnetization (Hus *et al.*, 2003). The subsequent measurement of a sample's magnetization vector, for example in a spinner magnetometer, is then a good approximation of its thermoremanence. Fisher statistics (see *Fisher statistics*) is used to assess the distribution of all the measured magnetization vectors of an

archeological feature by calculating a mean value for the direction together with its angular spread  $\alpha_{95}$ . The latter describes the distribution of all measured directions around the mean and is half of the opening angle of a cone (hence appearing as a "radius" on a stereographic plot) that contains the mean vector direction with a probability of 95%. The spread of the individual vector directions can be due to errors in sample marking, measurement errors, and the distribution of different directions within a single feature (see above). It has therefore become common practice to expect  $\alpha_{95}$  to be less than 5° for a reliable investigation (Batt, 1998).

Once the magnetization of an archeological feature has been established it can be compared to a calibration curve to derive the archeological age. The construction and use of such calibration data has been a matter of recent research. In Britain, a calibration curve was compiled by Clark et al. (1988) using 200 direct observations (since 1576 AD) and over 100 archeomagnetic measurements from features that were dated by other means, as far back as 1000 BC. All data were corrected for regional variations of the Earth's magnetic field and converted to apparent values for Meriden (52.43°N, 1.62°W). After plotting results on a stereographic projection, the authors manually drew a connection line that was annotated with the respective dates. Measurements from any new feature could be drawn on the same diagram and the archeological date was determined by visual comparison. This approach is compatible with the accuracy of the initial calibration curve but has clear limitations (Batt, 1997). Similar calibration curves exist for other countries and due to short-scale variations of the Earth's magnetic field's nondipole component (see Nondipole field), they are all slightly different and have to be constructed from individually dated archeological materials. The reference curve for Bulgaria, for example, now extends back to nearly 6000 BC (Kovacheva et al., 2004). Although the calibration curve by Clark et al. (1988) has been a useful tool for archeomagnetic dating, improvements are now being made. Batt (1997) used a running average to derive the calibration curve more consistently from the existing British data. Kovacheva et al. (2004) calculated confidence limits for archeological dates using Bayesian statistics (Lanos, 2004) for the combination of inclination, declination, and paleointensity of measured samples. To improve the accuracy and reliability of the archeomagnetic method, more dated archeological samples are required and comprehensive international databases are currently being compiled.

Some researchers have attempted to use magnetometer surveys over furnaces to derive archeomagnetic dates for their last firing. For this, the magnetization causing the recorded magnetic anomaly has to be estimated and can then be used with a calibration curve for the dating of the buried archeological feature. To accommodate the complex shape and inhomogeneous fill of partly demolished iron furnaces in Wales, Crew (2002) had to build models with up to five dipole sources to approximate the measured magnetic anomaly maps. The dipole parameters were chosen to achieve the best possible fit between measured and modeled data and their relationship with the magnetization of the furnaces' individual components is not entirely clear. In addition to the sought after thermoremanence, this magnetization also has contributions from acquired viscous remanence and from the induced magnetization in the current Earth's magnetic field. Even after estimates for these two sources have been taken into consideration, the results were in poor agreement with the archeomagnetic calibration curve. The magnetic anomalies from slag-pit furnaces in Denmark were approximated with individual single dipole sources by Abrahamsen et al. (2003). They found that the distribution of 32 adjacent furnaces produced an unacceptably high  $\alpha_{95}$  value of 18° and concluded that the method is therefore unsuitable for the dating of these features.

# Conclusion

There are many ways in which magnetic methods can be used in archeological research and this application has made them popular with the 30

public. Magnetometer surveys have become a tool for archeologists, nearly as important as a trowel. In an excavation, many archeological remains are only revealed by their contrast in color or texture compared with the surrounding soil. Searching for a contrast in magnetic properties is therefore only an extension of a familiar archeological concept. The science explaining the magnetic properties of buried features may be complex but the application of the techniques has become user-friendly. Similarly, archeomagnetic dating is an important part of an integrated archeological dating strategy. For archeological sites, dates are often derived with many different methods simultaneously, ranging from conventional archeological typological determinations over radiocarbon dating to luminescence methods. Combining these different data, for example with Bayesian statistics, allows a significant reduction of each method's errors and leads to improved results. The wealth of information stored in the magnetic record has certainly made an important contribution to modern archeology.

# ARCHEOMAGNETISM

The science and utilization of the magnetization of objects associated with archeological sites and ages. In practice, it is mostly concerned with the magnetic dating of archeological materials, but can also be used for reconstruction, magnetic sourcing, environmental analysis, and exploration. It depends on (1) the property of particular archeological materials containing magnetic impurities (particularly, the iron oxides, magnetite, and hematite) that can retain a record of the past direction and strength of the Earth's magnetic field, usually at the time that they cooled after being heated, but also when deposited, fluidized, or chemically altered; (2) the Earth's magnetic field gradually changes in both direction and intensity (secular variation, q.v.). As archeological materials normally record events, such as firing, at a specific point and time, most archeomagnetic records are intermittent in both space and time. The establishment of regional records of directions and intensities therefore require spatial corrections to be applied to individual determinations. Such "Master Curves" for directional studies are now mostly based on the assumption that the geomagnetic field, over an area of some 10<sup>6</sup> km<sup>2</sup>, can be represented by an inclined geocentric dipole model of the field and have been constructed for several areas, particularly in Europe, the Middle East, Japan, and Central and southwestern North America. Such corrections appear justified by studies of the regional variation of the present geomagnetic field but may not be valid for all areas and times. Spatial variations in intensity are usually modeled using an axial geocentric dipole model of the geomagnetic field.

#### History

Bricks were shown to be magnetic by Boyle, in 1691, and that they lose their magnetization when heated and acquire it while cooling. Volcanic rocks used in the amphitheatre of Pompeii were demonstrated to have retained their original magnetization for at least 2000 years by Melloni in 1853. Folgerhaiter examined the magnetization of pottery in 1894. Chevallier, in 1925, constructed a record of historical changes in the direction of the geomagnetic field using lavas from Mt Etna. Actual dating of archeological fired clays, involving incremental thermal demagnetization of their direction and intensity of magnetization, were initiated by Thellier in 1936.

#### Procedures

(a) Directional Studies. Oriented samples are selected from part of the structure or object considered to have been magnetized at the same time. Their initial directions of remanence are measured and the samples subjected to demagnetization in incremental steps. This demagnetization can by heating, alternating magnetic fields or tuned microwaves. The vectors at successive steps are then analyzed to determine the characteristic vector associated with the time when the sample had originally cooled. These vectors are then combined, giving each determination equal weight, to determine the mean direction for the site. When the age of the firing is already known, then this direction is incorporated into a "Master Curve" for that region. When the age is unknown, the direction is compared with the appropriate "Master Curve" to assess the likely age of firing.

(b) Paleointensity Studies. As the intensity of magnetization is a scalar quantity, it is unnecessary that the sample should be unoriented. This also enables the technique to be used for isolated objects, such as pottery shards, that are no longer in their original firing position. It is therefore a far more widely applicable method. Until 2000, most paleointensity determinations were based on comparing the observed intensity of magnetization of a sample with the intensity it acquired in a known external magnetic field strength. Assuming no chemical changes occurred, i.e., the bulk magnetic susceptibility (K) remains constant, there is a simple relationship in which the ancient geomagnetic field strength (A) equals the intensity of natural remanence (NRM) acquired in that field multiplied by the strength of laboratory field (F) divided by the intensity of thermal remanence (TRM) acquired in that field (F), i.e., K = NRM/A = TRM/F. The problems are to ensure there is no change in susceptibility and that the NRM thermal component that was actually acquired during the original cooling has been isolated from all other NRM components. Conventionally, various tests, such as monitoring the susceptibility, repeat readings of the NRM component at successive temperatures and testing for the linear NRM/TRM relationship during incremental heating are all used. However, even when these are all satisfied, there can still be discrepancies between paleointensity determinations on specimens taken from the same sample. While such discrepancies are few, they suggest that thermally induced changes in the magnetic properties are occurring during laboratory heating even when all such tests are satisfied. The origin of these effects remains unclear and possibly relates to thermally induced physical changes as well as chemical changes in the magnetic properties. While other tests are still being developed, the more recent microwave method offers a radically different technique of demagnetizing both the natural and laboratory remanences. The microwaves are tuned to preferentially affect the quanta of spin wave energy in magnetic materials, magnons. The microwave energy is imposed briefly at different power levels, resulting in incremental demagnetization at successive power increments. In the current systems, little of the microwave energy leaks into the thermal band and the consequent rise in temperature is less than 120°C at the current maximum power of 120 W at 14 GHz. Such a temperature rise could still affect some minerals, but the hydroxide minerals that are most likely to be affected will only be present in weathered samples that are, in any case, not suitable for paleointensity determinations. This form of energy could also affect the magnetic domain structures but, as for thermally induced chemical changes, the brevity of the energy application appears to inhibit all such changes. A major advantage is that it can be applied rapidly, currently enabling paleointensity estimates to be made in a fraction of the

time needed for standard thermal paleointensity methods. Nonetheless, several aspects of this method must still be considered experimental and it is mostly designed for materials containing magnetite rather than hematite.

#### Errors

In directional studies, the largest, non-Gaussian errors in regional "Master Curves" arise from original age inaccuracies. Individual determinations can be affected by magnetic anisotropy, magnetic refraction, but mainly from physical disturbances of the site since firing. The precision of measurement and inhomogeneity remain problems in paleointensity studies, although the former is reducing.

*Present Situation:* The longest, continuous, and most systematic record that is available is for Bulgaria (Figure A9) and includes both directional and intensity data. The most readily accessible data are for England and Wales, France, southwestern USA (Figure A10), and potentially for Japan. Standard methods of curve fitting are being applied to local sequences of directional and intensity determinations, mostly assuming the errors to be Gaussian. This assumption may not always be valid and can result in smoothing fluctuations in the readings that may be of geomagnetic origin. Paleointensities using

# AURORAL OVAL

The auroras have fascinated humans since prehistory, but it was not until 1770 that Captain James Cook reported that the aurora borealis in the Northern Hemisphere had a counterpart in the Southern Hemisphere, the aurora australis. It was later noted that the frequency of observation of the aurora did not increase all the way to the poles, but maximized near latitudes of  $\sim 70^{\circ}$  and decreased again as the poles were approached. This allowed Elias Loomis in 1860 to draw a map of greatest auroral frequency as an irregular oval encircling the northern pole, though with a centroid somewhat displaced toward the northern coast of Greenland, such that it ran through the northern reaches of Scandinavia, Canada, and Siberia. Subsequently, photographic surveys have shown that the auroral observations are organized by the geomagnetic field, the ovals being roughly centered on the geomagnetic poles, though displaced away from the Sun, such that a magnetic latitude and magnetic local time coordinate system is the most appropriate for describing auroral morphology. The auroras are located at higher magnetic latitudes ( $\sim 75^{\circ}$ ) on the dayside than on the nightside ( $\sim 70^{\circ}$ ); the oval has a typical radius of 1500–2000 km and a latitudinal width of some 200-1000 km (Feldstein and Starkov, 1967). The auroras tend to be most luminous and of greatest latitudinal extent near local midnight. Before the advent of the Space Age, the ovals could only be considered as a statistical phenomenon. However, with the launch of auroral imagers onboard spacecraft such as Dynamics Explorer 1, it was found that the ovals were visible as continuous rings surrounding the pole (Frank and Craven, 1988). In recent years, near-continuous, high-temporal resolution auroral imagery from the ground and space has provided a wealth of information regarding the nature of the auroral oval and its relationship to the dynamic magnetosphere (q.v.) (e.g., Milan et al., 2006).

# Auroral processes

The auroras are formed by precipitation of charged particles, electrons, and protons, following magnetic field lines from the magnetosphere into the atmosphere. Here, collisions with neutral atmospheric atoms or molecules can lead to the promotion of electrons from their ground state or, in cases where the collisional energy exceeds the ionization potential, produce ion-electron pairs to supplement the pre-existing ionosphere (q.v.) produced mainly by solar photoionization (e.g., Vallance Jones, 1974). Excited atoms and molecules emit photons as they relax back to their ground states, to form the luminous aurora; approximately 1% of the incoming kinetic energy is converted to visible light, the power output of a typical  $10 \times 1000$  km auroral arc being of the order of 1 GW. The initial kinetic energy of the precipitating particles determines the altitude at which most collisions occur, higher energy particles penetrating deeper into the atmosphere before being slowed significantly (Rees, 1989). Early triangulation of auroral altitudes (Størmer, 1955) showed that peak auroral emission occurred at 100-150 km altitude (the ionospheric E region), though significant luminosity could be observed higher, even above 250 km (F region). The auroral wavelengths produced depend on the atoms or molecules involved in the collisions, the atmospheric concentrations of which themselves depend on altitude. Although many spectral lines can be identified in the aurora, a few dominate. In the lower altitude regime, the main spectral line observed is the forbidden green oxygen line at 557.7 nm (<sup>1</sup>S to <sup>1</sup>D), produced by incoming electrons with energies of  $\sim 10$  keV. At higher altitudes, the red doublet at 630 and 636.4 nm (<sup>1</sup>D to ground state) dominates, generated by  $\sim$ 1 keV electrons. Weak hydrogen lines are also observed, as incoming protons are excited by their collisions with the atmosphere. In addition, emission outside of the visible spectrum, the N2 Lyman-Birge-Hopfield lines in the ultraviolet for instance, are important in auroral imaging from space. Other emission mechanisms include bremsstrahlung X-ray emission from highly energetic electrons penetrating to altitudes below 90 km.

The forms of aurora vary greatly, from auroral curtains or arcs, to curls, corona, and rayed aurora. Auroras can also be separated into *diffuse* and *discrete* forms, the latter often appearing embedded within the former. Discrete auroras are thought to arise due to acceleration processes taking place at relatively low altitudes (below 1 Earth radius). Low-Earth orbit observations of the characteristics of precipitating particles are shedding new light on these accelerating mechanisms (e.g., Carlson *et al.*, 1998). Spatial scales also vary from the global scale of the auroral ovals themselves, to meso- and microscale features within individual arcs; indeed, the closer the auroras are examined, the smaller the spatial scales that become apparent. One of the many open questions within auroral physics is the mechanism by which such diverse features, some as small as a few meters across, arise within the oval (Borovsky, 1993).

#### Auroral characteristics and the magnetosphere

The ultimate source of the precipitating electrons and protons is the solar wind plasma constantly streaming away from the Sun. Observing the morphology and dynamics of the auroral oval provides a great deal of information about the mechanisms by which solar wind particles gain entry to the magnetosphere, are distributed within it, and are subsequently accelerated to impact the atmosphere. The auroral ovals are not static, uniform features but display local time asymmetries and temporal variations on timescales ranging from subsecond, through minutes, hours, the seasons, and up to the 11-year solar cycle. In general, shorter timescale variations reflect internal magnetospheric dynamics such as magnetohydrodynamic wave activity, whereas longer changes are caused by magnetospheric responses to external stimuli, such as interactions between the terrestrial field with the Sun's magnetic field (q.v.) carried frozen-in (Alfvén's Theorem and the frozen flux approximation, q.v.) to the solar wind, where it is known as the interplanetary or heliospheric magnetic field. Solar cycle variations arise due to long-term changes in the characteristics of the solar wind and its magnetic field.

Magnetic reconnection between the interplanetary field and the magnetospheric field at the dayside magnetopause causes the two to become interconnected, such that the magnetosphere is no longer closed. The open field lines are eventually disconnected from the solar wind again by reconnection occurring in the magnetotail. It is this constant topological reconfiguration of the magnetospheric field that results in a general circulation and structuring of the magnetospheric plasma, as first proposed by James Dungey (Dungey, 1961), now known as the Dungey cycle. The open field lines allow solar wind plasma to enter the magnetosphere, in general streaming towards the Earth, funneled towards auroral latitudes in the noon sector by the dipolar nature of the geomagnetic dipole field (q.v.). Particles, which penetrate to sufficiently low altitudes that they can collide with atmospheric neutrals, give rise to *cusp* aurora in the dayside auroral oval, so-called after the magnetospheric cusp topology through which particles enter the magnetosphere. These particles tend to be relatively unaccelerated and so excite red line aurora. Those which do not collide are said to *mirror* on entering the higher field strength at low altitudes, return upwards along the magnetic field and are carried antisunward to populate the magnetotail. Such particles come eventually to reside near the equatorial plane where they are heated to form a dense hot *plasma* sheet. Confined in general to move along the near-dipolar magnetic field lines, these trapped particles approach the Earth most closely at auroral latitudes as they mirror backwards and forwards between conjugate hemispheres. At each bounce there is a possibility of an atmospheric collision and the generation of aurora; plasma sheet particles, having been accelerated in the magnetotail, give rise to green line aurora. The plasma sheet extends from the magnetotail around the Earth to the dayside, forming the familiar rings of aurora around the poles. The lower latitude boundary of the auroral oval is governed by the distance of the inner edge of the plasma sheet from the Earth in the equatorial plane, usually of order 7 Earth radii. The higher latitude 34

boundary of the oval is closely related to the transition from closed dipolar field lines to open field lines which map deep into the magnetotail and out into the solar wind. Such nondipolar field lines do not provide the trapping geometry that requires particles to constantly return to the atmosphere, and so auroral luminosities tend to be negligible poleward of 80° latitude. On occasions, Sun-aligned arcs can be observed at high latitudes inside the oval, also known as *transpolar arcs* or *theta aurora*, in the latter case due to the characteristic shape they form together with the oval. There is still much debate regarding the source of these auroras and the magnetospheric configuration that gives rise to them.

Seasonal variations have been found in the distribution of auroral luminosity within the ovals (Newell *et al.*, 1998) and the overall level of auroral activity (Russell and McPherron, 1973). The latter is in part a consequence of the differing reconnection geometries available at the magnetopause as the tilt of the rotational and magnetic axes of the Earth change the orientation of the magnetosphere with respect to the Sun-Earth line. However, variations in auroral distribution controlled by the extent of solar illumination of the polar regions point toward complex feedback mechanisms between ionosphere and magnetosphere.

#### The substorm cycle

The auroral oval is not static with time, but undergoes a 2–4 hr cycle of growth and decay known as the substorm cycle (intimately related to the Dungey cycle), first adequately described by Akasofu (1968). During periods of strong reconnection at the dayside magnetopause, generally when the interplanetary magnetic field points southwards, an increasing proportion of the terrestrial magnetic flux becomes opened. As a consequence, the auroral oval moves to lower latitudes as the open field line region expands, during what is known as the growth phase, which can last several tens of minutes. At some point the magnetosphere can no longer support continued opening of flux and reconnection is initiated in the magnetotail to close flux once again. This flux closure is associated with vivid nightside auroral displays, termed substorm break-up aurora, as plasma is accelerated earthwards into the midnight sector atmosphere. The nightside aurora expands rapidly polewards to form a substorm auroral bulge as the dim open flux region contracts, leading to this phase of the substorm cycle being known as expansion phase, which can last from 30 min to a few hours. The auroral bulge expands not only polewards but also rapidly westwards, spear-headed by the most luminous feature of the substorm, the westwards-travelling surge. Eventually, the substorm enters the recovery phase as the magnetosphere relaxes back to a more quiescent state. This phase is accompanied by large-scale wave-like perturbations of the poleward border of the postmidnight oval, termed omega bands after their characteristic appearance.

Associated with substorms are elevated levels of geomagnetic activity caused by currents flowing horizontally in the E region ionosphere, facilitated by enhanced ionospheric conductivity associated with the auroral ionization. These currents flow to close pairs of upward and downward field-aligned currents (Iijima and Potemra, 1978), also known as Birkeland currents, which transmit stress from the outer magnetosphere into the ionosphere and drive ionospheric convection, the counterpart of the magnetospheric circulation described by the Dungey/substorm cycle. The main components of the ionospheric current systems are the *westward* and *eastward electrojets* flowing along the auroral ovals in the dawn and dusk sectors, respectively, and the development of the *westward substorm electrojet* in the midnight sector during expansion phase. These currents are largely responsible for the magnetic deflections detected at the ground and compiled to form various geomagnetic indices that measure the general level of geomagnetic disturbance, such as the planetary  $K_P$  index devised by *Julius Bartels* (*q.v.*) (Bartels *et al.*, 1939) and auroral electrojet index *AE* (Davis and Sugiura, 1966).

# **BAKED CONTACT TEST**

#### Introduction

At the time of emplacement, an igneous unit (intrusion or volcanic flow) heats adjacent host rocks. Upon cooling in the Earth's magnetic field the igneous unit and adjacent host rocks acquire similar directions of remanent magnetization. The simple case of thermal overprinting of host rocks that have a consistent composition and magnetic mineralogy is illustrated in Figure B1. The host rock magnetization is completely reset in a "baked" zone adjacent to the contact, partially reset in a zone of "hybrid" remanence farther away, and unaffected in the "unbaked" zone at even greater distances.<sup>1</sup> On the other hand, a later regional metamorphic event would, if sufficiently intense, produce a consistent remanence direction throughout the profile.

Two types of baked contact tests utilize the paleomagnetic remanence across the contact of igneous units in order to establish whether the remanence in the igneous unit is primary. The standard *baked contact test* (or *contact test*) compares remanence directions in the igneous unit, the baked zone, and the unbaked zone (Figure B1). Although relatively robust, difficulties can arise with the interpretation of this test if chemical changes have occurred in the host rocks. A more rigorous test, herein called the *baked contact profile test*, includes a detailed study of overprinting in the hybrid zone (Figure B1). It can demonstrate conclusively that the overprint remanence was acquired as a thermoremanent magnetization (TRM) at the time of emplacement of the igneous unit. Both the standard baked contact and the more detailed baked contact profile tests are described and discussed below.

#### Importance of baked contact tests

Well-dated paleomagnetic poles (see *Pole, key paleomagnetic*) are a prerequisite to defining reliable apparent polar wander paths, tracking the drift of continents, and establishing continental reconstructions. In general, key paleopoles should be demonstrated primary and the rock unit from which they are derived should be precisely and accurately dated (Buchan *et al.*, 2001). In the Precambrian most key paleopoles are derived from igneous rocks because fossil evidence for the age of sedimentary rocks is usually lacking. Although there are several field tests of the primary nature of the magnetic remanence of igneous rocks (e.g., Buchan and Halls, 1990), the baked contact test is the most widely used.

<sup>1</sup>In some publications the "baked", "hybrid" and "unbaked" zones are referred to as the "contact", "hybrid" and "host (magnetization)" zones, respectively.

In a recent review of the worldwide database of paleomagnetic poles for the 1700–500 Ma period, Buchan *et al.* (2001) concluded that only 18 paleopoles, of many hundreds that are available, are sufficiently well-dated to be used for robust continental reconstructions. All 18 are from well-dated igneous rocks. Ten of the 18 have a baked contact test or a baked contact profile test demonstrating that the remanence is primary, whereas eight are shown primary using other types of tests. This emphasizes the importance of igneous rocks and baked contact tests in paleomagnetic studies, especially in the Precambrian.

# **Baked contact test**

Brunhes (1906) first proposed a comparison of the remanence of an igneous unit with that of adjacent baked host rocks, concluding that if the remanence direction is similar in the two units it is stable and primary. Everitt and Clegg (1962) pointed out that the Brunhes test was incomplete because regional metamorphism will result in simultaneous remagnetization of both igneous and baked rocks. Therefore, they proposed an extension of the Brunhes test in which unbaked host rocks farther from the intrusion are also sampled. Everitt and Clegg used their test to look for a difference in remanence characteristics between baked and unbaked sedimentary host rocks. Today, the Everitt and Clegg (1962) test is commonly referred to as the baked contact test (or contact test) and applied mainly to a comparison of the direction of remanent magnetization in an igneous unit and its igneous or sedimentary host rocks.

#### Method

The standard baked contact test requires collection of oriented paleomagnetic samples from the igneous unit, from baked host rocks and from unbaked host rocks in relatively close proximity to the igneous unit. In addition, the baked and unbaked host rocks should be of similar composition so that a direct comparison can be made of their rock properties.

The baked contact test is "positive" (Figure B2a) and the remanence considered primary if the igneous unit and baked host rocks carry a consistent, stable direction of magnetization, whereas the unbaked host rocks have a stable but different direction. It is important to reiterate that the unbaked host rock must be stably magnetized. An example of a positive baked contact test is shown in Figure B3. Here a Marathon dyke crosscuts an older Matachewan dyke in the Superior Province of the Canadian Shield. The Matachewan dyke far from the Marathon contact carries a stable SSW remanence direction, whereas the Marathon dyke and adjacent baked Matachewan dyke have similar SE remanence

**Figure B1** Direction of remanent magnetization with distance from the contact of an igneous intrusion. It is assumed that the magnetic mineralogy of the host rock is similar throughout the profile and that overprinting in the baked and hybrid zones is a thermoremanent magnetization.

**Figure B2** Baked contact tests. (a) Positive test. (b) Negative test. (c-h) Examples of inconclusive tests.

directions. This positive test indicates that the Marathon dyke carries a primary remanence from the time of its intrusion (Buchan et al., 1996).

Comparing the magnetic properties of the unbaked and baked host rocks may provide information on whether chemical alteration has occurred in the baked rocks at the time of emplacement of the igneous unit. The presence of chemical changes can make the test less reliable. For example, consider the case of an igneous unit with unblocking temperatures that are lower than those of host rocks into which it is intruded. Suppose that the unblocking temperatures of host rocks adjacent to the igneous unit are lowered as a result of chemical changes

**Figure B3** Example of a positive baked contact test for a ca. 2.10 Ga Marathon dyke which crosscuts a ca. 2.45 Ga Matachewan dyke in a roadcut at a locality in the Superior Province of the Canadian Shield. (a) Patterns indicate area of outcrop. Open and closed squares refer to samples for which typical Marathon and Matachewan remanence directions were obtained, respectively. (b) Paleomagnetic directions are plotted on an equal-area net. All magnetizations are directed up. Data are discussed in the text and in Buchan *et al.* (1996).

that occur due to heating by the igneous unit. Then a later mild regional reheating event can reset the remanence of the igneous unit and adjacent host rocks without resetting the remanence of distant host rocks that have retained their higher unblocking temperatures. This situation would yield a positive baked contact test even though the remanence of the igneous unit is secondary. (Note that the more detailed baked contact profile test described below can eliminate any uncertainty about chemical changes by clearly establishing that the remanence in the baked zone is a TRM and that it was acquired *at the time when the igneous unit was emplaced*).

A positive test also demonstrates that the unbaked host rocks carry a remanence that significantly predates the emplacement of the igneous unit.

The baked contact test is "negative" (Figure B2b) if the igneous unit and the baked and unbaked host all carry a similar stable direction of magnetization. A negative test usually indicates that the remanence of the igneous unit is secondary, having been acquired significantly after emplacement. However, there are specific situations in which the igneous unit carries a primary remanence, but the baked contact test is negative. These include cases where (a) the igneous unit and its host rocks are of similar age, (b) the host rocks acquired a regional overprint shortly before emplacement of the igneous unit, and (c) the direction of the Earth's magnetic field was similar at the time of emplacement of the igneous unit and at some earlier time when the host rocks were magnetized. Therefore, although a remanence can usually be established as primary with a positive baked contact test, it cannot be demonstrated as secondary with the same degree of certainty by a negative baked contact test.

Many baked contact tests do not meet the criteria described above for a positive or a negative test. In a few specific situations, some limited information concerning the age of the remanence in the baked zone can still be obtained. For example, if the igneous unit is unstably magnetized, but the baked and unbaked host rocks are stably magnetized and can be shown to have similar magnetic properties, similar remanence directions in the baked and unbaked host rocks likely indicate a secondary overprint, whereas dissimilar directions likely indicate that the remanence of the baked zone was acquired at the time of emplacement of the igneous unit. However, in most cases in which the criteria for a positive or negative test are not achieved, the test is "inconclusive" (e.g., Figure B2c-h) and does not provide information concerning the primary or secondary nature of the remanence.

#### Incorrect application of the baked contact test

The baked contact test is often applied incorrectly or misinterpreted in the literature. In addition, terminology applied to the test is often confusing or misleading. Examples of these problems are discussed below.

In some studies only the igneous unit and its baked zone are sampled and the remanence is interpreted to be primary based on similar remanence directions in these two units. However, as noted above, Everitt and Clegg (1962) described how this result would also be obtained if both units were overprinted at some later date. Such tests are incomplete and should not be referred to as baked contact tests because all three elements (igneous, baked host, and unbaked host rocks) that are necessary for a baked contact test have not been sampled.

There are also many examples in the literature where an igneous unit and baked host rocks carry a consistent direction of magnetization but unbaked host is unstably magnetized (Figure B2c). Terms such as "semipositive test," "not fully positive test," or "partial test" are sometime used in such cases. However, these terms are misleading and should not be used, because they imply incorrectly that the test gives some information on whether the remanence of the igneous unit is primary. For example, host rocks that are unstably magnetized before emplacement of the igneous unit can acquire a stable remanence in the baked zone at the time of emplacement as a result of chemical alterations that occur only in the baked zone. During a subsequent regional metamorphism the igneous unit and baked host will be remagnetized (with similar remanence directions), while the unbaked host remains unstably magnetized. This is especially likely if temperatures during the metamorphic event remain below that necessary to induce chemical changes in the unbaked host rocks. Thus, when unbaked host rocks carry an unstable remanence, the baked contact test is inconclusive and the age of the remanence in the igneous unit is uncertain.

In other studies, the unbaked host rocks are collected at great distance from the igneous unit and its baked host rocks, often as a result of a lack of suitable outcrop in the intervening area. This can cause serious problems in the interpretation of the results. For example, overprinting of the local area near the igneous unit may have occurred after its emplacement, resulting in remagnetization of the igneous unit and its baked zone, whereas the distant unbaked site may have escaped overprinting at that time. In addition, it is more likely that magnetic mineralogy will differ between such widely separated baked and unbaked host rocks, making the comparison of the magnetic directions between the two locations more problematic.

#### Baked contact profile test

Although the baked contact test described above is generally considered to be a robust test of primary remanence, there are some circumstances involving chemical alterations in the host rocks when it can be misleading. Buchan *et al.* (1993) and Hyodo and Dunlop (1993) pointed out that analyzing magnetic overprinting along a profile that includes the hybrid zone (Figure B1), following the procedure of Schwarz (1977), yields a more rigorous test of primary remanence than the standard baked contact test. In particular, such a baked contact profile test can demonstrate that the overprint component is a TRM and that it was acquired at the time of emplacement of the igneous unit (Buchan and Schwarz, 1987; Schwarz and Buchan, 1989; Hyodo and Dunlop, 1993).

The baked contact profile test is the most powerful method for establishing that remanence in igneous rocks is primary. However, it is not widely used because of the necessity of sampling a continuous profile, the difficulty in locating the often-narrow hybrid zone, and the difficulty in analyzing the hybrid zone magnetizations. To date it has only been applied in a few instances to the study of dyke contacts (e.g., Schwarz, 1977; Buchan *et al.*, 1980; Symons *et al.*, 1980; Buchan and Schwarz, 1981; McClelland Brown, 1981; Schwarz and Buchan, 1982; Schwarz *et al.*, 1985; Hyodo and Dunlop, 1993; Oveisy, 1998; Wingate and Giddings, 2000), usually as part of studies to determine ambient host rock temperatures and depth of burial (see *Magnetization, Remanent, Ambient Temperature and Burial Depth from Dyke Contact Zones*).

#### Method

A continuous profile is sampled from the igneous unit, through the baked and hybrid zones into the unbaked host zone (see Figure B1). The distance of each sample from the contact is recorded, as are the dimensions of the igneous unit.

Samples are thermally demagnetized in stepwise fashion in order to determine the maximum temperature ( $T_{max}$ ) to which each hybrid sample was reheated at the time of emplacement of the igneous unit. If the overprint component is a partial TRM (pTRM) resulting from heating by the igneous unit, the unblocking temperature spectra of the overprint component will occupy a range immediately below that of the earlier host component (Dunlop, 1979; McClelland Brown, 1982; Schwarz and Buchan, 1989; Dunlop and Özdemir, 1997). Any overlap of the two unblocking spectra should be explainable in terms of viscous pTRM.  $T_{max}$  is given by the maximum unblocking temperature of the overprint component, most easily determined using an orthogonal component (or Zijderveld) plot of the horizontal and vertical component of the thermal demagnetization data.  $T_{max}$  must be corrected for the effects of magnetic viscosity using published curves

**Figure B4** Positive baked contact profile test.  $T_{max}$ , the maximum temperature that is obtained at a given location in the host rocks as the result of emplacement of the igneous unit, is determined from orthogonal component projections in the hybrid zone. A systematic decrease in the  $T_{max}$  through the hybrid zone with increasing distance from the contact demonstrates that the overprint is a TRM.

for the appropriate magnetic mineral (e.g., Pullaiah *et al.*, 1975). The procedure for analyzing magnetic components in the hybrid zone and determining  $T_{\text{max}}$  is described in more detail in the article on *Magnetization*, *remanent*, *application* (*q.v.*).

If the overprint component is a chemical remanent magnetization (CRM),  $T_{\text{max}}$  cannot be determined. Schwarz and Buchan (1989) discuss how CRM components can be distinguished in hybrid zones.

The baked contact profile test is "positive" (Figure B4) if the criteria for a positive baked contact test are satisfied (i.e., the igneous unit and baked host carry a consistent, stable direction of magnetization, whereas the unbaked host has a stable but different direction) and if  $T_{\rm max}$  values in the hybrid zone decrease systematically away from the contact, as predicted by heat conduction theory (Jaeger, 1964). The critical aspect of the test is that  $T_{\rm max}$  values decrease systematically across the hybrid zone. The most detailed comparisons of experimental and theoretical  $T_{\rm max}$  values across hybrid zones have been described by McClelland Brown (1981).

A positive baked contact profile test demonstrates that the overprint remanence of the hybrid zone is a pTRM and that it was acquired as the igneous unit cooled following emplacement. The similarity between the direction of the overprint in the hybrid zone and that of the remanence in the igneous unit itself indicates that the latter is primary.

The baked contact profile test is "negative" if the igneous unit and all elements of the host profile yield consistent remanence directions. Interpretation of the negative baked contact profile test is similar to that of the negative baked contact test described above.

The test is "inconclusive" if the criteria for "positive" or "negative" test are not met. For example, if  $T_{max}$  values cannot be obtained from the hybrid zone or if they do not decrease systematically with distance from the contact, then it cannot be concluded that the overprint is a TRM from the time of emplacement of the igneous unit.

# **BANGUI ANOMALY**

"Bangui anomaly" is the name given to one of the Earth's largest crustal magnetic anomalies and the largest over the African continent. It covers two-thirds of the Central African Republic and the name derives from the capital city Bangui that is near the center of this feature. From surface magnetic survey data, Godivier and Le Donche (1962) were the first to describe this anomaly. Subsequently high-altitude world magnetic surveying (see *Aeromagnetic surveying*) by the US Naval Oceanographic Office (Project Magnet) recorded a

greater than 1000 nT dipolar, peak-to-trough anomaly with the major portion being negative (Figure B5). Satellite observations (Cosmos 49) were first reported in 1964 (Benkova et al., 1973); these revealed a -40nT anomaly at 350 km altitude. Subsequently the higher altitude (417-499km) Polar Orbiting Geomagnetic Observatory (POGO) satellites data recorded peak-to-trough anomalies of 20 nT. These data were added to Cosmos 49 measurements by Regan et al. (1973) for a regional satellite altitude map. In October 1979, with the launch of Magsat (see Magsat), a satellite designed to measure crustal magnetic anomalies, a more uniform satellite altitude magnetic map was obtained (Girdler et al., 1992). From the more recent CHAMP (see CHAMP) satellite mission a map was computed at 400 km altitude, a greater than 16 nT anomaly was recorded (Figure B6/Plate 6c). The Bangui anomaly is elliptically shaped and is approximately 760 by 1000 km centered at 6° N, 18° E (see Magnetic anomalies, long wavelength). It is composed of three segments, with positive anomalies north and south of a large central negative anomaly. This displays the classic pattern of a magnetic anomalous body being magnetized by induction in a zero inclination field. This is not surprising since the magnetic equator passes near the center of the body.

While the existence and description of the Bangui anomaly is wellknown, what is less established and controversial is the origin or cause that produced this large magnetic feature. It is not possible to discuss its origin without mentioning the other associated geophysical and geologic information. There is a -120 mGal Bouguer gravity anomaly coincident with the magnetic anomaly (Boukeke, 1994) and a putative

**Figure B5** Total field aeromagnetic anomaly profile data over the Central African Republic from Project MAGNET, US Naval Oceanographic Office (from Regan and Marsh, 1982, their figure 3, Reproduced by permission of American Geophysical Union).

**Figure B6/Plate 6c** Satellite altitude (400 km) scalar magnetic anomaly map of the Central African Republic region from CHAMP mission data. Anomaly maximum, minimum, standard deviation and contour interval are given on the figure (Hyung Rae Kim, UMBC and NASA/GSFC).

topographic ring some 810 km diameter associated with this feature (Girdler et al., 1992). In Rollin's (1995) recently compiled tectonic/ geologic map of the Central African Republic, Late Archean and Early Proterozoic rocks are exposed beneath the central part of the anomaly. Lithologically the area is dominated by granulites and charnockites (a high temperature/pressure granite believed to be part of the lower crust). There are, in addition, significant exposures of greenstone belts and metamorphosed basalts with itabrite (a metamorphosed iron formation). There are several theories for the origin of the anomaly. Regan and Marsh (1982) proposed that a large igneous intrusion into the upper crust became denser on cooling and sank into the lower crust with the resulting flexure producing the overlying large basins of this region (see Magnetic anomalies for geology and resources). The intrusion the source of the magnetic anomaly; the sedimentary basin fill the source of the gravity anomaly. Another hypothesis is that it is the result of a large extraterrestrial impact (Green, 1976; Girdler et al., 1992). Ravat et al. (2002) applied modified Euler deconvolution techniques to the Magsat data and their analysis supports the impact model of Girdler et al. (1992). Unfortunately, it is not possible to discriminate between these theories based solely on geophysical data. However, the key to the solution may lie in the origin of carbonados (microcrystalline diamond aggregates). Carbonados are restricted to the Bahia Province, Brazil and the Central African Republic, with the latter having a greater number. Smith and Dawson (1985) proposed that a meteor impacting into carbon-rich sediment produced these microdiamonds. More recently De et al. (1998) and Magee (2001) have failed to confirm this hypothesis. The origin of this large crustal anomaly remains uncertain.

# **BARLOW, PETER (1776–1862)**

A British mathematician and physicist, born at Norwich, England, Peter Barlow is now remembered for his mathematical tables, the Barlow wheel and Barlow lens. His contributions to science in general and magnetism in particular are most impressive. We will concentrate here chiefly on his contributions in direct relation with geomagnetism, which are too often not given the attention they deserve.

Despite lacking formal education, Peter Barlow became assistant mathematical master at the Royal Military Academy in Woolwich in 1801. He was promoted to a professorship in 1806 and worked in Woolwich until retiring in 1847. His first researches were mainly focused on pure mathematics (his "Theory of Numbers" appeared in 1811), but in 1819 he began to work on magnetism. In May 1823, Peter Barlow was elected fellow of the Royal Society. He later also became a member of several of the leading overseas societies (including correspondant of the French Académie des Sciences in 1828). He worked on problems associated with magnetic mesurements and the issue of deviation in ship compasses caused by iron pieces in the hull. In 1825, he was awarded the Royal Society Copley Medal for his method of correcting the deviation by juxtaposing the compass with a suitably shaped piece of iron used as neutralizing plate.

Guided by a suggestion from John Herschel, Peter Barlow conducted experiments on the influence of rotation upon magnetic and non-magnetic bodies. In a letter to Major Colby dated December 20, 1824, he relates:

"Having been lately speculating on the probable causes of the earths magnetic polarity. It occured to me that it might possibly be due to the rotation, and if so the same ought to be the case with any revolving mas of iron. I therefore fixed one of our 13 inch shells upon one of the turning lathes in the arsenal driven by the steam engine, and the very few trials were most conclusive and satisfactory."

The next year, in the *Philosophical Transactions*, Peter Barlow describes how the experimental mesurements were made extremely difficult because of the disturbing influence of the lathe and other machinery on the needle. After careful investigations, he reports negative conclusions:

"I have certainly found a stronger effect produced by rotation than I anticipated, yet it does not appear to be of a kind to throw any new light upon the difficult subject of terrestrial magnetism. I think there are strong reasons for assuming, that the magnetism of the earth is of that kind which we call induced magnetism; but at present we have no knowledge of the inductive principle, (...)"

Years later, *Lord Blackett* (*q.v.*) revisited this possibility with similar conclusions (Blackett, 1952).

Following on Öersted's discovery of the magnetism associated with electrical current (Experimenta circa effectum Conflictus Electrici in Acum Magneticam, 1820), the French physicist André-Marie Ampère proposed (Annales de chimie et de physique, 1820) that electrical currents within the Earth could account for the geomagnetic field (these currents were then assumed to be of galvanic origin). Barlow was the first to test the practicability of Ampère's proposal and designed a remarkable experiment to that end. This experiment is presented in the *Philoposphical Transactions* for 1831. Barlow built a wooden hollow globe 16 in. in diameter and cut grooves in it. A copper wire was placed around the sphere along the grooves in the manner of a solenoid. When this globe is connected to a powerful galvanic battery, current passing through the coils sets up a dipolar magnetic field. Barlow describes how, if one turns

"(...) the globe so as to make the pole approach the zenith, the dip will increase, till at the pole itself the needle will become perfectly vertical. Making now this pole recede, the dip will decrease, till at the equator it vanishes, the needle becoming horizontal. (...) Nothing can be expected nor desired to represent more exactly on so small a scale all the phenomena of terrestrial

**Figure B7** Teaching instrument, based on Barlow's sphere, used to demonstrate how a current passing through a coil produces a dipolar field similar to that of the Earth. [The Physics Museum of the University of Coimbra, CAT. 1851: 25.0.III,  $39 \times 25.8 \times 41$ , wood, brass, and copper. magnetism, than does this artificial globe (...) I may therefore, I trust, be allowed to say, that I have proved the existence of a force competent to produce all the phenomena of terrestrial magnetism, without the aid of any body usually called magnetic."

This interpretation of the principal geomagnetic field clearly represents the premise of present dynamo theory. Barlow's globe was originally constructed in 1824; this experiment yielded a teaching apparatus still preserved in some universities around the world (see Figure B7).

Peter Barlow also did work with geomagnetic observations, in 1833 he constructed a new declination chart (then called "variation" chart) in which he embraced earlier magnetic observations. This chart is illustrated and described in the *Philoposphical Transactions* in 1833. Barlow notes that the lines of equal variation (following the terminology introduced by E. Halley in his original 1701 chart) are very regular, denoting the deep origin of these structures. Barlow also discusses the evolution of these lines in time by comparison to previous charts (i.e., the secular variation).

Barlow concludes his opus by noting that he shall be most happy if this

"labour should furnish the requisite data for either a present or future development of those mysterious laws which govern the magnetism of the terrestrial globe, an object as interesting in philosophy as it is important in navigation."

Peter Barlow died in March 1862 in Kent, England.

# **BARTELS, JULIUS (1899–1964)**

Amongst the 20th century scientists working in the field of geomagnetism, Julius Bartels was certainly one of the outstanding contributors. He is known to most geophysicists as the author, along with Sydney Chapman (q.v.), of the two-volume monograph Geomagnetism, which used to be the bible of geomagnetism for several decades. Born on August 17, 1899 in Magdeburg (Germany), his life and scientific career was intimately related with the development of the field of geophysics to become a scientific discipline of its own. Julius Bartels studied mathematics and physics at the University of Göttingen as a student of Emil Wiechert as well as David Hilbert, Max Born, and James Franck. In 1923 he received his Ph.D. with a dissertation on "New methods of the calculation and display of daily pressure variations, especially during strong nonperiodic oscillations," which was supervised by Wilhelm Meinardus. Also his habilitation thesis "On atmospheric tides," which he submitted to the University of Berlin, dealt with the determination of tidal-like oscillations of the atmosphere using long-term pressure observations.

Trained as a mathematician Julius Bartels always had a keen interest in developing and applying statistical methods to geophysical problems. He became interested in geomagnetism when studying daily variations of the geomagnetic field caused by tidal oscillations of the ionosphere. His teacher in this new field was Adolf Schmidt whose assistant he became in 1923 after he graduated from Göttingen.

In 1929 he was offered professorship in meteorology and geophysics at the Forestry College in Eberswalde, close to Berlin. After several years of teaching there he took over the chair of geophysics at the University of Berlin and became the director of the Geomagnetic Observatory in Potsdam, which later became the Observatory of Niemegk. During his years in Potsdam, Julius Bartels laid the foundation for our current quantitative knowledge about geomagnetic variations and their relation to solar activity. With these statistical methods, he was able to disprove many widely accepted geophysical models on the one hand and develop some very useful and easy to apply geophysical indices on the other. In particular, the *K*-index and its planetary counterpart,  $K_P$ , have been developed in these years. The  $K_P$  index was, and partially still is, the key index to describe geomagnetic activity.

Eliminating regular variations of the Earth's magnetic field, Bartels demonstrated the impact of solar wave and particle radiation on the geomagnetic field. He recognized that seizing this concept in numbers would form a powerful tool for scientists in the research of solar-terrestrial relations. Bartels realized that his  $K_P$  tables would only be accepted by the scientific community if they were presented in a clearly arranged manner. The striking success of the  $K_P$  index is also due to its appealing representation as a kind of musical diagram. Using only geomagnetic data and statistical methods, Bartels claimed the existence of M-regions on the Sun that are responsible for geomagnetic activity. The claimed M-regions were later identified as coronal holes, which are the source of the fast solar wind that intensifies geomagnetic activity.

Between 1931 and 1940 Bartels also worked as a research associate at the Department of Terrestrial Magnetism at the Carnegie Institution (Washington, D.C.) for longer periods of time, where he closely cooperated with his friend Sydney Chapman. In 1940, the first edition of their book *Geomagnetism* was printed. After the Second World War, Bartels accepted an offer from the University of Göttingen to take over the chair of geophysics there, succeeding Gustav Angenheister. In 1956 Julius Bartels also became the director of the Institute for Stratospheric Research of the Max-Planck-Institut für Aeronomie, now the Max-Planck-Institute for Solar System Research.

Following the tradition of *Carl-Friedrich Gauss* (q.v.), Wilhelm Weber, and *Alexander von Humboldt* (q.v.), who initiated the "Göttinger Magnetischer Verein," Julius Bartels strongly favored international cooperation. He was one of the initiators of the International Geophysical Year 1957/1958, served as the president of the *International Association of Geomagnetism and Aeronomy* (q.v.) from 1954 to 1957, and became

the vice-president of the International Union of Geodesy and Geophysics in 1961. Julius Bartels was an elected member of the Academies in Berlin and Göttingen, the Deutsche Akademie der Naturforscher und Ärzte Leopoldina in Halle, the Royal Astronomical Society in London, and the International Academy of Astronautics in Paris. His outstanding scientific contribution to the field of geomagnetism was honored by the Emil Wiechert Medal of the Deutsche Geophysikalische Gesellschaft, the Charles Chree Medal of the British Physical Society, and the William Bowie Medal of the American Geophysical Union. His published work spans 23 monographs and 143 scientific papers. Julius Bartels died on March 6, 1964 in Göttingen.

# BAUER, LOUIS AGRICOLA (1865–1932)

Louis Agricola Bauer (January 26, 1865 to April 12, 1932) founded and directed the Department of Terrestrial Magnetism (DTM) of the Carnegie Institution of Washington from 1904 until the 1920s. (See *Carnegie Institution of Washington, Department of Terrestrial Magnetism*). Seizing the opportunity provided by a large bequest by Andrew Carnegie, Bauer conceived of a tightly structured, worldwide magnetic survey that would be completed in a single generation. This goal was largely achieved by the time he was replaced as director of the DTM by John Adam Fleming (q.v.).

Bauer was born in Cincinnati, Ohio, as the son of German immigrants Ludwig Bauer and Wilhelmina Buehler. Bauer was the sixth of nine children. He studied civil engineering at the University of Cincinnati, graduating in 1888 and moving directly into a position as an aide in the US Coast and Geodetic Survey's computing division. Here he worked under Charles Anthony Schott, a German immigrant of 1848 who had dedicated his career at the Survey to geomagnetism. Under Schott, Bauer learned how to use magnetic instruments and how to reduce magnetic data. After four years at the Survey, Bauer enrolled in 1892 at the University of Berlin, Germany, to earn a Ph.D. in physics and learn the theoretical background to geomagnetic research. There he studied under Max Planck, Wilhelm von Bezold, and Wilhelm Foerster, and in 1895 successfully defended a dissertation on geomagnetic secular variation. Many geomagnetic researchers are still familiar with "Bauer plots" of declination versus inclination, which he introduced in 1895. These appear to indicate a cyclical behavior of the magnetic field (Bauer, 1895; Good, 1999).

While at the University of Berlin, Bauer worked as an observer at the magnetic observatory at Telegraphenberg, Potsdam. While a student, he met Adolf Schmidt, one of the most important geomagnetic researchers of the time, with whom he collaborated throughout his career.

Bauer returned to the United States as one of the country's first selfproclaimed geophysicists, with a prestigious Ph.D. from Germany. In 1896 he founded the international journal *Terrestrial Magnetism*, which became the *Journal of Geophysical Research* in 1948. He taught physics and mathematics at the University of Chicago and the University of Cincinnati in the late 1890s and then returned to the US Coast and Geodetic Survey in 1899 to direct its new division of terrestrial magnetism. Although he periodically taught a course on geomagnetism at the Johns Hopkins University in Baltimore, his move to the Survey marked a permanent transition away from academia and toward a life dedicated to researching geomagnetism full time. He was following, as he saw it, the tradition of Edmond Halley (q.v.), Alexander von Humboldt (q.v.), and Carl Friedrich Gauss (q.v.). His goal was to understand Earth's magnetism in all its facets, including the origin of the main field, secular variation, and shorter term variations due to "cosmic" influences. The Coast and Geodetic Survey gave him the opportunity to develop an ambitious magnetic survey across the broad expanse of the United States and also the opportunity to elaborate a chain of magnetic observatories, which would allow him to investigate the variation of the field on different timescales. Here he also learned to manage an instrument shop, a computational division, field operations, cartographers, and publications. He soon deployed these skills on a global scale.

In 1902, Andrew Carnegie endowed the Carnegie Institution of Washington to encourage scientific research beyond the established disciplines. Bauer saw an opportunity in this to move beyond the borders of academic and government science and to address for the first time the global nature of geomagnetism. He established the *Department of Terrestrial Magnetism* (q.v.) at the Carnegie Institution in 1904. Bauer intended the DTM to observe Earth's magnetism everywhere that others were not. This meant Asia, Africa, South America, and the polar and ocean regions. The DTM was also to act as a coordinating and standardizing bureau to guarantee that data obtained by all observers would be intercomparable. The DTM under Bauer completed the first "World Magnetic Survey," sending out 200 land-based survey teams and circling the globe numerous times with the oceangoing magnetic observatories, the ships *Galilee* and *Carnegie* (q.v.) (see Figures B8 and B9). He also established magnetic observatories

**Figure B9** Louis Agricola Bauer, portrait presented to the crew of the *Carnegie* on its maiden voyage in 1909. Bauer was noted for his sense of duty. Photo courtesy of Carnegie Institution of Washington.

at Huancayo, Peru, and Watheroo, Western Australia. The survey was nearly complete by 1929, when the *Carnegie* burned at Apia, Samoa (Good, 1994).

Bauer saw the need to professionalize and coordinate geomagnetic research and wanted to see progress made both in observational programs and in theory. Toward the end of his career, he participated extensively in the formation of the International Union of Geodesy and Geophysics, and served as general secretary (1919–1927) and as president (1927–1930) of the Section of Terrestrial Magnetism and Electricity (now the *International Association of Geomagnetism and Aeronomy or IAGA*, *q.v.*). His retirement from the DTM was gradual, as he experienced increasingly intense periods of depression from 1924 on. Fleming was "acting director" from 1927 until 1932. In 1932, the *Washington Post* reported Bauer's death (by suicide) on the front page. Bauer's influence on geomagnetic research in the early 20th century was immeasurable.

#### BEMMELEN, WILLEM VAN (1868–1941)

Dutch geophysicist and meteorologist Willem van Bemmelen was born on August 26, 1868 in Groningen (the Netherlands) as the son of Prof. Dr. Jacob Maarten van Bemmelen and Maria Boeke. As a student of physics and mathematics in his early twenties, he became interested in the Earth's magnetic field through the work of Christopher Hansteen (q.v.) (Hansteen, 1819), who had derived isogonic charts and a geomagnetic hypothesis from historical magnetic measurements gathered from ship's logbooks. Aware of Hansteen's limited coverage of the seventeenth century and the period before 1600 and having encountered an abundance of original manuscript sources in various Dutch archives during an attempt to construct a secular variation curve for the city of Utrecht, Van Bemmelen decided to fill the gap with all useful data he could find from the period 1540-1690. The results he initially laid down in his Ph.D. thesis (Bemmelen, 1893), which tabulated the original declination observations gleaned from 38 ships' logbooks (169 on land, about 1000 at sea). The thesis moreover included secular variation curves for 19 cities and six isogonic reconstructions, at 1540, 1580, 1610, 1640, 1665, and 1680.

After receiving his doctorate, he extended this research during the next three years, covering additional archives in the Netherlands (1893-1896), London (early 1896), and Paris (summer 1897). Later that year he sailed to the East Indies, where he was appointed director of the Dutch Royal Magnetical and Meteorological Observatory at Batavia (Djakarta). There he met his future wife, Soetje Hermanna de Iongh (November 6, 1876, Pankal Pinang to July 5, 1969, Driebergen), whom he married on January 10, 1899. That same year appeared Van Bemmelen's "Die Abweichung der Magnetnadel" (Bemmelen, 1899), a substantial extension of the earlier compilation, which contained 388 observations on land, 5276 at sea (about 60% from original sources), 20 small isogonic charts for the period 1492-1740, and six larger ones on Mercator projection for 1500, 1550, 1600, 1650, and 1700. A decade later, he published a geomagnetic survey of the Dutch East Indies (1903-1907), which included the readings obtained at the Batavia observatory (Bemmelen, 1909). In the next decade, he directed his attention increasingly to meteorological investigations in the Dutch colony (notably rain and wind). He eventually returned to his native country, where he died at The Hague on January 28, 1841. His collected declinations have since become incorporated in the world's largest compilation of historical geomagnetic data, held at the World Data Center C1 at Edinburgh, United Kingdom.

# BENTON, E. R.

Edward R. Benton, known to all as "Ned", is remembered for both his geophysical research and administration. He began his career as an applied mathematician, receiving the PhD degree in that discipline from Harvard University in 1961 under the supervision of Professor Arthur E. Bryson, Jr. Ned's early research focused on aerodynamics, beginning with a dissertation on "Aerodynamic origin of the magnus effect on a finned missile".

Following a year as lecturer in mathematics at the University of Manchester, Ned moved to Boulder, Colorado, taking a position as a staff scientist at the National Center for Atmospheric Research (NCAR) in the fall of 1963. In 1964 he became a lecturer in the Department of Astro-Geophysics (now the Department of Astrophysical, Planetary and Atmospheric Sciences) at the University of Colorado (UC), thus beginning an employment oscillation between NCAR and UC that lasted through 1977. Milestones along the way included academic appointments at UC to assistant professor in 1965, to associate professor in 1967, and Full Professor in 1971, and serving as assistant director of the NCAR Advanced-Study Program from 1967 to 1969, departmental chairman from 1969 to 1974, special assistant to the president for university relations of the University Corporation for Atmospheric Research (the parent organization for NCAR) from 1975 to 1977 and associate director of the Office of Space Science and Technology of UC from 1986 to 1987.

Ned's transition from engineer to geophysicist began with the publication in 1964 of a study of zonal flow inside an impulsively started rotating sphere. This work blossomed into a series of fundamental studies of the combined effects of rotation and magnetic fields on confined fluids, culminating in 1974 with a review of spin up (Benton, 1974). During this period, Ned also had a secondary interest in solutions of Burghers' equation. The next geophysically related area in which Ned took an interest was "kinematic dynamo theory," with a series of three papers published in 1975–1979 on Lortz-type dynamos. These papers developed a systematic categorization of these simple kinematic dynamos and provided some useful insights into their possible structures. This work was not continued as Ned's interest was soon drawn in other directions.

The work up until 1979 was prelude to his major scientific contribution in the area of inversion of the geomagnetic field. In that year he published a burst of papers on this topic, highlighted by papers on "Magnetic probing of planetary interiors" and "Magnetic contour maps at the core-mantle boundary" (Benton 1979a, b). In the mid-60s, workers had peered through this geomagnetic window on the Earth's core, but when it was shown that the view was both incomplete and flawed, interest in this subject had languished. Following Ned's revitalization of the subject, it has flourished, with contour maps of magnetic field and velocity at the top of the core being published by a number of groups. Now, the accurate determination of these features is a vital part of solving the dynamo problem.

Many know Ned best for his service as chairman of Study of the Earth's Deep Interior (**SEDI**) from 1987 to 1991. SEDI began as an idea at the IAGA Scientific Assembly in Prague, Czechoslovakia, in August, 1985, when IAGA Working Group I-2 (on theory of planetary magnetic fields and geomagnetic secular variation) called for the creation of a project to study the Earth's core and lower mantle. Ned cochaired the approach to IAGA and IUGG which led to SEDI's adoption, and served as its first chairman from 1987 to 1991. During his term as chairman, SEDI held symposia at Blanes, Spain, in June 1988, and Santa Fe, New Mexico in August 1990, as well as a large number of special sessions at various meetings of AGU, EGS, IAGA and IASPEI. Also, a number of national SEDI groups were formed, including those in Britain, Canada,

France, Japan and the United States. Several of these groups were successful in instituting national scientific projects with the help of SEDI. Also, SEDI endorsed several new scientific projects, including ISOP, INTER-MAGNET, and the Canadian GGP. All these activities were a great boon for the deep-earth geoscientific community and helped these studies maintain their visibility and viability. This success was due in large part to Ned's steady hand at the helm during SEDI's crucial formative years.

Ned received a number of honors for his scientific research and service, including NASA's Group Achievement Award in 1983, a scholarship from the Cecil H. and Ida M. Green Foundation for Earth Sciences, and election as Fellow of the American Geophysical Union shortly before his untimely death. The loss of his scientific talents, leadership ability, and companionship is still felt strongly by his many colleagues.

# **BINGHAM STATISTICS**

When describing the dispersion of paleomagnetic directions expected to have antipodal symmetry, it is a standard practice within paleomagnetism to employ Bingham (1964, 1974) statistics. The Bingham distribution that forms the basis of the theory is derived from the intersection of a zero-mean, trivariate Gaussian distribution with the unit sphere. For full-vector Cartesian data  $\mathbf{x} = (x_1, x_2, x_3)$  the Gaussian density function is

$$p_{g}(\mathbf{x}|\mathbf{C}) = \frac{1}{(2\pi)^{3/2}|\mathbf{C}|^{1/2}} \exp\left[-\frac{1}{2}\mathbf{x}^{\mathrm{T}}\mathbf{C}^{-1}\mathbf{x}\right],$$
 (Eq. 1)

where **C** is a covariance matrix. But for directional data the Cartesian vectors  $\hat{\mathbf{x}} = (\hat{x}_1, \hat{x}_2, \hat{x}_3)$  are of unit length, and the corresponding density function is Bingham's distribution

$$p_{b}(\hat{\mathbf{x}}|\mathbf{E}\mathbf{K}\mathbf{E}^{\mathrm{T}}) = \frac{1}{F(\kappa_{1},\kappa_{2},\kappa_{3})} \exp[\hat{\mathbf{x}}^{\mathrm{T}}\mathbf{E}\mathbf{K}\mathbf{E}^{\mathrm{T}}\hat{\mathbf{x}}].$$
(Eq. 2)

The matrix **E** is defined by the eigenvectors  $\mathbf{e}^m$  of the covariance matrix **C** (see *Principal component analysis for paleomagnetism*). The diagonal concentration matrix

$$\mathbf{K} = \begin{pmatrix} \kappa_1 & 0 & 0\\ 0 & \kappa_2 & 0\\ 0 & 0 & \kappa_3 \end{pmatrix},$$
 (Eq. 3)

is formed from the Bingham concentration parameters  $\kappa_m$ . Normalization of (Eq. 2) is obtained through the confluent hypergeometric function, represented here as a triple sum (see Abramowitz and Stegan, 1965):

$$F(\kappa_1, \kappa_2, \kappa_3) = \sum_{i,j,k=0}^{\infty} \frac{\Gamma(i+\frac{1}{2})\Gamma(j+\frac{1}{2})\Gamma(k+\frac{1}{2})}{\Gamma(i+j+k+\frac{3}{2})} \frac{\kappa_1^i \kappa_2^j \kappa_3^k}{i!j!k!},$$
(Eq. 4)

Let us now examine some of the properties of the Bingham distribution. The density function (Eq. 2) is clearly antipodally symmetric:

$$p_{\mathbf{b}}(\hat{\mathbf{x}}) = p_{\mathbf{b}}(-\hat{\mathbf{x}}). \tag{Eq. 5}$$

The distribution is also invariant for any change in the sum of the concentration parameters,

$$\sum_{m} \kappa_{m} \to \sum_{m} \kappa_{m} + \kappa', \qquad (\text{Eq. 6})$$

where  $\kappa'$  is an arbitrary real number. Therefore, for specificity, we set the largest parameter equal to zero, and we choose an order for the other two, so that

$$\kappa_1 \le \kappa_2 \le \kappa_3 = 0. \tag{Eq. 7}$$

Thus, the Bingham distribution is a two-parameter distribution. For all possible values of  $\kappa_1$  and  $\kappa_2$ , the density (Eq. 2) describes a wide range of distributions on the sphere (see Figure B10). In spherical coordinates of inclination *I* and declination *D* the Bingham density function reduces to

$$p_{b}(\hat{\mathbf{x}}|\kappa_{1},\kappa_{2},\mathbf{e}^{1},\mathbf{e}^{2}) = \frac{1}{F(\kappa_{1},\kappa_{2})}$$
$$\exp\left[\kappa_{1}(\hat{\mathbf{x}}\cdot\mathbf{e}^{1})^{2} + \kappa_{2}(\hat{\mathbf{x}}\cdot\mathbf{e}^{2})^{2}\right]\cos I,$$
(Eq. 8)

where the unit data vectors are given by

$$\hat{x}_1 = \cos I \cos D, \quad \hat{x}_2 = \cos I \sin D, \quad \hat{x}_3 = \sin I,$$
 (Eq. 9)

where the unit eigenvectors are given by

$$\hat{e}_1^m = \cos I^m \cos D^m, \quad \hat{e}_2^m = \cos I^m \sin D^m, \quad \hat{e}_3^m = \sin I^m,$$
(Eq. 10)

and where the normalization function is

$$F(\kappa_1, \kappa_2) = \sqrt{\pi} \sum_{i,j=0}^{\infty} \frac{\Gamma(i+\frac{1}{2})\Gamma(j+\frac{1}{2})}{\Gamma(i+j+\frac{3}{2})} \frac{\kappa_1^i \kappa_2^i}{i! j!}.$$
 (Eq. 11)

**Figure B10** Bingham density function, with representative contours for a (a) uniform density  $\kappa_1 = \kappa_2 = 0$ , (b) symmetric bipolar density  $\kappa_1 < \kappa_2 \ll 0$ , (c) asymmetric bipolar density  $\kappa_1 < \kappa_2 \ll 0$ , (d) asymmetric girdle  $\kappa_1 \ll \kappa_2 < 0$ , and (e) symmetric girdle density  $\kappa_1 \ll \kappa_2 = 0$ . (After Collins and Weiss, 1990).

Three important special cases are worthy of attention, which are most clearly illustrated in the coordinate system determined by the eigenvectors  $e^m$ . First, for  $\kappa_1 = \kappa_2$  we have a axially symmetric bipolar distribution, with density function

$$p_3(\theta|\kappa) = \frac{1}{F(-\kappa)} \exp\left[-\kappa \cos^2 \theta\right] \sin \theta, \quad \text{for} \quad \kappa \le 0, \qquad \text{(Eq. 12)}$$

**BINGHAM STATISTICS** 

(see (Eq. 19) of *Statistical methods for paleomagnetic vector analysis.*) The angle  $\theta$  is defined by the directional datum  $\hat{x}$  and the principal axis determined by the eigenvector with the largest eigenvalue  $\mathbf{e}^3$ 

$$\cos \theta = \hat{\mathbf{x}} \cdot \mathbf{e}^3, \tag{Eq. 13}$$

normalization is given by

$$F(\kappa) = \sum_{i=0}^{\infty} \frac{\Gamma(i+\frac{1}{2})}{\Gamma(i+\frac{3}{2})} \frac{\kappa^i}{i!}.$$
 (Eq. 14)

Second, for  $\kappa_1 < \kappa_2 = 0$  the distribution is a axially symmetric girdle, with density function (Dimroth 1962; Watson 1965)

$$p_1(\theta|\kappa) = \frac{1}{F(\kappa)} \exp[\kappa \cos^2 \theta] \sin \theta, \quad \text{for} \quad \kappa \le 0$$
 (Eq. 15)

The angle  $\theta$  is defined by the directional datum  $\hat{x}$  and the principal axis determined by the eigenvector with the smallest eigenvalue  $e^{1}$ 

$$\cos \theta = \hat{\mathbf{x}} \cdot \mathbf{e}^1. \tag{Eq. 16}$$

These two special cases of the more general Bingham distribution are useful for describing the dispersion (Eq. 12) of bipolar data about some mean pole, and the dispersion (Eq. 15) of bipolar data about some mean plane. And, finally, the third symmetric distribution is uniform, obtained for  $\kappa_1 = \kappa_2 = 0$ . In spherical coordinates this is just

$$p_0(\theta|\kappa) = \sin \theta$$
, for  $\kappa = 0$ . (Eq. 17)

The uniform distribution has no preferred direction and so  $\theta$  can be measured from an arbitrary axis. Of course, if we now allow  $\kappa$  to be positive or negative (or zero), then the full range of axially symmetric density functions is available (Mardia, 1972, p. 234):

$$p_{1,3}(\theta|\kappa) = \frac{1}{F(\kappa)} \exp\left[\kappa \cos^2 \theta\right] \sin \theta, \quad \text{for} \quad -\infty \le \kappa \le \infty.$$
(Eq. 18)

The off-axis angle  $\theta$  is then defined by the axis of symmetry of the distribution. Symmetric density functions, ranging from bipolar to girdle, obtained for a variety of values of  $\kappa$ , are illustrated in Figure B11.

#### Maximum-likelihood estimation

In fitting a Bingham distribution to paleomagnetic directional data a convenient method is that of maximum-likelihood; for a general review see Stuart *et al.* (1999). With this formalism, the likelihood function is constructed from the joint probability-density function for the existing data set. Using the general form of the Bingham density function (Eq. 8) the likelihood for N data is just

$$L(\kappa_1,\kappa_2,\mathbf{e}^1,\mathbf{e}^2) = \prod_{j=1}^N pb(I_j,D_j|\kappa_1,\kappa_2,\mathbf{e}^1,\mathbf{e}^2).$$
(Eq. 19)

**Figure B11** Examples of the axially symmetric Bingham probability density function  $p_{1,3}(\theta)$ , (Eq. 18) for a variety of  $\kappa$  concentration parameters:  $0, \pm 1, \pm 4, \pm 16$ . Note that as  $|\kappa|$  is increased the dispersion decreases.

Maximizing *L* is accomplished numerically (Press *et al.*, 1992), an exercise yielding a pair of eigenvectors  $e^1$  and  $e^2$  and their corresponding concentration parameters  $\kappa_1$  and  $\kappa_2$ . The third eigenvector  $e^3$  is determined by orthogonality and its concentration parameter by convention (Eq. 7) is zero. Some investigators (e.g., Onstott, 1980; Tanaka, 1999) prefer a two-step estimation method, where the eigenvectors are determined by principal component analysis, but these vectors are identical to those found by maximizing (Eq. 19). In any case, obtaining the eigenvalues of the data set through principal component analysis is still required for establishing confidence limits.

# **Confidence limits**

It is unfortunate that the relationship between the concentration parameters  $\kappa_m$ , determined (usually) by maximum likelihood, and the eigenvalues of the covariance matrix  $\lambda_m$ , determined (usually) by principal component analysis, is very complicated. This fact makes the establishment of confidence limits on the eigenvectors difficult. However, Bingham (1974, p. 1220) has discovered an approximate formula for the confidence limit valid under certain circumstances. The confidence ellipse, within which a specified percentage (%) of estimated eigenvectors  $\mathbf{e}^m$  can be expected to be realized from a statistically identical data set, is given by the elliptical axes

$$\alpha_{\%}^{mn} = \left[\frac{\boldsymbol{\chi}_{\%}^2}{2N\boldsymbol{\Delta}_{mn}}\right]^{1/2},\tag{Eq. 20}$$

for

Eigenvalue	Eigen direction		Bingham $\kappa_m$	Confidence axes		
	<i>I</i> (0)	<i>D</i> (0)		$\alpha_{95}^{m1}$	$\alpha_{95}^{m2}$	$\alpha_{95}^{m3}$
0.0304	-14.6	87.6	-9.8749		>1	0.0765
0.0601	-58.9	-48.4	-9.3490	>1		0.0801
0.9088	31.1	-1.5	0.0000	0.0765	0.0801	

Table B1 Principal component and maximum likelihood analysis of the Hawaiian paleomagnetic directional data recording a mixture of normal and reverse polarities over the past 5 Ma

**Figure B12** Equal-area projection of Hawaiian directional data, defined in (a) geographic coordinates and (b) eigen coordinates. Also shown are the projections of the variance minor ellipse, defined by  $\lambda_1$  and  $\lambda_2$ , and, inside of that, the  $\alpha_{35}^{95}$  confidence ellipse. As is conventional, the azimuthal coordinate is declination (clockwise positive, 0° to 360°), and the radial coordinate is inclination (from 90° in the center to 0° on the circular edge).

and where  $\chi_{\%}^2$  is the usual chi-squared value for two degrees of freedom. Alternative methods have been proposed for establishing confidence limits, most notably the bootstrap method popularized within paleomagnetism by Tauxe (1998).

Using the mixed-polarities directional from Hawaii covering the past 5 Ma (see *Principal component analysis*), in Table B1 we summarize the statistical parameters, and in Figure B12 we show the 95% confidence limit  $\alpha_{95}^{3n}$  about the eigenvector defining the mean bipolar direction ( $e^3$ ). Note that the confidence limit is much smaller than the variance of the data.

BIOMAGNETISM

## BIOMAGNETISM

Biomagnetism has emerged from a somewhat checkered earlier history. Indeed it has the dubious honor through Dr. Mesmer of contributing the verb mesmerize to the language and to have been the butt of Da Ponte and Mozart's humor in Così fan Tutte. However, it has survived to become a mature science covering a wide range of areas including animal navigation and orientation, possible harmful effects of magnetic fields, and searches for mechanisms explaining these phenomena are underway. In addition, electromagnetic instrumentation plays a major role in medicine and synthetic magnetic particles have been used to measure viscosity in cells and to transport chemicals within the human body, Here we discuss biological sensitivity to magnetic fields, the biogenic synthesis of magnetite, and its possible role in neurodegenerative diseases in humans. We leave the major areas of electromagnetically based medical instrumentation techniques, such as magnetocardiagrams, magnetoencephalograms, and the uses of nanoparticles of magnetite for other reviews.

#### Sensitivity to magnetic fields

The most readily demonstrated sensitivity to magnetic fields is that of magnetotactic bacteria. Several discussions of the phenomena are given in "Magnetite Biomineralization and Magnetoreception in Organisms" by Kirschvink *et al.* (1985), which provides an excellent source for work in this research area up to that time. As is well known, the bacteria are flagellum driven and the presence of a linear chain of magnetite particles results in their motion being constrained to move along, but not across magnetic lines of force. However, the sense of motion with respect to the field is more complicated than originally recognized and can in some cases change during the course of the day. The simple chain enables the bacterium to navigate between oxygenated and anoxic conditions at different depths in the water column as it swims.

#### Use of the geomagnetic field as a navigational cue

A wide variety of animals have been shown to sense the geomagnetic field and to use it as a navigational cue, e.g., salmon (Quin, 1980) honeybees (Gould et al. 1978), robins (Wiltschkow and Wiltschkow, 1972), homing pigeons (Walcott, 1977, 1978, 1996), field mice (Mather and Baker, 1981) and it has been suggested that human beings can also sense the geomagnetic field (Baker, 1980). There is no longer any doubt that certain animals can sense the magnetic field and indeed detect small changes in that field (e.g., Walker and Bitterman, 1989). The homing pigeons appear to use the gradient of the field (Walker, 1998, 1999), although this work remains controversial. The geomagnetic field intensity is of the order of tens of microteslas and typical gradients are a few nanoteslas per kilometer. To detect the necessary changes in the field to establish the gradients over distances of kilometers would therefore require sensitivity to field differences of the order of nanoteslas. Yet, pigeons appear to be able to do this (Windsor, 1975; Walker, 1998). It has long been thought that a magnetite-based sensory receptor makes this possible.

The nature of the magnetic sense organ has proved elusive, but an example of a magnetite based sensor has been exquisitely demonstrated in the rainbow trout by Walker *et al.* (1997). Behavioral studies established that the animal could discriminate between the presence and the absence of a field comparable to the geomagnetic field. Intracellular magnetite was discovered in its nose. Magnetic force microscopy observations of the magnetite were consistent with the magnetic behavior of single domain magnetite particles (Diebel *et al.*, 2000). Finally, neural signal responses to field changes were recorded in nerves from this region. Other detailed demonstrations of magneto-reception are likely to emerge as various animals, known to be capable of sensing the field, are examined by similar techniques. Indeed demonstrations of

changes in firing rates in response to small magnetic field variations have been reported for some time (Figure B13) (for example, see Semm and Beason, 1990; Schiff, 1991). Magnetite in the bee abdomen has been implicated in the orientation of honeybees during their "dance" with a sensitivity to local magnetic field variations many times smaller than the geomagnetic field (Kirschvink *et al.*, 1997).

Having established that certain animals can sense the geomagnetic field, the next question is "how is the sensing used in navigation?" One of the most extensively investigated topics is avian navigation, which has recently been reviewed (Wiltschkow and Wiltschkow, 2003). Here we restrict the discussion to the pigeon (for which some of the most convincing evidence of a magnetic compass is available), although as noted above, the topic remains controversial (e.g., Walcott, 1977, 1978, 1996; Walker, 1998, 1999; Walraff, 1999; Reilly, 2002). Kramer's map and compass model (e.g., Kramer, 1961) is the starting point of most interpretations. In such magnetic navigational systems the two necessary requirements are: (1) some means whereby the animal can locate itself in relation to its loft and (2) some form of compass whereby it can set and maintain a course for its target. These require sensing of the magnetic field and of relatively small changes in the field, as we noted above.

How exactly the ability to sense the field is used to provide a map or compass, remains obscure and may well differ from species to species. A particularly important clue has emerged in the case of the homing pigeon from studies of the direction flown immediately after release (Windsor, 1975; Walker, 1998). This is illustrated in Figure B14, in which we see that initial departure directions are symmetrical about the local field gradient, which is indicated by the heavy solid NW/SE line. If birds are released close to this line, the errors are small, but they increase as release sites depart from it. Moreover, if the birds are released to the SW of the gradient line, the starting direction errs to the SW, and conversely if they are released from the site to the NE they err to the NE. Walker (1998) proposed a vector summation model to account for the directions and final return to the loft. It is clear that the chosen directions for the most part take the bird up or down the local gradient in the appropriate sense to move toward the loft. When the release site is close to the local gradient leading to the loft, errors are small, but when the site is away from this line flying down the gradient gives rise to large errors.

**Figure B13** Observation of enhanced firing rates in response to magnetic field changes in the Bobolink. The response of a single ganglion cell to field intensity changes—(a) spontaneous activity, (b) response to 200 nT change, (c) response to 5000 nT change, (d) response to 15000 nT change, (e) response to 25000 nT change, and (f) response to 100000 nT change. Note the geomagnetic field is of the order of 10000 nT, or gammas, or tens of microteslas. The stimulus is indicated by the horizontal heavy line. The vertical bar indicates 2 mV and the horizontal bar 50 ms (From Semm and Beason. 1990).

**Figure B14** Initial departure directions of pigeons released at various distance and azimuthal direction from their loft. Note that the departure directions are symmetrical about the local field gradient indicated by the heavy NW/SE line (From Windsor, 1975 and Walker, 1998).

Indeed, some of the birds released due west of the loft appear to set off in completely the wrong direction. The overall pattern of directions demonstrates that the birds are able to determine the local field gradient and have a memory of whether the field is higher or lower at the release site than at the loft. The birds appear to use the gradient of the field in their navigation, which is a long standing idea in homing noted by Wiltschkow and Wiltschkow (2003), but it is not clear whether they use nonmagnetic clues or a more sophisticated vector summation magnetic model, such as that suggested by Walker (1998) to complete their return to the loft. These ideas have been strongly criticized by Wallraff (1999) and Reilly (2002), but given the observation of the relation of initial flight directions to the field gradient (Windsor, 1975; Walker, 1998), it is hard to avoid the interpretation that the pigeon is able to sense and follow the field gradient.

Many other animals are able to sense the geomagnetic field. There are examples demonstrating determination of the direction of the horizontal component and of the inclination of the total field vector field. Beason (1989) demonstrated sensitivity to the sign of the vertical component of a magnetic field in the Bobolink (Dolichonyx orzivorous), which is a nocturnal migratory species. The experiments were carried out in a planetarium and the initial departure directions were found to reverse with the reversal of the vertical component of the field. The experiment provided convincing evidence of an inclination based compass because the direction of horizontal component of the field was maintained when the vertical component was reversed and yet the initial departure directions reversed. Particularly convincing evidence of the ability to sense the direction of the horizontal component of the field comes from species which orient themselves, e.g., resting termites (Roonwal, 1958) or structures they build, e.g., termite galleries (Becker, 1975), and honey bee hives (Lindauer and Martin, 1972). These and other examples are presented in an excellent review of orientation in Arthropods (Lehrer, 1997). With all the many examples of sensitivity to the geomagnetic field in animals, it is natural to ask whether human beings are sensitive to the Earth's field and claims that we are indeed able to sense the field have been made

(Baker, 1980), but the results have not been replicated. A review of human magnetoreception is given in Kirschvink *et al.* (1985).

In addition to useful magnetic field sensing in relation to navigation, there is a broader issue of field sensitivity including possible harmful effects of magnetic fields. Such effects are not likely to be related to the normal field strength of the geomagnetic field because animals have evolved in the presence of this field. Rather, it is the absence of the geomagnetic field, or the presence of much stronger fields that may prove harmful. During the period of low field intensity associated with field reversals, when the simple geometry of the field is also lost, animals relying on the field for navigation will presumably experience difficulty. In a more direct test of the importance of the geomagnetic field, Shibab *et al.* (1987) reported impairment of axonal ensheathment and myelination of peripheral nerves of newborn rats kept in 10 nT and 0.5 mT environments compared with controls.

## Sensitivity to ac fields and dc fields larger than the geomagnetic field

Studies of effects of alternating magnetic fields and static fields that are stronger than the geomagnetic field have also tested sensitivity of the nervous system to these fields, but the main emphasis of the studies is on possible harmful effects, such as carcinogenesis, mutagenesis, and developmental effects. Much of this work has been stimulated by epidemiological studies such as that of Feychting and Ahlbom (1995), which suggested links between power line exposure and cancer in children. This has generated an enormous literature, but no conclusive evidence of cause and effect has emerged.

As an example of an effect of a static field only marginally larger than the geomagnetic field, Bell et al. (1992) reported changes in electrical activity in the human brain on exposure to fields of 0.78 G, or 78 µT. Power spectra of electroencephalograms (EEG) were found to be modified in all but one case, and in most cases an increase was observed. Interictal (between seizure) firing rates in the hippocampus of epileptic patients are increased by fields of the order of milliteslas. Such fields are some 20 times larger than the geomagnetic field (Dobson et al., 1995; Fuller et al., 1995, 2003). The procedure had some clinical value in the preoperative evaluation of patients with drug resistant epilepsy. In contrast to the generally observed increases in activity, activity was inhibited when the field was applied during periods of strong activity (Dobson et al., 1998). Work on hippocampal slices by Wieraszko (2000) showed a complicated response pattern, with initial inhibition of firing followed by an amplification phase after the field was removed. The amplification was modulated by dantrolene, which is an inhibitor of intracellular calcium channels. In contrast, to the observations of neural responses to field changes observed in animals that use the field sensitivity for navigation, these responses were on a relatively long timescale of seconds and increased firing rates persisted in some case for tens of minutes. This suggests that these phenomena are very different from the magnetite sensor-mediated responses discussed above in the trout and the Bobolink. In those cases, the response took place within milliseconds of the field change and was completed within seconds.

Wikswo and Barach (1980) showed that very large fields of 24 T would be needed to bring about a 10% difference in conduction, in the discussion of the direct effect of magnetic fields on nerve transmission. In this, they noted that they had specifically ignored "microscopic chemical effects as well as those due to induced fields." It is evidently through these more subtle effects that weak magnetic fields affect biological systems.

The direct effect of magnetic fields on the rate of recombination of free radicals is an example of a mechanism that could play a role in field sensitivity. Moreover, given the importance of free radicals in biological systems this could be a significant effect. It arises because the probability of recombination of free radicals depends upon their spin state, which in turn can be affected by a dc field (McLauchlan, 1989) and possibly by ac fields (Hamilton *et al.*, 1988).

Whereas the sensitivity of the trout to the geomagnetic field is clearly through the intermediary of a magnetite based sensory receptor, it may well be that there are also direct effects of magnetic fields on the nervous system. Indeed, it seems that the effects on the epileptic patients are very different from the process in the trout and may result from direct effects on cell processes.

## **Biogenic magnetite**

Biogenic magnetite clearly plays a central role in the sensitivity of the trout to magnetic fields and probably in many other animals. Biogenic magnetite was first discovered in organisms as a capping on the radula (teeth) of the chiton—a marine mollusk (Lowenstam, 1962). Since that time it has been found in many organisms ranging from bacteria to humans. In some species it has been demonstrated to form a part of a geomagnetic field receptor system (e.g., Frankel, 1984; Walker *et al.*, 1997; Wiltschko and Wiltschko, 2002; Kirschvink and Walker, 1995; Lohmann and Lohmann, 1996), but in most it is not obviously linked to magnetic orientation/navigation and its role is unclear.

Magnetite is ferrimagnetic because of the imbalance of Fe<sup>2+</sup>, which is confined to one of the two opposed sub-lattices, i.e., on the octahedral sites. It has a saturation magnetization of  $4.71 \times 10^5$  A m<sup>-1</sup> at room temperature, a Curie (Néel) point of 578°C and a high density of 5.2 g cm<sup>-3</sup>. It is presumably the high density and hardness that account for its presence in the radula of Chiton. In magnetotactic bacteria and in species that sense the magnetic field, it plays a role in detecting the field. However, magnetite is also a source of ferrous iron, which can generate potentially harmful free radicals. Here we will discuss the synthesis of magnetite, its occurrence in organisms including human beings and its possible role in neurodegenerative diseases.

#### Synthesis and occurrence of biogenic magnetite

Perhaps the best understood example of biogenic magnetite occurs in the various species of magnetotactic bacteria. These motile, gramnegative bacteria synthesize chains of highly pure and crystallographically perfect magnetite nanoparticles for use as a navigational aid—a phenomenon known as "magnetotaxis" (Blakemore, 1975; Frankel, 1984). The morphology of these particles is characteristic of the various species, however, in all cases, the size of the particles is generally just above the superparamagnetic limit such that they are magnetically blocked. This enables the chain to experience a torque when the geomagnetic field is at an angle to the long axis of the chain.

Recent work from Bertani and others (2001) has led to the identification of genes, which are involved in the synthesis of magnetite in magnetotactic bacteria. Though this gives an indication of the processes involved in magnetite synthesis, the mechanism employed by the bacteria to form perfect crystals of very specific size has remained difficult to identify. Work published recently, however, characterized proteins associated with biogenic magnetite crystals from the bacterium *M. magnetotacticum*, which are believed to regulate crystal growth (Arakakai *et al.*, 2003). The authors were able to use these proteins to direct the synthesis of magnetite nanoparticles in the laboratory with sizes and shapes very similar to those found in *M. magnetotacticum*.

#### Biogenic magnetite in organisms

Biogenic magnetite is found in many organisms; however, its physiological role in most of these is not well understood (Webb *et al.*, 1990). The mineral is also found in human tissue. Biogenic magnetite, along with maghemite ( $\gamma$ Fe<sub>2</sub>O<sub>3</sub>—an oxidation product of magnetite), was first reported in humans in 1992 by a group at the California Institute of Technology led by Joseph Kirschvink (Kirschvink *et al.*, 1992). In that study, the group examined human brain tissue samples taken from cadavers and this work proved somewhat controversial.

In order to allay this controversy and to examine the possibility of contamination and *postmortem* changes in brain iron chemistry, a series of studies on tissue removed from the human hippocampus was undertaken. The analyses were performed on tissue resected during amygdalohippocampectomies (a surgical procedure in which the damaged hippocampus of focal epilepsy patients is removed) as well as from cadaver tissue. Thus it was possible to control *post mortem* artifacts, which may have complicated the interpretation of Kirschvink's earlier results. These studies demonstrated clearly that biogenic magnetite is present in human brain tissue and confirm the results of the Cal Tech group (Dunn *et al.*, 1995; Dobson and Grassi, 1996; Schultheiss-Grassi and Dobson, 1999). In addition, recent results appear to demonstrate that biogenic magnetite concentration increases with age in males; however, this relationship is not seen in female subjects (Dobson, 2002).

While initial analysis of human brain tissue focused on magnetometry studies and the identification of biogenic magnetite by proxy, particles of this material also have been extracted, imaged, and characterized using transmission electron microscopy (TEM) (Kirschvink et al., 1992; Schultheiss-Grassi et al., 1999) (Figure B15). The particles are generally smaller than 200 nm and, in most cases, are on the order of a few tens of nanometers. While some particles exhibit dissolution edges, others preserve pristine crystal faces, and all particles examined thus far are chemically pure (this is common in biogenic magnetite). Morphologically, many of the particles are similar to those observed in magnetotactic bacteria (Schultheiss-Grassi et al., 1999) though other particles are more irregularly shaped. A particularly intriguing transmission electron image has suggested that the iron oxide present in some hippocampal tissue may be concentrated in or near the cell membrane (Dobson, et al., 2001) (Figure B16). Whether this location is related to cell membrane transport, or simply iron storage. is not known. However, the high concentration of iron oxide in this cell suggests a degree of specialization because such a concentration in all hippocampal tissue would give an unrealistically high concentration in this tissue. Unfortunately, magnetic particles have, for the most part, only been observed in tissue extracts, and work is currently underway to develop new techniques for imaging the particles in tissue slices and mapping their distribution to tissue structures.

Biogenic magnetite also has been found in the human heart, spleen, and liver. Again, this was determined by magnetometry studies, and calculation of magnetite concentrations showed that the heart has the highest levels of all organs examined thus far (Schultheiss-Grassi *et al.*, 1997). These investigations are continuing with the aim of determining the origin and role of biogenic magnetite in the human body.

**Figure B15** Transmission electron micrograph of biogenic magnetite extracted from the human hippocampus. Inset shows an electron diffraction pattern confirming the presence of magnetite. (From Schultheiss-Grassi *et al.*, 1999).

**Figure B16** Electron microscope image of cell with iron oxide particles. (a) scale bar 200 nm and (b) scale bar 100 nm (From Dobson *et al.*, 2001).

## Biogenic magnetite and neurological disorders

Though the physiological role of magnetite in humans is not yet known, recent studies have demonstrated a tentative link between magnetite biogenesis and neurodegenerative disorders such as Alzheimer's disease (AD) (Dobson, 2001, 2004; Hautot *et al.*, 2003). It has been known for 50 years that neurodegenerative diseases are associated with elevated levels of iron (Goodman, 1953). However, since that discovery, very little progress has been made in identifying the iron compounds present, their role, and their origin until this recent work.

Magnetite was first reported in AD tissue in the original study of human brain tissue by Kirschvink et al. (1992). These results did not demonstrate any correlation between elevated levels of biogenic magnetite and AD. Although the results were negative, it appears that this may have been due to the particular measurement technique rather than the absence of a correlation altogether. The isothermal remanent magnetization (IRM) of the tissue was measured using the superconducting quantum interference device (SQUID) magnetometry. One of the drawbacks of this method is that the contribution of very fine (superparamagnetic) particles (less than  $\sim$  50 nm) is lost from the signal, particularly when measured at 0°C as was the case in this first study. In this case, any concentration which is calculated from the data depends on making some assumptions-one assumption being that the signal is due to particles which are large enough to contribute to the remanent magnetization (i.e., blocked). In this study, that may not have been a true picture of all the biogenic magnetite in the tissue samples.

Recently, Hautot *et al.* (2003) have developed methods for measuring the total biogenic magnetite signal. This is done by measuring the magnetization vs. applied field and then modeling the contributions from material such as the diamagnetic tissue, ferritin, and heme iron. In this way, the total concentration of magnetite—regardless of grain size—can be determined. Using this method, preliminary evidence of a correlation between biogenic magnetite concentration has been demonstrated in female AD patients.

By measuring other parameters, such as magnetic interactions between groups of magnetite particles, it has also been shown that there is preliminary evidence of a correlation between particle packing geometry and focal epilepsy. There was no demonstrable correlation between biogenic magnetite concentration and epileptic tissue, but again, these results are from measurements of remanent magnetization.

New studies using microfocused synchroton x-ray sources have now enabled iron compounds in brain tissue to be located and characterized in situ with subcellular resolution (Mikhaylova *et al.*, 2005; Collingwood *et al.*, 2005). This breakthrough allows, for the first time, the mapping of specific iron compounds including magnetite, to structures and cells within neurodegenerative tissue. Magnetite-rich iron anomalies have been unequivocally identified in AD tissue using this method, and it shows great promise for furthering our understanding of the role of magnetite and other iron compounds in neurological disorders.

## Conclusion

Biomagnetism is now a major research area with a healthy mix of biologists, physicists, and chemists involved. We can safely conclude that many organisms sense the geomagnetic field and use it as a navigational cue, or for other purposes, such as nest alignment. Again it is clear that strong magnetic fields can produce mutagenic effects and produce harmful developmental effects in the several animals investigated. It is much less clear how much damage the relatively weak fields of power lines, mobile phones, and other electrical devices of modern society actually harm human beings. Magnetite is synthesized by many organisms and is involved in field detection in some. It is however present in many organisms in which its role is unclear. Indeed, as we noted, magnetite may be harmful as a source of free radicals. Presently, the possibility that magnetite may play a role in neurodegenerative diseases, such as Alzheimer's, Parkinson's, or Huntington's, is being investigated and may explain the association of iron enrichment and these diseases.

Magnetization, Isothermal Remanent Rock Magnetism

## BLACKETT, PATRICK MAYNARD STUART, BARON OF CHELSEA (1887–1974)

Blackett (Figure B17) came to geophysics late in a remarkable career. He had been educated at Osborne Naval College and Dartmouth and joined the Royal Navy, seeing action at the Battles of Jutland and of the Falklands in the Great War, as it was then known. After the war, he resigned from the navy, went to Cambridge to Magdalene College, and read for the Natural Science Tripos. He joined Lord Rutherford's group at the Cavendish as a graduate student in 1921, where he worked on transmutation of atoms using cloud chambers, carrying out in the succeeding two decades much of the work for which he was eventually awarded a Nobel Prize in Physics in 1948.

In 1933 he became professor of physics at Birkbeck College, London and in 1937 he moved to Manchester University as the Langworthy Professor of Physics. Prior to the Second World War, he had been brought into the Air Defense Committee and with the advent of the war was involved in many technical projects and made notable contributions in operations research. After the Second World War, he returned to Manchester and to research and was instrumental in establishing the first chair in radioastronomy and in the development of the Jodrell Bank Research Station that would lead to the famous steerable radio telescope. Meanwhile he became interested in magnetic fields in stars and planets, which led to his research in geophysics. In 1953, he was appointed professor and head of the physics department at Imperial College and built up an influential group in rock magnetism and paleomagnetism. Professor Blackett was elected president of the Royal Society in 1965 and made a life peer in 1969. He died in 1974.

Blackett was a member of the heroic generation of physicists, most of whom were European, who revolutionized physics between the two world wars. As one of Lord Rutherford's students, he was assigned to study the disintegration of elements using the cloud chamber, which had been invented by C.T.R. Wilson at Cambridge nearly a quarter of a century earlier. With it, Wilson had demonstrated the tracks of ionizing alpha particles emitted from a small radioactive source. In his initial studies of thousands of photographs using such a source and with the cloud chamber containing nitrogen, Blackett found just eight, in which something remarkable was recorded. As Figure B18 shows, most of the alpha particles from the radioactive source below the chamber pass through it, not striking the atoms of nitrogen gas in the chamber. However, on the left a track shows that an alpha particle has hit a nitrogen atom. This has yielded a heavy oxygen isotope and a proton that leaves to the right of the original track. The heavy oxygen leaves to the left with a stronger track and is seen to collide again. Blackett had trapped a nuclear transmutation on film! He went

Figure B17 P.M.S. Blackett.

**Figure B18** Cloud chamber photograph showing alpha particles traversing the chamber and an example on the left of a collision between an alpha particle and a nitrogen atom, yielding a heavy oxygen isotope and a proton. The proton leaves to the right of the initial track (after Close *et al.*, 1987).

on to establish the nature of the scattering of alpha particles from a number of nuclei of varying mass.

A major problem with the cloud chamber used in Blackett's early experiments was that thousands of photographs were needed to have a good chance of seeing an interesting transmutation. This problem became all the more daunting when the cloud chambers were turned to the analysis of cosmic rays. It was then a matter of chance, whether a cosmic ray crossed the chamber close to the time of expansion. The problem was solved by Blackett and a young Italian physicist Giuseppe Occhialini. Occhialini had studied with Rossi at Florence and brought with him knowledge of the work on coincident signals from Geiger counters. Blackett and Occhialini's solution was to place a Geiger counter above and below the cloud chamber so that a simultaneous signal from the two could be used to detect a cosmic ray particle and fire the cloud chamber. Of course by that time, the cosmic ray particle was long gone, but the ionization trail was still there and produced the necessary condensation for a track to be formed when the chamber was expanded. Although Anderson was the first to detect Dirac's antielectron, or positron as it has become known, Blackett and Occhialini confirmed its existence with their technique and demonstrated the production of positrons. To do this they had placed a copper plate above the cloud chamber, which produced gamma rays from the interaction of energetic cosmic ray electrons with the copper. Within the chamber numerous symmetrically divergent tracks were formed, as the particles with opposite electric charge formed and responded to the strong magnetic field imposed. These divergent tracks recorded the generation of matter, in the form of electrons and positrons, from energy, in the form of gamma rays, as predicted by Einstein. The citation for Blackett's 1948 Noble Prize was "for his development of the Wilson cloud chamber method and his discoveries therewith in the fields of nuclear physics and cosmic radiation."

Blackett's Nobel acceptance speech in 1948 reveals his social sensitivity. After expressing his personal feelings of satisfaction in the award, he remarked that he saw the Nobel Prize "as a tribute to the vital school of European Experimental Physics." He then went on to address the problem of avoiding the catastrophe of nuclear war, noting that "technological progress and pure science are but different facets of the same growing mastery by man over the force of nature. It is our task as scientists and citizens to ensure these forces are used for the good of men and not their destruction." In 1948 he published more on these ideas in the book *Military and Political Consequences of Atomic Energy*. His socialist political thought caused difficulty with the America of that time, but his recognition of the dangers of a world divided into very poor and very rich countries remains all too relevant to this day.

Blackett was clearly an excellent experimentalist and it was this ability that led him into the development of a sensitive magnetometer that opened up the field of paleomagnetism of the weakly magnetized sediments. Blackett had very skillfully constructed a sensitive magnetometer to test a theory of his about magnetic fields and the rotation of massive bodies. The idea was in relation to the origin of the magnetic fields of stars and of the Earth as a fundamental property of their rotation. The work developing this system and the negative result were described in a famous paper by Blackett entitled "A Negative Experiment Relating to Magnetism and the Earth's Rotation" and published in the Transactions of the Royal Society. There used to be a reprint of this paper in the geophysics library at Madingly Rise, Cambridge, with a note from Blackett, apologizing for the mistaken theoretical basis for the experiment. However, his instrument provided the means of measuring the weak magnetization of sediments, which was essential to test the idea of continental drift. This was one mistake that had a substantial silver lining!

Blackett's rock magnetism group worked initially at Manchester and then moved with him to Imperial College. His laboratory at Imperial College, with its orderly arrangement of instruments and polished wooden floors, was reminiscent of the quarterdeck of a Royal Navy battleship, presumably a legacy of his naval days. Important work was done both in fundamental rock magnetism and in paleomagnetism. Leng and Wilson demonstrated the reality of geomagnetic field reversals. Haigh made critical contributions to the understanding of magnetization acquired by magnetic materials as they grow in a magnetic field. Everitt studied the acquisition of magnetization as magnetic particles cooled in a magnetic field and developed the baked contact test-one of the standard paleomagnetic field tests. The paper by Blackett, Clegg, and Stubbs (1961) was one of the most convincing early demonstrations by paleomagnetism of the veracity of the idea of continental drift. Blackett's lectures on rock magnetism taken from his Second Weizman Memorial Lectures of 1954 is a little gem, combining insight on the grand scale, but also reflecting the pleasure of experimental work (Blackett 1956).

Blackett's main contributions were outside of geophysics. One immediately thinks of his experimental skills and the insights that came from the cloud chamber work; his leadership during World War II; his contributions to the development of radioastronomy. In addition to all this, his experimental skills played an important role in the development of rock magnetism and paleomagnetism. The way in which his group operated was in a direct lineage from Rutherford's Cavendish, which was brought to our field. We were lucky that our subject was touched by Blackett.

## BULLARD, EDWARD CRISP (1907–1980)

Edward Crisp Bullard, known to everyone as Teddy, was the greatest geophysicist working in the United Kingdom in the second half of the 20th century (Figure B19). He made seminal contributions to the theory of the origin of the magnetic field, to the analysis of the westward drift and secular variation, and to studies of electromagnetic induction. He championed a number of developments in the theory of plate tectonics, and placed his department at the centre of the plate tectonic revolution of the 1960s. His full biography is in McKenzie (1987).

Teddy was born in Norwich into a wealthy family of brewers. The building that housed the brewery still stands in an attractive part of Norwich, but the business was taken over in the 1960s and Bullard's beer can no longer be found; the name enjoyed a revival in the early days of the campaign for Real Ale and won a prize at the 1974 Cambridge beer festival. The young Bullard was educated at Repton School where his physics teacher, A.W. Barton, initiated his interest in physics. He studied physics in Cambridge, where he found the lectures dull with the exception of J. Larmor (q.v.), Rutherford, and Pars, and proceeded to research in Rutherford's laboratory. He was in fact supervised by P.M.S. Blackett (q.v.), although Rutherford was probably the greater influence. His Ph.D. project was on electron scattering, but on taking up a position in the Department of Geodesy and Geophysics he began work on the measurement of gravity with pendulums and made observations with them in East Africa. His Ph.D. thesis, only 26 pages long, includes both the electron scattering and gravity work. He was elected a fellow of the Royal Society in 1941; the citation includes work on seismics, heat flow, and gravity: everything, in fact, except geomagnetism.

On the outbreak of the Second World War he joined the Admiralty Research Laboratory and set to work on reducing the magnetic fields around ships. The Germans had laid magnetic mines in shallow waters around Britain, which sank 60 ships in the "phoney war" in December 1939. The "degaussing" was successful (Bullard, 1946). He subsequently joined Blackett to work on what later became known as operational research. The degaussing of ships was his first work on magnetism, the only previous reference being to the effect of the Earth's magnetic field on the period of invar pendulums (Bullard, 1933), but during his war work he read Chapman and Bartels (1940), and this probably stimulated him to work on geomagnetism after the war was over.

Postwar Cambridge offered little for an ambitious researcher, particularly in geophysics, and Teddy moved to Toronto. There followed the most productive period of his career. He used his knowledge of

Figure B19 "Teddy" as the author knew him in about 1970.

heat flow to develop the convection theory for the dynamo (Bullard, 1950) and analyzed global observations for secular variation and the westward drift (Bullard *et al.*, 1950). Both these studies remain substantially correct today, although his theory for westward drift, that the magnetic field acted on the lower mantle to drive it eastwards by an electric motor effect, is no longer believed because the electrical conductivity of the mantle is thought to be too small.

*W.M. Elsasser* (q.v.) also began working on the origin of the Earth's magnetic field at this time, but he concentrated on the mechanism by which a magnetic field could be generated by flow in the core, whereas Bullard had worked with the observations and on the heat sources driving the convection. Elsasser derived some fundamental results in dynamo theory and constructed a formalism for solving the equations, but did not attempt to solve them. This was a very formidable problem for that time—indeed, it is still a very difficult problem with today's computers. Bullard and a research student at Toronto, H. Gellman, attempted to find a solution with the tools at hand (see *Bullard-Gellman dynamo*). In 1950 Bullard moved back to the United Kingdom as director of the National Physical Laboratory, where he had access to one of the most powerful computers of the day.

Although Bullard and Gellman (1954) is one of the most influential papers ever published in dynamo theory, their solutions had not converged and their claim to have found a working dynamo was subsequently proved incorrect (Gibson and Roberts, 1969). Nonetheless, it was a brave and very early effort to carry out a numerical solution of a partial differential equation governing a problem in fluid mechanics. The dynamo failed because they chose a fluid flow that lacked helicity. It is clear that they intended to design a flow with helicity because their paper contains a discussion of magnetic field lines being pulled and twisted to reinforce the dipole field, but they were restricted by numerical considerations to a very simple flow. Bullard was undoubtedly influenced by Elsasser's ideas, which were later developed by E.N. Parker into what is now known as an  $\alpha$ -effect dynamo (Parker, 1955). Kumar and Roberts (1975) eventually found a working dynamo using the Bullard-Gellman formalism and a more complicated fluid flow.

Bullard desperately wanted to return to Cambridge. Eventually a post became available when *S.K. Runcorn* (q.v.) moved to Newcastle, and Bullard accepted a very junior position, lower than the one he occupied before the war. He was eventually promoted as reader then professor in 1964, over 20 years since his election to fellowship of the Royal Society and 10 years after his knighthood.

On the question of polarity reversals he sat on the fence, much to Runcorn's annoyance, remaining sceptical because of the discovery of self-reversal in certain minerals. He was finally won over by the classic work of Cox *et al.* (1963), and when Harry Hess visited Cambridge in 1962 and talked about his ideas on seafloor spreading he encouraged Fred Vine, then a research student, to pursue his interpretation of reversely magnetized seafloor in terms of Hess' model. The result is now known as the *Vine-Matthews-Morley hypothesis* (*q.v.*).

In later years he had a succession of successful research students working on electromagnetic induction, among them Bob Parker, Nigel Edwards, and Dick Bailey. He put his name to very few scientific papers written during this period, but his influence was everywhere, both on the group as a whole and on individual students. Bullard worked to the end, finishing his last paper on historical measurements at London with Stuart Malin (Malin and Bullard, 1981) shortly before he died.

## CARNEGIE INSTITUTION OF WASHINGTON, DEPARTMENT OF TERRESTRIAL MAGNETISM

When the Carnegie Institution of Washington (CIW) was established in 1902 with a large bequest from Andrew Carnegie, one of its goals was to encourage research in the "borderlands" between the scientific disciplines. In its first years, the CIW established two departments that became stages for research in the geosciences: the Geophysical Laboratory and the Department of Terrestrial Magnetism (DTM). While the Geophysical Laboratory moved quickly in the direction of geochemical investigation and toward developing laboratory techniques to study how rocks behave at great depth within the Earth, the DTM focused on a series of problems related to geomagnetism and geo-electricity during its first several decades. The DTM branched out starting in the 1920s to investigate the atomic nucleus, cosmic rays, and even cosmology. These two departments have now existed for over a century and today are located on a single campus where their researchers can more easily interact (Trefil and Hazen, 2002).

The geophysicist Louis Agricola Bauer (q, v), who had been engaged in geomagnetic research for over a decade, established the DTM in 1904 with the general goal of studying Earth's magnetic and electric phenomena, but with a definite project to prosecute "quickly" a magnetic survey of the planet. This project was to be completed within a generation in order to provide data which could be more easily reduced to a common epoch than the data then available. Magnetic data had only been gathered since the mid-19th century with any degree of consistency, and even then, it was concentrated in just a few regions and was spread over decades. Entire continents were uninvestigated and charts available for magnetic declination in the world's oceans were frequently in error by  $1^{\circ}$  and  $2^{\circ}$ , while inclination measurements were 1°-3° off. Moreover, outside the main shipping lanes very few readings had been made at all (Good, 1994b). Bauer proposed a World Magnetic Survey to the Carnegie Institution of Washington because, as a nongovernmental agency, it would enjoy greater credibility for mounting expeditions in Africa, Asia, South America, and other places where the institutions of major governments might be looked upon with suspicion. Moreover, free of any government connection, the DTM could directly approach scientific officials in other countries without going through their supervising bureaucracies. As he put it in his mission statement for the new department, the DTM would survey the magnetism of areas not being studied by others. This was most of the globe.

The DTM was to have a second purpose too: to coordinate and standardize magnetic measurements then being undertaken by dozens of governments and agencies around the world. That is, it would be the international standardizing bureau. It would carefully compare the great variety of geomagnetic instruments (see *History of Instrumentation*) and promote the best methods of investigation and measurement. To this end, for decades the DTM had its traveling "magneticians" visit major magnetic observatories around the world to standardize instruments and to learn and teach different working methods. DTM promoted data exchange and uniform methods of reduction. In these regards the DTM acted in the way that various commissions of the *International Association for Geomagnetism and Aeronomy* or *IAGA* (*q.v.*) and *Intermagnet* do today.

Bauer set the DTM's first task as evaluation of existing data for secular variation studies and he contracted Adolph Schmidt to determine the status of data on magnetic storms. The second over-arching goal was to "establish the facts" and to convince theoreticians that the data and mathematical tools could become available for decisive testing among different theories.

Bauer also brought his journal *Terrestrial Magnetism and Atmospheric Electricity* (since 1948 the *Journal of Geophysical Research*) to the DTM, where he and his associate director *John A. Fleming* (q.v.) used it to provide a disciplinary and international identity for geomagnetic researchers. In its pages, Bauer published critical studies of various instruments, theoretical discussions, and "news of the profession," including capsule biographies of geomagnetic role models like *Edmond Halley* (q.v.), *Alexander von Humboldt* (q.v.), and *Carl Friedrich Gauss* (q.v.).

Bauer's most dramatic project, however, was the global magnetic survey. Between 1905 and World War II, the DTM employed two hundred magnetic observers on land expeditions. Counting the number of expeditions is a little difficult, since many of them split and rejoined and they varied from a few weeks to many months in duration. The DTM reported in 1928 that 178 land expeditions had thus far occupied 5685 magnetic stations. This averaged 271 stations per year. By 1928, when Fleming was taking over supervisory duties for the DTM, the main land survey was completed. Dwindling numbers of expeditions from then until the mid-1940s concentrated on secular variation measurements at a smaller number of *repeat stations* (q.v.).

These troops of magneticians were a tightly organized, well-trained army of observers. They learned the physics of electricity and magnetism, the use of magnetometers, induction coils, and sine galvanometers (see *History of Instrumentation*) and the techniques of data reduction. They also were resourceful, independent travelers. Unlike other expeditionaries, these scientists often traveled alone and rarely in groups of more than three. They transported hundreds of kilograms of instrumentation and other gear and frequently traveled by camel or canoe, as well as by steamer or locomotive. The magnetic data was hard won and surprisingly, not one observer died of disease or accident in all of those travels into the Polar Regions, Amazonia, and bandit-

ridden China (Figure C1).

**Figure C1** Magnetic observer Frederick Brown traveled around Asia by camel and sedan chair. This photo is from April 1915. Photo courtesy of Carnegie Institution of Washington. Photo DTM 5769.

Meanwhile, Bauer carefully executed a parallel set of oceanic expeditions. He consulted in 1904 and 1905 with experts in geomagnetism (e.g., Arthur Schuster) and hydrographers (e.g., George W. Littlehales and Ettrick W. Creak) (Good, 1994b). In 1906, 1907, and 1908 the brig *Galilee* followed three, spiraling loops in the northern Pacific Ocean, providing magnetic measurements within each 5° quadrangle in the region, or one station every 200 miles. The DTM constantly improved sea-going magnetic instruments, so that by 1908, magnetic observers read declination to within  $0.5^\circ$ , compared with  $0.1^\circ$  for land observers. By this last cruise, errors due to iron on board ship was a larger source of error than the instruments.

Hence, Bauer obtained funding from the CIW for construction of a nonmagnetic yacht, the *Carnegie* (q.v.), which was launched in 1909. This yacht was magnificent, if peculiar. Its dominant peculiarity was the deck house, a glass enclosed galley with a glass observing dome at each end. Protected within, magnetic observers could make measurements even in quite rough seas. From 1909 until its demise in 1929, the *Carnegie* conducted seven cruises, including a celebrated fastest-ever circumnavigation of Antarctica for a sailing vessel in 118 days; all the while the observers continued their scientific work.

A map published by the DTM in 1929 shows the globe enmeshed in the observations of Bauer's remarkable World Magnetic Survey (Figure C2). Bauer had imagined an ambitious plan to make thousands of measurements around the globe in a single generation and he found the funding, personnel, and instruments to do it. The effort required to produce this first geomagnetic "snap-shot" was nothing short of remarkable.

**Figure C2** A map showing all of the expeditions undertaken by the DTM for the first World Magnetic Survey, 1904 to 1929. Each dot is a discrete station. The lines on the oceans indicate the tracks of the *Galilee* and the *Carnegie* between 1905 and 1929. Map courtesy of Carnegie Institution of Washington.

Although the DTM still exists, its focus on expeditionary, geomagnetic work ended with World War II. The department published two volumes in 1947, coordinated by E.H. Vestine, in which the data of the enterprise were summarized and analyzed (Vestine *et al.*, 1947a,b). Although the DTM has continued to conduct geophysical research since then, its character has been much more varied, including research in seismology and nuclear physics.

## CARNEGIE, RESEARCH VESSEL

When Louis Agricola Bauer (q.v.) established the Department of Terrestrial Magnetism (DTM) at the Carnegie Institution of Washington (cv) in 1904, he intended to focus the DTM's efforts strongly on an oceanic magnetic survey. The oceans represented both the largest and the most accessible gap in geomagnetic data. Bauer felt that most of the oceanic data available was not of high enough quality and that it was mainly restricted to coastal waters and trade routes. From 1905 to 1908, the DTM leased a wooden sailing vessel, the brig *Galilee*. Bauer had the steel rigging replaced with hemp and stripped away as much other iron as possible, but bolts and nails had to stay. The *Galilee* sailed over 70000 miles and established 442 magnetic stations, but its most important result was this: The *Galilee* demonstrated that a completely nonmagnetic ship was necessary to carry on this research.

Bauer convinced the Carnegie Institution's Board (and Andrew Carnegie) that the DTM needed its own yacht, specially designed for magnetic research. The shipyard in Brooklyn, New York that had built Kaiser Wilhelm's *Meteor* (and the winner of the 1906 Atlantic cup race) designed and built a most peculiar ship: the *Carnegie* (Figure C3). It was 155 feet long and carried 13000 square feet of sails. Bauer stationed a magnetic investigator at the shipyard for 7 months to guarantee that no magnetic materials were used in its construction. The planking was all wood, the nails were of locust tree, and the bolts were copper or bronze. Its bronze anchors each weighed 5500 lb and instead of anchor chains,

**Figure C4** A full complement of *Carnegie* observers in the two observing domes. Captain W.J. Peters is on the deck above. The photo was taken in the Indian Ocean in 1911. Courtesy of Carnegie Institution of Washington. Photo H-118.

the ship used 11-in. hemp cable. At \$115000 (perhaps ten million dollars today), the *Carnegie* cost more than any other scientific instrument in history.

The most important part of the ship for geomagnetic research was the observation deck, a special glass-enclosed room with a circular observation dome at each end (Figure C4). The domes were of glass panels with a brass framework. Magnetic observations were made in foul weather and fair, in order to obtain the density of measurements that was required.

A crowd of 3500 people turned out to launch the ship in 1909. It sailed the world's oceans for 20 years, collecting many thousands of magnetic measurements, and sailed on seven cruises, the equivalent distance of circumnavigating the globe twelve times. It met its demise in 1929 in the harbor at Apia, Samoa, when a gasoline engine exploded during refueling. The Carnegie Institution never again operated its own research vessels. Although the British government proposed a new "non-magnetic" research vessel in the 1930s, the *Research*, World War Two

prevented it being placed in service. The Soviet government did launch the nonmagnetic schooner *Zarya* in the 1950s and continued to use it for several decades. (The name *Zarya* is now attached to the Russian component of the International Space Station.)

Simultaneously with the oceanic surveys of the *Galilee* and the *Carnegie*, the DTM (see Carnegie Institution of Washington, Department of Terrestrial Magnetism) conducted an ambitious magnetic land campaign. The goal was to gather enough magnetic data in a generation to provide a much better "snapshot" of Earth's magnetism than was then available. While this survey was completed by about 1930, the DTM continued to send observers to selected "*repeat stations*" (q.v.) to obtain data useful for studying secular variation.

## CHAMP

Challenging Minisatellite Payload (Figure C5) is a satellite mission dedicated to improving gravity and magnetic field models of the Earth. CHAMP was proposed in 1994 by Christoph Reigber of GeoForschungsZentrum Potsdam in response to an initiative of the German Space Agency (DLR) to support the space industry in the "New States" of the united Germany by financing a small satellite mission. The magnetic part of the mission is lead by Hermann Lühr. CHAMP was launched with a Russian COSMOS vehicle on July 15, 2000 onto a low Earth orbit. Initially planned to last 5 years, the mission is now projected to extend to 2009 (Figure C6). The official CHAMP website is at http://op.gfz-potsdam.de/champ/.

#### Satellite and orbit

A limiting factor for low Earth satellite missions is the considerable drag of the atmospheric neutral gas below 600 km altitude. This

brought down *Magsat* (*q.v.*) within 7 months, despite of its elliptical orbit, and necessitated the choice of a higher altitude orbit for Ørsted (*q.v.*). To achieve long mission duration on a low orbit, CHAMP was given high weight (522 kg), a small cross section (Figure C5), and a stable attitude. It was launched onto an almost circular, near polar ( $i = 87.3^{\circ}$ ) orbit with an initial altitude of 454 km. While Magsat was on a strictly sun synchronous dawn/dusk orbit, CHAMP advances one hour in local time within eleven days. It takes approximately 90 min to complete one revolution at a speed of about 8 km s<sup>-1</sup>.

## Magnetic mission instrumentation

#### Magnetometers

At the tip of the 4 m-long boom, a proton precession Overhauser *magnetometer* (*q.v.*), measures the total intensity of the *magnetic field* (*q.v.*) once per second. This instrument, which was developed by LETI, Grenoble, has an absolute accuracy of <0.5 nT. Its measurements are used in the absolute calibration of two redundant vector magnetometers, located mid-boom on an optical bench. These fluxgate magnetometers were developed and supplied by DTU Lyngby, Denmark. They sample the field at 50 Hz with a resolution <0.1 nT.

#### Star cameras

The orientation of the optical bench in space is given by a star camera, which was developed and supplied by DTU Lyngby, Denmark. Attitude uncertainty is the largest source of error in satellite vector magnetic data. Star cameras are often blinded by the sun or moon, and provide unreliable attitude with regard to rotations about their direction of vision (boresight). For this reason, CHAMP was equipped with a dual head star camera, improving relative attitude by an order of magnitude to 3 arc seconds, corresponding to around 0.5 nT accuracy for the vector components. Since this high accuracy is only achieved in dual head mode (62% of CHAMP data), future magnetic field missions (e.g., the European Space Agency mission *swarm*, scheduled for launch in 2010) will have triple head star cameras. A further, redundant dual head star camera on the body of CHAMP is of limited utility for the magnetic field measurements, due to the flexibility of the boom.

#### Electric field, electron density, and temperature

A digital ion drift meter (DIDM) and a planar Langmuir probe (PLP) were provided by the Air Force Research Laboratory, Wright-Patterson Air Force Base, Ohio. The DIDM, designed to measure the electric field from ion velocities, partly failed due to frictional overheating during the launch phase of CHAMP. The PLP, which was not damaged, provides

**Figure C5** Front view of the CHAMP satellite (courtesy GFZ Potsdam). The acronyms POD and CoG stand for Precise Orbit Determination and Center of Gravity, respectively.

**Figure C6** The decay of CHAMP's orbital altitude (*left scale*) depends on the neutral gas density, which is enhanced by solar activity (*right scale*). CHAMP's orbit has been raised thrice to prolong the mission, which is predicted to end after the solar activity minimum in 2009 (courtesy of F.-H. Massmann, GFZ Potsdam).

the spacecraft potential, electron temperature, and electron density, once in 15 s. As discussed below, these quantities can be used to correct magnetic field measurements for the diamagnetic effect of the plasma surrounding the satellite. The PLP measurements have thus, turned out to be essential for accurate geomagnetic field modelling.

#### GPS receiver

Apart from providing the accurate position of CHAMP, the Black Jack GPS receiver (supplied by NASA) has the important task of providing an absolute time frame. A pulse delivered every second is used to synchronize all of the instruments on board. Furthermore, it provides a stable reference frequency for the proton precession magnetometer readings, giving them absolute accuracy.

#### Data products

CHAMP's standard science products are labelled from level-0 to level-4, according to the amount of preprocessing applied to the original data. Scientific utility starts with level-2 products, which are calibrated, flagged, and merged with accurate orbits and are supplied as daily files in common data format (CDF). Level-3 products comprise the final processed, edited, and calibrated data, as well as the rapid delivery products. Derived products such as the initial CHAMP main field model CO2 (Holme *et al.*, 2003) are classified as level-4. The level-2 to level-4 products are archived and distributed by the Information System and Data Centre (ISDC) at GFZ Potsdam (http://isdc.gfz-potsdam.de/ champ/).

## Early science results

#### Main field models

Combined analysis of measurements from the three magnetic satellite missions (CHAMP, Ø*rsted* (*q.v.*) and SAC-C) has to a breakthrough in main field model accuracy (Holme *et al.*, 2003). While models from ground-based observations are limited in resolution to about 5000 km wavelength, the new combined satellite models resolve the main field (q.v.) and its secular variation (q.v.) to 3000 km. Shorter wavelengths of the main field are masked by the *crustal magnetic* field (q.v.).

#### Crustal field models

With its low altitude, circular, polar orbit, CHAMP is particularly suited for mapping the field caused by the magnetic minerals in the Earth's crust. The first CHAMP crustal field model (Maus *et al.*, 2002)—extending to spherical harmonic degree 80, corresponding to a wavelength of 500 km—shows that the Earth's crustal magnetic field is weaker than indicated by earlier observations from Magsat.

#### Magnetic signal of ocean flow

The flow of electrically conducting seawater through the Earth's magnetic field acts as a global dynamo, inducing electric fields which drive electric currents and thus, give rise to secondary magnetic fields. Focussing on the dominant semidiurnal lunar tide, periodic ocean flow magnetic signals were clearly identified in CHAMP satellite data (Tyler *et al.*, 2003).

#### Diamagnetic effect of ionospheric plasma

A diamagnetic substance responds to an applied magnetic field by circular currents that produce a magnetisation opposing the applied field. Such a diamagnetic response, which is a well-known property of plasma in the outer magnetosphere and the solar wind, was until recently, thought to be negligible in the ionosphere. However, bands of enhanced plasma density on both sides of the magnetic equator have been found to cause depressions of the order of 5 nT in the geomagnetic field intensity (Lühr *et al.*, 2003). With the electron density and temperature acquired by the PLP instrument, CHAMP's magnetic field readings can be corrected for this effect. A related phenomenon is the formation of surface currents on plasma cavities. The CHAMP satellite has made it possible for the first time to directly observe these currents in their magnetic field signature (Lühr *et al.*, 2002).

## CHAPMAN, SYDNEY (1888–1970)

Sydney Chapman received 17 degrees (mostly honorary doctorates), published seven books and over 400 scientific papers, received nine major medals (including the Royal and Copley medals of the Royal Society), held ten visiting chairs, was president of eight professional societies, and fellow of many more. Rather than try to encompass a career of such breadth and depth, it is mainly his contribution to geomagnetism that is considered here, though he also contributed massively to, *inter alia*, solar-terrestrial physics, ionospheric physics, meteorology, aurorae, and the kinetic theory of gasses.

Chapman was born in Eccles, Lancashire, on January 29, 1888. He was set to enter an engineering firm, but, before doing so, he won the last of 15 university scholarships offered by Lancashire and went on to take an engineering degree at Manchester University. He stayed on for a further year and added a mathematics B.Sc. On the advice of Horace Lamb, he then tried for and obtained a Cambridge mathematics scholarship. He completed the examinations after two years at Trinity College, but was required to stay on for a further year before graduating. During this time he received a visit from Frank Dyson, the Astronomer Royal, offering him the prestigious and well-paid post of Chief Assistant at the Royal Observatory, Greenwich. (The other Chief Assistant at the time was the cosmologist Arthur Eddington, with whom Chapman devised the cycling performance measure *n*, which is the number of occasions on which *n* or more miles have been cycled in a day. Eddington achieved n = 77, and Chapman rather more.)

Chapman was at Greenwich from 1911 to 1914, and again from 1916 to 1918 to help out when many of the staff were at the war. He was a conscientious objector during the World War I—a far from easy option—but had revised his views by the time of World War II. While at Greenwich, Chapman was introduced to geomagnetism. He organized the re-instrumentation of the magnetic observatory, took part in the routine magnetic observations (on his own admission he was not a good observer), and set about the interpretation of geomagnetic variations.

In 1919 he moved from Trinity College, Cambridge, to succeed Lamb in the chair of mathematics and natural philosophy at Manchester. In the same year he was elected to Fellowship of the Royal Society at the early age of 31. This was largely for his work on the theory of solar and lunar daily geomagnetic variations.

In 1924, Chapman became chief professor of mathematics at Imperial College, London, where he remained until 1946. While there, he won the John Couch Adams essay prize, the subject of which (chosen at the suggestion of Dyson, with Chapman in mind) was the theoretical interpretation of geomagnetic phenomena. One of the conditions of the award was that the work should be published, which Chapman satisfied with a number of papers. But he also felt obliged to turn the essay into a book. In this he collaborated with the young German scientist *Julius Bartels* (q.v.) to eventually produce the two-volume *Geomagnetism* in 1940. This became the "bible" for geomagneticians for half a century. Though the instrumental part and the bibliography are now outdated, the mathematical sections are still of sufficient value to make this book an important part of any geomagnetic library.

It was also during his time in London that Chapman started his collaboration with V.C.A. Ferraro on the theory of magnetic storms, which was to be superseded only when satellite observations became available. With another of his students, *A.T. Price* (q.v.), he examined the currents induced in the Earth by Sq and their implication for mantle conductivity.

In 1946, Chapman moved to Oxford University to become Sedleian Professor of Natural Philosophy, a post he held until approaching compulsory retirement at 65. Rather than retire, he moved to the United States, where he already held visiting appointments. This was during the lead-up to the 1957/8 International Geophysical Year (IGY) and Chapman, as president of the IGY Special Committee, took the opportunity to travel widely, soliciting support for the project. As well as his theoretical work, he had undertaken many analyses of vast quantities of observational data and was well aware of the need for such data on a world-wide basis.

In the final, though far from inactive, part of his career (more than 150 papers were published after his "retirement"), Chapman divided his time between the Universities of Colorado and Alaska. In Alaska he worked with S.-I. Akasofu on geomagnetic disturbance phenomena and in Colorado with several colleagues, largely updating and extending earlier work in the light of recently acquired data, including IGY data. He was still actively working until a few days before his death on June 16, 1970.

Chapman's personal qualities were as remarkable as his scientific ability. He was slightly built, but very athletic, though his feats were of endurance rather than speed. Some mention has already been made of his cycling prowess. He gave up cycling at about 70, mainly because American highways were not cyclist-friendly, as he and his wife discovered experimentally. He swam half a mile a day throughout his life, going to considerable lengths to avoid missing a day. The nearest he came to owning a car was a half-share in one with Bartels, but only briefly. He much preferred to walk. He was a gentleman with strong moral principles and was always greatly considerate of the feelings of others. His many colleagues and students valued him as much as a friend as for his teaching.

## COAST EFFECT OF INDUCED CURRENTS

#### Introduction

When changes in Earth's magnetic field are measured on timescales of about 1 hour, the vertical component near most coastlines is abnormally large and correlates with the onshore horizontal component. This phenomenon is known as the geomagnetic coast effect. It is caused by electromagnetic induction occurring naturally in the Earth's surface layer.

The "primary" currents in the induction process are electric currents, which flow external to the Earth and change with time. As the solid Earth and its oceans conduct electricity, "secondary" currents are induced to flow in them. At Earth's surface, observations of magnetic and electric variations record the effects of the primary and secondary fields combined. Because in many instances the primary fields are uniform and spatially uncorrelated from one induction event to the next, spatial patterns occurring systematically reflect spatial patterns in the secondary fields due to structure in the electrical conductivity of the Earth.

The main electrical conductivity contrast at Earth's surface is between land and seawater. Seawater is a relatively homogeneous material, with its electrical conductivity,  $\sigma$ , depending mainly on salt content and temperature. A typical value for  $\sigma$  throughout the world's oceans is 3.3 S/m, in a range of 3 S/m for cold, less saline water to 6 S/m for warm, salty water (Bullard and Parker, 1970).

Land generally consists of inhomogeneous rock material and its conductivity, in contrast to that of seawater, varies by orders of magnitude (Sheriff, 1999). However the electrical conductivity of rock material generally is less than that of seawater. Further, the electrical conductivity of rock material is generally less than 1 S/m, leading to the common use of electrical resistivity  $\rho$  (the reciprocal of conductivity  $\sigma$ ) when describing rock material. Thus a resistivity of 1  $\Omega$ m is equivalent to a conductivity of 1 S/m and a resistivity of 10  $\Omega$ m is equivalent to a conductivity of 0.1 S/m.

Then rock material typically has a resistivity of some hundreds of  $\Omega$  m in the crust and possibly thousands of  $\Omega$  m in ancient cratonic rocks. In sedimentary basins the resistivity may be less, say tens of  $\Omega$  m. In ore bodies, and in crustal concentrations of the good conductor graphite, the resistivity may be only small fractions of an  $\Omega$ m; however such good conductors form only a minor part of the total volume of crustal rocks.

The land-ocean conductivity contrast exerts a strong effect on electromagnetic induction at Earth's surface. Induction at places of such conductivity contrast is characterized by the generation of a vertical magnetic field component. Near a land-ocean contrast, this vertical component is seen as the geomagnetic coast effect.

#### Discovery of the coast effect

The coast effect was first observed by Parkinson (1959, 1962) and the discovery demonstrated that conductivity contrasts at and near Earth's surface could be detected by using natural electromagnetic induction at periods of about 1 hour. Parkinson's early results for Australia are shown in Figure C7 (see *Parkinson, Wilfred Dudley*).

At about the same time detailed observations of magnetic fluctuation patterns were also made in other continents, for example by Schmucker (1963); Rikitake (1964); Price (1967). The advent of digital recording and time-series analysis using electronic computers led to numerical analysis methods replacing Parkinson's graphical methods and the phenomenon was investigated as a function of frequency (Everett and Hyndman, 1967; Schmucker, 1970). One consequence of this development was then to demonstrate in-phase and out-of-phase components of the coast effect. Generally the in-phase component is stronger than the out-of-phase component (a result of the high conductivity of seawater) and often the effect is described and interpreted simply in terms of the in-phase component. If the out-of-phase component is being studied, care must be taken with the definition of phase (see Lilley and Arora, 1982). See also *induction arrows* (q, v).

## Observation of the coast effect

The review by Parkinson and Jones (1979) gives a global survey of the observation of the coast effect, which is still geographically representative. The authors note that the few coastal locations where the coast effect is absent are tectonically anomalous. In a regular coast effect, the strength of the phenomenon, as reckoned by the response in the vertical component of the fluctuating field, reduces to about half its coastal strength at a distance of some hundreds of kilometers inland.

**Figure C7** Early Parkinson arrows for Australia, after Parkinson (1964). Small magnetic vector changes at an observatory tend to lie in a "preferred plane." The horizontal projection of the downwards normal to this plane gives arrows as shown which, generally pointing to the high conductivity side of a nearby conductivity contrast, point to the deep ocean.

The authors also note that the coast effect varies only slightly with period, reaching a broad maximum in the period range 30-90 min. An important quantity is the electromagnetic "skin depth,"  $\delta$ ,

$$\delta = \sqrt{\frac{2}{\mu\sigma\omega}} \tag{Eq. 1}$$

where  $\omega$  denotes angular frequency and  $\mu$  denotes the permeability of the material (usually taken as that of free space). For the period range 30–90 min, the skin depth of seawater is some 20 km, which is greater than the ocean depth. Thus an external magnetic fluctuation signal reaches the ocean floor and penetrates the seafloor rock material and the ocean may be regarded as an electromagnetic "thin sheet."

An example of induction arrows for the coast effect of southeast Australia, observed on both land and seafloor, is shown in Figure C8 (White *et al.*, 1990). The site is favorable for a clear demonstration of the effect, as the coastline runs relatively straight for hundreds of kilometers, the continental shelf is narrow, and at the foot of the continental slope the seafloor is deep (almost 5000 m) and flat, comprising the Tasman Abyssal Plain. Included in the compilation are sites spaced down the continental slope. As can be seen from the induction arrows, the coast effect is at a maximum about halfway down the slope into the deep ocean.

An example of the data recorded in this particular case is shown in Figure C9. Displayed are the horizontal and vertical components of magnetic variation at five stations. It is in the vertical components that the coast effect is evident and the signal can be seen to be a maximum at station 4 (the trace marked CS4Z).

Fluctuations in the geomagnetic field occur over a wide frequency band, and the coast effect has also been investigated at shorter and longer periods. At shorter periods, the effect has been demonstrated to occur in "pulsations" of period order 1 min and less. At these short periods the skin depth of seawater no longer is greater than the depth of the deep ocean, and the effect takes place in the upper layer of the ocean. The relatively shallow seawater of the continental shelf becomes important.

At longer periods, a natural frequency band at which to examine the coast effect is that of the magnetic daily variations (termed "Solar quiet," and denoted Sq). However, for these signals different observation and analysis techniques are required due to the presence of a significant vertical component in the Sq source field.

Generally there is agreement that major "electric current gyres" are induced to flow in the oceans by the Sq source fields (Beamish *et al.*, 1983) and these also have a measurable effect at observatories near coast lines. Bennett and Lilley (1973) showed how a coast-effect vertical component could be separated from an observed record by subtracting an inland record observed simultaneously, which was taken to be a "normal" (i.e., background) component.

**22AUG86 Figure C9** Examples of magnetic fluctuation records for one day, showing the coast effect (White *et al.*, 1990). The top five traces, with suffix H, are the horizontal north components for stations 1 to 5, as marked on Figure C8. The middle set of traces, with suffix D, are the horizontal east components. The lower five traces, with suffix Z, are the vertical components. The strength of the signal in the vertical component characterizes the coast effect, as it is the result of the electrical conductivity structure at the land-sea interface. Note this signal is strongest at station 4, half way down the continental slope.

#### Analogue modeling of the coast effect

The relative electrical conductivities of rock material and seawater lend themselves to analogue model studies. Following the initial global "terrella" model of Parkinson (1964), model studies have been carried out on geometries seen in coastlines worldwide (Dosso, 1973). These analogue models have the ability to model 3D situations, such as the islands of Tasmania (Dosso *et al.*, 1985) and New Zealand (Dosso *et al.*, 1996).

**Figure C10** A two-dimensional model for the coast effect shown in Figures C8 and C9, with seawater layer and contrasting electrical conductivity structure beneath continent and ocean (Kellett *et al.*, 1991).

**Figure C11** The electromagnetic response of a thin-sheet model of Australia presented as induction arrows, for period 1 h (in-phase) from Corkery and Lilley (1994). (Scale: an arrow which exactly spans a grid unit has a magnitude of 0.3).

## Calculation of the coast effect

The basic calculation of the coast effect is a two-dimensional problem and the forward problem was solved in one of the early achievements of numerical modeling of electromagnetic induction in the Earth (Jones and Price, 1970; Weaver, 1994). Given that the ocean bathymetry is generally known well, the calculation becomes an exercise in modeling the rock material beneath the seawater. Figure C10 shows such a 2D model for the observed data shown in Figures C8 and C9.

As abilities in 2D and 3D numerical modelling and inversion have progressed, the coast effect has been a basic case for testing new methods and techniques. As an example, which may be compared with Figures C7 and C8, the induction arrow response for a numerical model of the Australian continent set in its surrounding seas (Corkery and Lilley, 1994) is shown in Figure C11.

#### Geophysical ocean-coast transects

Geophysical studies now frequently address the tectonic boundaries, which may be present at coastlines. By making observations along a transect, which crosses the coast line from deep ocean to inland, information may be obtained, which characterizes the structure and history of the region. Electromagnetic studies to obtain electrical conductivity information have been foremost amongst such transects, which have included subduction zones (Yukutake *et al.*, 1983; EMSLAB-Group, 1988) and passive margins (Wannamaker *et al.*, 1996). These transects

**Figure C12** Diagram showing, near a buried body of high electrical conductivity, the "preferred plane" in which small vector magnetic changes tend to lie, and the normal **n** to the preferred plane. When the normal **n** is parallel or antiparallel to the main field **F**, a total-field magnetometer such as a proton-precession instrument will be insensitive to the small vector changes (Lilley *et al.*, 1999).

have given some of the most comprehensive observations of the coast effect, with electric and magnetic field measurements on both land and seafloor. Note also that Hitchman *et al.* (2000) made observations of the coast effect offshore at the sea surface, using a floating total-field magnetometer.

## An application of the coast effect

Coast effects cover large regions and their influence may be widespread. An example is the "amphidrome" effect, which, as a result of the coast effect, exists across a wide swath of southern Australia (Lilley *et al.*, 1999). Here the coast effect causes the Parkinson preferred plane to be approximately orthogonal to the main magnetic field vector. Thus fluctuation events, which generally lie in the preferred plane, tend to be orthogonal to the main field and the component of them measured by a "total field" magnetometer (as in an aeromagnetic survey) is much reduced.

Figure C12 illustrates the "amphidrome effect" in which magnetic fluctuation signals, measured by a "total field" magnetometer, are suppressed when the normal to the Parkinson preferred plane is parallel to Earth's main magnetic field vector.

#### Conclusion

The geomagnetic coast effect is regarded as being well understood, and is primarily due to the electrical conductivity contrast between land and seawater, controlling natural electromagnetic induction in the environs of a coastline.

#### COMPASS

A freely suspended, magnetized iron needle will attempt to align itself with the ambient magnetic field vector (**F**); when made to float in a bowl of liquid, or balanced horizontally on a pivot, it will orientate itself along the local magnetic meridian (**H**, the horizontal part of the vector). At what specific instant during the Middle Ages this attribute was first discovered remains shrouded in the mists of time; China, the Arab world, Greece, Italy, France, and Scandinavia have all claimed primacy in this respect. The ubiquity of *lodestone* (or *loadstone*, various iron-rich, permanently magnetized minerals) at and near the Earth's surface must have enabled many cultures to become aware of this mysterious, but highly useful, property.

Technically speaking, any contraption incorporating magnetic alignment to indicate direction can be considered a compass. The word itself can be traced back to Mediterranean countries around the mid-13th century, initially referring to sailing directions (both written instructions and nautical charts). Two centuries later, its meaning had expanded to include dividers applied in course plotting on a chart, whereas in German-speaking regions the word additionally became associated with pocket sundials, which contained a small dry-pivoted magnetic needle, inset at the base, for meridional orientation. It would take another century before the term would be predominantly associated with the currently typical magnetized needles bearing a graduated card, often encased and in cardanic suspension. The following discussion will outline some of the most notable aspects of this evolution, focussing in turn on its basic design, the observation compass, technical improvements, and the problem of deviation.

#### Basic compass design

The earliest unequivocal evidence of a magnetized piece of iron used for orientation stems from China around the turn of the 12th century A.D., in sources describing the floating magnetic "compass fish," and south-pointing needles magnetized by lodestone touch suspended with a silk wire or balanced on a fingernail. The floating needle (in a little water-filled saucer, marked with 12 or 24 wind directions) was probably incidentally used at sea during overcast weather by both Chinese, Korean, and Japanese navigators, until "dry" compasses were introduced by European ships from the 16th century. However, Southeast Asian shipping was primarily coastal and monsoon-driven, limiting reliance on the magnetic pathfinder. By contrast, contemporary Arabian navigators traversing the Indian Ocean set their courses using a 32-point sidereal card without a needle, deriving directions instead from the near-perpendicular rise and set of specific stars, such as Altair (East) and Antares (Southeast). Their 13th-century adoption of the compass on Mediterranean voyages was established through European contacts.

In western Europe, references to floating needles start to appear from the 12th century, in accounts by A. Neckam (1187), P. de Maricourt (Petrus Peregrinus, 1269), and in various ship's inventories. Over the next century, notions of magnetization and compass needles became so commonplace that they were increasingly used in a metaphorical sense in literature. During the 14th century, dry-pivoted instruments came to replace their floating precursors and the needle was attached to a starch-stiffened paper disk depicting the rose of the winds (6-8 in. in diameter); its cardinal points were painted blue, the half cardinals red. The direction of Jerusalem (east) was initially marked with a cross, the others with the first letter of their associated Mediterranean wind. The north-indicating letter "T" (for Tramontana) may have mutated into the ornamental fleur-de-lys around 1500. Points division grew from 8 through 16-32 in the 16th century. From about 1650, standardized designs engraved in copper plate replaced hand-drawn cards, while during the 18th century, a more austere appearance with rim graduation became the norm. At the time, maximum steering accuracy of square-rigged vessels generally did not exceed one quarter point  $(2^{\circ}49')$ .

With the advent of commercial cartography and triangulation, the surveying compass rose to prominence on land. This instrument was usually tripod-mounted and equipped with a plumb line to be aligned with the sighted object. Its pivoted, straight needle rotated over a card attached to the inside bottom of the case. In the 17th century, the mounting of more elaborate sighting devices (double visors, cross-hairs, small telescopes) allowed more precise readings to be taken. Another compass-like instrument, used on land from the late 16th century, was the *versorium*, an arrow-shaped iron needle, up to a foot long, applied by natural philosophers such as *W. Gilbert* (q.v.) and N. Cabeo to investigate electrical and magnetic phenomena, for example, to detect the electrostatic attraction produced by rubbed amber.

At sea, the mariner's needle became attached to the underside of the card, providing instantaneous identification of all directions and a larger moment of inertia. By the late 16th century, the whole became encased in a round or square bowl or box made of wood, copper, or brass, suspended in brass or tin gimbals, inside a larger square box. The box was covered with a glass or crystal lid, sealed with putty or wax to keep out wind, dirt, and moisture, while its bottom was detachable for maintenance purposes, so the watertight top seal did not have to be broken each time the needle required retouching.

The steering compass was housed on deck inside the binnacle, which was horizontally divided into three compartments; the two outer ones each held a compass, the middle one a lantern. When sailing craft grew larger, the fore-and-aft line that indicated the ship's heading became less clearly distinguishable to the helmsman, so a corresponding mark inside the compass bowl, the *lubber's line*, was introduced as a steering aid. Various production centers mushroomed, such as Sicily, Genoa, and Venice (Mediterranean), Danzig (Baltic), and Seville, Lisbon, La Rochelle, Bordeaux, Rouen, and Flanders (west European coasts). From the 17th century, the capitals of the seagoing nations likewise became the seat of compass making firms and individual craftsmen, which soon came to dominate the manufacture of these instruments.

To compensate for magnetic declination in steering, the needle was sometimes affixed to the card at an angle to true north; another physical solution was the *rectifier*, a second, rotatable card on top of the first, with which changing declination values along a voyage could be compensated by applying a variable (usually fixed-step) shift. To compensate for magnetic inclination, which changes with latitude along the voyage and dips the needle, thus increasing friction, a lump of wax was attached to the card; from the 18th century, increasingly sophisticated, adjustable counterweights were used.

Regarding needle shape, at its crudest stage, a single piece of iron wire was bent into rhombic form, the two ends forming an acute angle at one apex, and the middle of the wire forming another at the opposite end, allowing space in the middle for a cap to balance the needle on the pivot. Alternatively, two separate curved pieces of iron could be joined at the ends to form a lozenge or two empty parentheses. Single, straight needles of well-tempered steel (enabling more intense, longer-lasting magnetization), rose to prominence in the first half of the 18th century. Metal caps then became replaced by glass and agate ones, which suffered less wear from pivotal friction. Admiralties and commercial shipping companies adopted standardized, often patented designs (from 1766), for example, by G. Knight and R. Walker (18th century), and by the firms of Stebbing, Weilbach, and Kleman (19th century).

#### The observation compass

The main difference between a steering compass and an observation compass is a sighting device mounted on top of the box (see Figure C13), to be aligned with a landmark (surveying and charting), the ship's wake (estimating leeway), or a celestial body (determining magnetic declination). Such compasses could be set up on land or anywhere on deck using a wooden stool or special tripod. Despite great

**Figure C13** Cross section of an early-modern amplitude compass, as used in oceanic navigation. 1, needle; 2, card; 3, cap; 4, pin; 5, balancing weight; 6, inclination counterweight; 7, glass lid; 8, cardanic suspension; 9, compass bowl (inner box); 10, outer box; 11, rotatable verge ring; 12, fiducial line; 13, crosshair visor.

variability of design, all types had cards graduated in degrees (or less) to measure the horizontal arc between two imaginary great circles perpendicular to the horizon and meeting in the zenith. The arc distance from true east was called *amplitude*; that from true north was called *azimuth*. The most significant practical distinction between *amplitude compass* and *azimuth compass* is that the former, older device only allowed near-horizontal sightings directly over the card, whereas the latter's much taller visors, introduced in many countries in the second half of the 18th century, permitted multiple observations to be taken in short succession, and at a much greater altitude above the horizon. The acceptance of azimuth as a superior measurement was, however, reliant on adequate technology, the implementation of the new, longer calculations, and awareness of the problems associated with amplitude readings (limited opportunity, poor sighting conditions at the horizon due to clouds and haze and atmospheric refraction).

The first description of an observation compass can be found in De Maricourt's "Epistle on the Magnet" (1269). Apart from a silver or brass transverse index, it carried a sighting rule with upright styles at both ends to align with heavenly bodies. Similar 16th-century descriptions are known from the Portuguese J. de Lisboa (1508), Italian L. Sanuto (1588), Dutchman R. Pietersz van Twisk (1595), and Englishman W. Barlowe (1597, with a rotatable verge ring carrying a brass ruler with two upright, triangular sights). In France, two types of amplitude compass existed concurrently, one with small pins fixed to the rim of the box, the other with two small glass windows in opposite sides, furnished with crosshairs. French navigators adopted azimuth visors only from the 19th century onward. Some English 17th-century amplitude compasses had a large, broad semicircle made of brass, which extended beyond the compass rim and could be rotated around it. Opposite this dial was a large foldable style, carrying a sight and a hypotenusal thread from the top of the index down to the plate that could cast a noonday shadow onto the card. This method was rarely used at sea.

In terms of measurement accuracy, by taking the average or (more often) the median of a series of magnetic declination readings obtained in the course of a nautical day, a standard deviation of little under half a degree was maintained by the majority of early-modern navigational practitioners engaged in oceanic shipping. On land, with the aid of more accurate instruments and fixed meridians engraved in stone, this margin could sometimes be reduced to a few arc minutes. Around 1820, a more modern version of the azimuth compass was introduced

at sea, allowing celestial measurements near the zenith with a card divided in half degrees.

#### **Compass design improvements**

Besides complaints about careless construction, low-quality materials, skewed or warped cards, and the aforementioned wear on pin and cap, the most serious defect of the instrument, mentioned time and again in early-modern documents, was weak magnetization. Needles made of iron wire (in use up to the early 18th century) required several retouchings at sea on long voyages, which is why some vessels still carried lodestones on board as well. Magnetization itself was deemed highly dependent on the proper method; suggestions range from repeatedly striking the needle with a hammer while placed on the lodestone, through rotating its tips inside small holes made at the lodestone's poles, to (1-12) stroking motions of the lodestone along (half or all of) the needle's length. A separate debate focussed on the various types and qualities of lodestone, using color, density, and origin as decisive characteristics. With the 18th-century advent of steel needles and artificial magnets (fully magnetized steel rods, much stronger than natural magnets), the earlier dependence on lodestones, both by compass makers and sailors, was greatly reduced.

A different way to improve directivity was to increase the number of needles inside the instrument; by placing two, four, or even eight straight needles in parallel under the card; their combined directive property would greatly exceed that of any single one. The first controlled experiment that compared the performance of single- and parallel needle compasses dates from 1649, by C.J. Lastman and I. Blaeu, two navigation officials employed by the Dutch East India Company. The superior results of parallel needles were disseminated in leaflets and navigation textbooks, and from 1655 until about 1710, Dutch Eastindiamen routinely carried two or more such instruments.

After incidental descriptions in French and Spanish textbooks without practical implementation, Danish naval officer and hydrographer Lous rekindled interest from 1767, advocating a compass with four flat, steel needles of 150 mm in length, held in a wooden or brass frame. Similar designs were proposed by French mathematician C. de Borda (1772) and astronomer P.-C. Le Monnier (1776), and by English captain C.H. Lane (1788). However, it would take until 1840 before the new British Admiralty's standard compass would carry four straight steel needles attached to a ring beneath the card, itself to be supplanted by the improved card invented by W. Thomson (1878, adopted 1889), which carried eight parallel needles suspended by wire. In subsequent decades, this dry compass fought a losing battle against another design improvement which would be universally adopted in the 20th century: the liquid compass.

The liquid compass has the advantages of damping needle movements and exterior disturbances and supporting the card to reduce friction, but at the cost of introducing such new complications as freezing, leakage, and temperature-induced changes of volume or pressure. After Royal Society experiments with lodestones acting under water in the 1660s, E. Halley (q.v.) seems to have demonstrated a rudimentary liquid compass there in 1690. The first comprehensive description appeared in 1779, written by Dutch physician J. Ingen-Housz: a large, sensitive needle inside a steel tube with a float, housed in a waterproof casing filled with linseed oil. Several other designs were propounded by instrument makers G. Wright (1781), Barton (1792), and C.C. Lous (1795); liquid compass patents were, for example, issued to inventor Francis Crow (1813), and the Danish compass production firm of Weilbach (1830). The problem of variable fluid volume was finally solved by W.R. Hammersley's system of expansion chambers (1856). A late-19th century liquid compass with two parallel artificial magnets is depicted in Figure C14.

#### Compass deviation

The deflection of compass needles away from the geomagnetic vector due to the attraction of magnetized iron nearby is known as compass

**Figure C14** An American 19th-century liquid steering compass with two parallel needles (on *left*), and a Swedish late 20th-century handheld, dry-pivoted scouting compass (author's collection).

deviation (the term was coined by Arctic explorer J. Ross, ca. 1820). The effect was first recorded by Portuguese navigator J. de Castro in 1538, who ascribed inconsistent readings of magnetic declination to a cast iron gun on deck. From the 17th century onward, regulations regarding compass use warned both mariners and surveyors against wearing clothing attributes made of iron and prompted them to take note of metal structures that might affect the readings. On the largely wooden ships, the disturbance remained limited to incidental aberrations of a few degrees at most, the cause of which was usually identified swiftly, and either removed or avoided thereafter.

The introduction of iron and steel in ship construction, however, radically exacerbated the problem. Despite the advantages of stronger, longer, cheaper, more spacious hulls, the increasing reliance on structural iron parts (late 18th and first half of the 19th century) and extensive armor plating (Crimea War, 1854–56), all introduced substantial sources of magnetic deviation, up to tens of degrees. The period from the first iron-hulled clippers (ca. 1800) up to all-steel ship design (1877) was hallmarked by the scientific investigation of deviational compass error, and the invention of various methods of compensation.

Possibly the oldest method to investigate compass deviation was "swinging the ship," which involved turning the ship about a vertical axis, and recording the incurred deviation on all headings. The procedure was first suggested by American surveyor J. Churchman in 1790. British naval surveyor M. Flinders, while traversing Tasmanian waters in 1798, likewise noticed that the amount of compass error varied as a function of course. On his next assignment in the region, he identified (latitude-related) geomagnetic inclination as another factor to be considered. Subsequent captivity on the French isle of Mauritius (1803–1810) allowed him to develop his theory of compass error further, using his findings to correct and redraw much of his survey. Upon his return to England, he suggested a counter attractor, the "Flinders bar" (an iron rod of specific length placed inside the binnacle, opposite the side of greatest deviation), which was eventually introduced on board ship some 50 years later.

Research intensified from the 1810s, amongst others by explorer W. Scoresby, astronomer F. Arago, Board of Longitude secretary Th. Young, and *Professor P. Barlow* (*q.v.*), who developed a disk ("Barlow's plate," 1819) to quantify deviation aboard ship. Theoretical aspects received attention in a series of treatises (1821–1838) by French mathematician S.D. Poisson, relating geomagnetism and ship magnetism using C.A. de Coulomb's inverse-square law. Soon thereafter, Astronomer Royal G.B. Airy started a series of experiments on iron ships, using combinations of bar magnets and iron chains as counteracting physical correctors. In the second half of the century, hydrographer Frederick Evans worked with mathematician A. Smith on the problem, based on the Hydrographic Office's first isogonic

chart (1858), resulting in the "Admiralty Manual for Deviations of the Compass" in 1862.

Notwithstanding these efforts, deviation proved a highly complex phenomenon that was never fully defeated. A different solution ensuring accurate and safe navigation free from interference was eventually found in the gyrocompass, based on the gyroscopic principle, which forces the axis of any sufficiently fast spinning top to keep a fixed orientation, for example, relative to the Earth's axis (described in 1836 by E. Sang in Britain, and in 1852 by J.B.L. Foucault in France). The first fully operational models were patented by H. Anschütz-Kaempfe and E. A. Sperry in the early 20th century, and underwent sea trials from 1907. Over the next few decades, the gyrocompass proved a worthy successor to the magnetic compass, which became relegated to the more modest role of auxiliary safety backup on large ships. Nevertheless, the magnetic compass continues to serve the majority of smaller, private vessels, as well as scouts, hikers, and other travelers on land (see Figure C14). In addition, the historical accumulation of magnetic compass readings recorded in ship's logbooks presently provides an invaluable source of data on geomagnetic secular variation over the last four hundred years.

## CONDUCTIVITY GEOTHERMOMETER

#### Introduction

The concept of the electrical conductivity geothermometer comes from the laboratory-demonstrated dependence of the electrical conductivity of rock material on temperature (Hinze, 1982). These laboratory results are consistent with theoretical considerations.

Beneath various complications that arise in the upper crust of Earth, rock material is generally considered to conduct electricity according to the physical mechanism of electronic semiconduction. The partial melting of rock material may also increase rock conductivity once connectivity is established for the melt fraction (Shankland *et al.*, 1981).

For electronic semiconduction, the relationship is the Arrhenius one between electrical conductivity  $\sigma$  and absolute temperature *T*, given by (Parkinson and Hutton, 1989)

$$\sigma = \sigma_{\rm e} \, \exp(-E_{\rm e}/kT) + \sigma_{\rm i} \, \exp(-E_{\rm i}/kT) \tag{Eq. 1}$$

Here the first term in Eq. (1) describes extrinsic conduction, operating through thermally activated crystal defects and impurities, and the second term describes intrinsic conduction at higher temperatures. The terms  $\sigma_e$  and  $\sigma_i$  are the high-temperature asymptotes for each type of conduction,  $E_e$  and  $E_i$  are activation energies, and k is the Boltzmann's constant.

The strategy is to exploit the phenomenon of electromagnetic induction at Earth's surface by natural source fields (Campbell, 1997) to obtain a  $\sigma$  profile. Then, in terms of parameters  $\sigma_e$ ,  $\sigma_i$ ,  $E_e$  and  $E_i$  determined experimentally from laboratory studies or on the basis of other laboratory information, to obtain a *T* profile from the  $\sigma$  profile. The procedure is thus in two parts, which will now be discussed in turn.

## Determining electrical conductivity as a function of depth

The observed data are time-series of magnetic and electric fields measured at various places over the surface of Earth. Generally these places are well-established magnetic observatories, sometimes supplemented by more temporary magnetotelluric stations. The primary signals have generally come to the solid Earth from outside it, and because they change with time they induce secondary fields within Earth, as the planet is an electrical conductor. At the surface, observations record both primary and secondary fields combined. A process of data inversion is needed, based on the known physics of induction in the Earth (Weaver, 1994), to give from these observations a profile of electrical conductivity with depth.

Activity in this topic is now such that specialist workshops on Electromagnetic Induction in the Earth have been held in different parts of the world every two years since the first one in Edinburgh, Scotland in 1972. Review and contributed papers are published, for example see Weaver (1999). Data on electrical conductivity structure from electromagnetic observations are used to obtain information on geological structure, composition, and history.

An important point is that the process of electromagnetic induction in the Earth is frequency dependent. An indication of the depth of penetration into a material by an induction process is given by the electromagnetic "skin depth,"  $\delta$ ,

$$=\sqrt{\frac{2}{\mu\sigma\omega}}$$

(Eq. 2)

where  $\omega$  denotes angular frequency,  $\sigma$  denotes the electrical conductivity of the material, and  $\mu$  denotes the permeability of the material (usually taken as that of free space).

Thus lower frequency signals penetrate deeper into the Earth and information on deep Earth conductivity depends on them. A natural limit to the lowest frequencies which can be observed is imposed by the spectrum of the source fields. Commonly the longest period studied is 1 year, exploiting a periodicity which has its origin in the seasonal cycle of Earth. A longer period of 11 years, which has its origin in a periodicity seen in solar activity, is also sometimes used. A limit may also be imposed by the length of observatory record needed to obtain data for these lowest frequencies.

If the Earth had ideal spherical symmetry, and its properties (including electrical conductivity) varied with depth only, the analysis of observations to give structure would be more straightforward. This situation, termed one-dimensional (1D), has mathematics which, while far from simple, are not as complicated as the next stages of complexity, which are termed two-dimensional (2D) and three-dimensional (3D) respectively (Weaver, 1994). For a 2D situation, the conductivity varies with two spatial parameters such as depth and one horizontal direction; while in a 3D situation the conductivity may vary in all directions.

Many case histories now demonstrate that departures from 1D are common in the electrical conductivity structure of the crust and upper mantle of Earth (Booker and Chave, 1989; Gough, 1989; Mareschal *et al.*, 1995). In addition to the possibility of "conductivity anomalies" caused by partial melt, other notable causes of increased conductivity are graphite and water (ELEKTB-Group, 1997).

However it is common to model the deeper regions of the Earth's mantle as 1D. This action is taken on the grounds that the material is expected to be more homogeneous than the more easily inspected crust.

An example of global conductivity profiles thus obtained by inverting surface observations are those of Olsen (1999) shown in Figure C15.

**Figure C15** Profiles of electrical conductivity of the Earth as a function of depth, after Olsen (1999). The different profiles result from different data inversion procedures.

70

In this case, as in others, the mantle-core boundary is taken to be a step to effectively infinite conductivity, due to the molten metallic material of the Earth's core.

#### Determining temperature from electrical conductivity

When a conductivity profile with depth has been obtained, there is then the question regarding what mineral data should be used to convert the conductivity data to temperature. While there is general agreement about the main mineralogical composition of Earth, some fine points, upon which conductivity is highly dependent, remain uncertain. Prime amongst these is the oxygen state, in Earth's mantle, of the mineral olivine (Shankland and Duba, 1990; Constable and Roberts, 1997).

Figure C16 from Shankland (1981) combines data on rock and mineral conductivities. It shows firstly that electrical conductivity is an Earth quantity which varies by orders of magnitude in common rock materials. Then, within the range of conductivity values shown, the two lines (on the log-log graph) for synthetic "hot-pressed olivine" give an indication of the range of values in Eq. (1) possible when inverting conductivity data to give an "electrogeotherm" (and see Xu and Shankland (1999) for more recent experimental results). Such inversions are made on the basis (generally accepted by mineralogists) that the mantle of Earth is comprised mainly of olivine.

A number of research workers have thus published temperature profiles for the Earth based on analyses of electromagnetic induction at Earth's surface. The early result of Duba (1976), shown in Figure C17, is instructive regarding the general magnitudes of the quantities involved. Note that Constable (1993) explores the possibility that the temperature at 410 km is less than as shown in Figure C17, for consistency with experimental evidence that a phase transition at that depth should occur at 1400°C. The electrogeotherm models of Constable

**Figure C16** Conductivities of possible upper mantle constituents (after Shankland (1981) and Rai and Manghani (1978)).

(1993), incorporating results from Constable *et al.* (1992), are shown in Figure C18.

It is important to note also that at the high temperatures near the base of the mantle, Eq. (1) becomes less temperature dependent, as its asymptotic form for high temperatures is approached. Thus electrical conductivity, even if known, becomes less useful in predicting temperature at such high temperatures.

## Conclusion

Increasing research into the various elements needed to construct an electrical conductivity geothermometer has produced the result (common in research) that the matter is more complicated than might have at first been expected. While increased computer power enables continued progress in the numerical modeling of complicated conductivity structures and of the inversion of observed data in terms of them

**Figure C17** Olivine electrogeotherm for Earth's upper mantle compared with geotherms determined petrologically (after Duba, 1976).

**Figure C18** Upper mantle electrogeotherms, after Constable (1993). The different curves result from different data inversion techniques, especially regarding a possible step increase in electrical conductivity at depth 600 km.

(Fujii and Schultz, 2002), uncertainty about the details of the main constituent of the mantle (olivine, and in particular its oxygen fugacity) remain and limit the application of the strategy.

In fact at mantle depths the relationship between electrical conductivity and temperature is increasingly being examined from another view point. Rather than assume that the material in the mantle is known, it is increasingly the case that the temperature is estimated from other considerations. Then, such temperature estimates are used with laboratory measurements of different minerals to determine, from electrical conductivity profiles, the mineralogy of the mantle (Shankland *et al.*, 1993; Constable, 1993).

Conductivity, Ocean Floor Measurements Geomagnetic Deep Sounding Magnetotellurics Mantle, Electrical Conductivity, Mineralogy

## CONDUCTIVITY, OCEAN FLOOR MEASUREMENTS

The ocean floor presents a particularly harsh environment in which to carry out electrical measurements, with pressures of up to 600 atm (60 MPa), temperatures of around 3°C, and no possibility of radio contact with instrumentation. Furthermore, seawater is a corrosive, conductive fluid. Thus, progress in the field of electrical conductivity studies has largely followed the availability of reliable underwater technology and has not become truly routine until recently.

Most electromagnetic methods can be adapted for seafloor use, but the high conductivity of seawater dominates both how data are collected and how they are interpreted. Seawater conductivity depends on salinity and temperature; in practice salinity variations are too small to be significant and so to a good approximation seawater conductivity is given by (3 + T/10) S/m where *T* is temperature in degree celsius. The bulk of the ocean thus has a resistivity of about 0.3  $\Omega$ m, with warmer surface waters 0.2  $\Omega$ m.

DC resistivity is only practical for shallow investigations where the seafloor conductivity is similar to or greater than the seawater. The most common EM method applied to seafloor studies is the magnetotelluric (MT) method (q.v.). First experiments date from the 1960s, and Charles Cox, Jean Filloux, and Jimmy Larson (1971) report an MT response from measurements made in the Pacific in 1965, using 1 km long cables on the seafloor and a new seafloor magnetometer developed by Filloux. Filloux later also developed a system for making electric field measurements using short (about 3 m) pipes acting as salt bridges and a device to reverse the connection of electrodes to the pipes, allowing any electrode self potential to be removed from long period electric field variations (Filloux, 1987). Although this technique is still important for studies of ocean currents using seafloor E-field recorders, it has since proved unnecessary for MT studies, and it is now common practice to simply mount electrodes at the ends of four approximately 5 m plastic arms to give 10 m E-field dipoles. The torsion fiber magnetometers originally used by Filloux to keep power consumption low have been replaced in more recent instrumentation by fluxgate sensors and induction coils.

There are advantages and disadvantages to the seafloor MT method. On the advantage side, it is easy to make a low impedance, low noise electrical contact with the environment. The sensor of choice for this is silver-silver chloride nonpolarizable electrodes although a new carbon fiber electrode has been developed for short period studies. The seafloor is also free of the cultural noise that can plague land MT surveys. Access is good and permitting, if required, is usually valid for the entire survey area. Arrays of seafloor MT recorders lend themselves well to the new array processing techniques available.

On the other hand, the skin depth (exponential decay length for EM fields) at 1 Hz in seawater is only 270 m and so the overlying ocean removes the short period source fields, a problem exacerbated by the red nature of the geomagnetic spectrum (see *Geomagnetic temporal* 

*spectrum*). Depending on water depth and the type of instrumentation, data are limited to periods longer than 10 to 1000 seconds. Water motion produces a Lorenz ( $\mathbf{E} = \mathbf{V} \times \mathbf{B}$ ) field that is prominent at tidal periods and eventually dominates the induced fields (see *Electromagnetic ocean effects*). Thus, seafloor MT is ultimately band limited. The recent use of induction coil *magnetometers* (*q.v.*) on marine MT instruments (Constable *et al.*, 1998), coupled with high gain, AC-coupled electric field amplifiers, optimizes the collection of higher frequency data, but even with this system one is limited to about 10 s period data on the deep seafloor (in 4–6 km water).

The geomagnetic *coast effect* (*q.v.*) is very much more severe on the ocean side. Electric charge accumulating on coastlines from the MT fields leak into the conductive part of the mantle over a boundary layer distance *L* given approximately by  $\sqrt{ST}$  (Cox, 1980), where *S* is the conductance of the oceans and *T* is the resistivity-thickness product of the uppermost seafloor rocks. We know from CSEM studies that *T* is about 10<sup>9</sup>  $\Omega$ m<sup>2</sup>, so long period MT anomalies from the coast effect are attenuated horizontally over an *L* of 3000 km. Undoubtedly, there is electrical connection between the ocean and conductive mantle at volcanic regions and possibly at subduction zones, but at passive margins the coast effect is so strong that *T* can be estimated from land MT data and global induction studies. For these reasons, it is important in marine MT interpretations include coastlines and bathymetry during modeling and interpretation.

In the late 1970s, Charles Cox (1981) proposed replacing the highfrequency energy lost to the magnetotelluric signal with a deep towed human-made transmitter, and carried out the first experiments in 1979 (Spiess et al., 1980). This controlled source electromagnetic (CSEM) sounding method complements the MT method, because not only is it sensitive to shallower structure, but also it is preferentially sensitive to resistive seafloor, whereas the MT signal is induced in conductive rocks. In the most common application of this technique, a horizontal electric transmitting dipole is towed close to the seafloor, and the resulting electric fields are measured as a function of range and frequency by a number of seafloor electric field recorders. At a typical transmission frequency of 1 Hz, the skin depth in seawater is so small that receivers placed more than a few kilometers from the transmitter record only signals that have propagated through the more resistive seafloor. For two decades the marine CSEM method remained an exotic technique used to study deep seafloor and mid-ocean ridges, but during the first years of the 21st century it was enthusiastically embraced by the petroleum industry. Hydrocarbon reservoirs are relatively resistive (10-100  $\Omega$ m) compared to the marine sediments in which they are often found (around 1  $\Omega$ m), and this resistivity contrast combined with CSEM sounding's ability to detect thin resistive layers makes the method useful for mapping oil and gas reservoirs (Constable and Weiss, 2005).

Nigel Edwards (1985) and colleagues developed a marine application of a land technique called magnetometric resistivity (MMR) sounding, in which a bipolar vertical electric field transmitter extends from the ship to near the seafloor. A low-frequency current is transmitted and the resulting magnetic fields are measured by seafloor recorders some distance away. Since the essentially DC current flow from the transmitter is distorted by the resistive seafloor rocks, the horizontal magnetic fields become a measure of seafloor conductivity.

Figure C19 illustrates the three types of measurements discussed here. The recorders are essentially the same in every case, except that for long-period MT measurements a fluxgate magnetometer would supplement or replace the induction coil sensors. Figure C20 illustrates the current understanding of oceanic conductivity structure. Seawater, as noted, is around 0.3  $\Omega$ m except above the thermocline near the surface. The upper 400–600 m of oceanic crust is composed of extrusive volcanics, lava flows, and pillow lavas. Corresponding to seismic layer 2, these rocks are highly porous and have resistivities between 1 and 10  $\Omega$ m. They are more conductive at mid-ocean ridges (MORs) because porewater is heated by volcanic action. Any sediments overlaying the basalts will have a resistivity between that of seawater and about 1  $\Omega$ m.

At a depth of about 500 m, porosity, permeability, and electrical conductivity all drop as the lithology changes to intrusive basaltic volcanics (dikes and sills). Away from ridges, resistivity will be a few tens of  $\Omega$ m in this layer. At around 2 km below the seafloor, we find the gabbros that make up most of the crust. Away from the MOR axes, resistivity increases to several tens of thousands of  $\Omega$ m by the time mantle depths are reached; whether this increase occurs at the top of the gabbroic layer, or deeper in the crust, is hard to determine because resistivity is monotonically increasing below the seafloor and the resolving kernels of EM methods are intrinsically smooth. At fast MOR spreading centers, and at currently active places on slowly spreading ridges, this layer contains the magma chamber that fuels crustal accretion. Resistivity within the magma chamber will be between that of basaltic magma (0.3  $\Omega$ m) and about 30  $\Omega$ m, depending on melt content.

Off-axis, crustal conductivity is simply a reflection of porosity, and any conductivity contrast at the moho, which would typically be below 600 °C, will be small, and the lithospheric mantle, like the lower crust, is many thousands of  $\Omega$ m. It is possible that the oceanic upper mantle, depleted in volatiles during crustal formation at mid-ocean ridges, is about an order of magnitude more resistive than continental mantle. At the base of the thermal lithosphere (from 6 to 100 km deep, depending on plate age), conductivity increases to between 100 and 500  $\Omega$ m consistent with the electrical conductivity of dry subsolidus

**Figure C19** Experimental layout for seafloor-controlled source EM (CSEM) sounding (*left*), magnetometric resistivity (MMR) sounding (*center*), and magnetotelluric (MT) sounding (*right*). In all cases the receiver instruments are very much the same; for MT sounding a CSEM or MMR transmitter is not required.

**Figure C20** Approximate seafloor conductivity profiles below a mid-ocean ridge (*broken line*) and older, normal oceanic lithosphere (*solid line*).

olivine near its melting point, or perhaps a little more conductive (see *Conductivity geothermometer*). Many early marine MT studies reported a highly conductive layer thought to correspond to the asthenosphere between about 100 and 200 km deep. Although there may well be a conductivity anomaly associated with the base of the lithosphere, the very high conductivities originally modeled are probably an artifact of using one-dimensional interpretation on data that are affected by the *coast effect* (q.v.). The controversy that once surrounded this issue seems to be abating, however, and more recent multisite, multidimensional studies often include the coastlines explicitly and tend not to require an asthenospheric conducting layer.

Both laboratory studies of high pressure mantle minerals (see *Mantle, Electrical conductivity, Mineralogy*) and induction studies using long-period magnetic observatory records (see *Geomagnetic deep sounding*) show that the lower mantle (believed to be composed of silicate perovskite and mangnesio-wüstite) is very much more conductive than the upper mantle and is about  $0.2-0.5 \ \Omega m$ . Whether this conductivity increase occurs entirely at 670 km or starts shallower in the transition zone is unclear. Recent laboratory measurements on the high-pressure phases of olivine suggest that conductivity should increase at 440 km and some induction studies support this. However, the jump in conductivity inevitably exhibit an increase starting at shallower depths.

## **CONVECTION, CHEMICAL**

Convection is the differential motion which occurs due to the action of the gravitational body force on density inhomogeneities within a fluid body. The density of a fluid body is a function of its pressure, temperature, and chemical composition. Pressure variations cannot cause convection; they play a secondary role, at most. "Chemical convection" refers to motions which arise due to spatial variations in density arising from variations in the chemical content of the fluid; an alternate and equivalent name is "compositional convection." Similarly, motions which arise due to spatial variations in temperature are called "thermal convection."

The study of convection is facilitated by assuming that the density,  $\rho$ , is independent of pressure and is a linear function of both temperature, *T*, and chemical content (i.e., mass or volume fraction of one of two chemical constituents), *C*; for example,

$$\rho = \rho_0 - \rho_0 \alpha [T - T_0] - \rho_0 \beta [C - C_0],$$

where  $\alpha$  is the coefficient of thermal expansion,  $\beta$  is the compositional expansion coefficient, and a subscript 0 denotes a constant (reference) value. For normal fluids  $\alpha > 0$  (hot fluid is lighter than cold), while the sign of  $\beta$  depends on whether *C* measures the fraction of denser or less dense constituent. Commonly, *C* is taken to quantify the less dense constituent and then  $\beta > 0$ . In the core, *C* quantifies the nonmetallic constituent and  $\beta$  is of unit order.

74

If the surfaces of constant density are not perpendicular to the local acceleration of gravity, convection invariably occurs. On the other hand, if these surfaces are everywhere perpendicular to gravity, then a quiescent state is always possible. An important question is whether convection can and will occur in such a fluid body. The fluid is stable if all perturbations of arbitrary form and amplitude decay with time. On the other hand, if any small perturbation of the quiescent state leads to motions which increase in amplitude with time, the fluid is said to be (convectively) unstable.

The tendency for a fluid body to convect is measured by the Rayleigh number:

$$Ra = \frac{(\Delta \rho)gh^3}{\rho_0 v\kappa}$$

where g is the acceleration of gravity, h is the vertical extent of the body,  $\Delta \rho$  is a measure of the density perturbations (excluding those due to pressure), v is the kinematic viscosity of the fluid, and  $\kappa$  is the diffusivity of the factor causing density variations (either temperature or composition). Often the symbol D is used in place of  $\kappa$  when variations are due to composition. Commonly  $\Delta \rho$  is defined such that a positive value denotes lighter fluid beneath denser and a negative value denotes denser fluid beneath lighter.

There is a dynamic similarity between the situation in which the density of the fluid depends only on the relative proportions of two chemical constituents of the fluid (with  $\Delta \rho / \rho_0 = \beta \Delta C$ ) and that in which density depends only on the temperature (with  $\Delta \rho / \rho_0 = \alpha \Delta T$ ). In either case the fluid is convectively unstable when the Rayleigh number exceeds a critical value, the magnitude of which depends on the shape and nature of the boundaries of the fluid body (see Chandrasekhar, 1961). If the density is a function of both temperature and composition, then the stability of the fluid body depends on two Rayleigh numbers, measuring the density changes due to these two variables, and is significantly more complicated (see Turner, 1974).

The existence of Earth's magnetic field is very strong evidence that convection occurs in the outer core, as there is no plausible explanation for the origin of this field other than dynamo action driven by convective motions (see *Geodynamo*). The outer core convects because it is cooled and the principal sources of buoyancy are the latent heat and light material released as the inner core grows by solidification of the denser component of the liquid outer core (see *Geodynamo*, *energy sources* and *Core convection*). That is, convection is likely due to both thermal and chemical (or compositional) differences; both the thermal and compositional Rayleigh numbers are likely to be positive, particularly near the inner-core boundary.

Chemical convection of another sort can occur within the uppermost portion of the inner core. It is likely that the inner core is not completely solid, but rather a mixture of solid and liquid, sometimes called a *mush*. The solid and liquid phases are in phase equilibrium, placing a constraint on the temperature and composition of the liquid phase. Ignoring pressure effects, this may be characterized by a simple linear liquidus relation:

$$T = T_0 - \Gamma[C - C_0],$$

where  $\Gamma$  is a constant quantifying the rate at which the temperature of pure iron is decreased by addition of (nonmetallic) impurities in the core. Using this constraint to eliminate composition from the equation for density,

$$\rho = \rho_0 - \rho_0 \left[ \alpha - \frac{\beta}{\Gamma} \right] [T - T_0].$$

For almost all materials, the change of density with composition is sufficiently large that  $\beta > \alpha \Gamma$ . In this case, the normal density-temperature relation is reversed; in a mush, cold fluid is less dense than warm.

In the core, pressure effects are important; and in the above formulas, one must replace the temperature by the potential temperature, or equivalently, normalize the temperature with the adiabatic temperature (see *Core, adiabatic gradient*). While the actual temperature in the core increases with depth, the normalized temperature decreases with depth. (This is why the outer core solidifies at the bottom, rather than the top.) The point to be emphasized is that this situation prevails in the mush at the top of the inner core and the liquid phase is prone to convective instability. Within the mush, thermal and chemical effects are no longer independent and it is not proper to consider thermal and chemical convections separately. However, given the dominance of density changes due to chemical differences, convection is properly characterized as chemical.

Chemical convection within mushy zones is commonly observed in the casting of metallic alloys (e.g., see Worster, 1997). The situation in Earth's core is simulated when an alloy is cooled from below and the denser phase freezes first. In this situation, convection within the mush has a curious structure. Upward motion induces melting of the crystals of the solid phase, thereby reducing the resistance to flow. This provides a positive feedback leading to the formation of discrete chimneys in the mush. The cold, chemically buoyant fluid in the mush convects by moving laterally to and rising up these chimneys; mass is conserved by a downward return flow of warm, chemically denser fluid into the mush away from the chimneys. It is uncertain whether chimney convection occurs in the core, where both Coriolis and Lorentz forces act on the moving fluid.

## CONVECTION, NONMAGNETIC ROTATING

Various physical processes are responsible for maintaining motion, possibly turbulent, in the Earth's fluid core (see *Core motions*), which is ultimately responsible for the geodynamo (q.v.). Here, however, we focus attention on thermal convection (see Core convection) driven by an unstable temperature gradient. Compressibility will be ignored except where density variations lead to buoyancy forces, the so-called Boussinesq approximation (q.v.). The basic model (Chandrasekhar, 1961) generally adopted in theoretical studies concerns a self-gravitating sphere, gravitational acceleration  $-g\mathbf{r}$ , in which fluid is confined to a spherical shell, inner radius r<sub>i</sub>, and outer radius r<sub>o</sub>. Relative to cylindrical polar coordinates  $(s, \phi, z)$ , the system rotates rapidly about the z-axis with constant angular  $\mathbf{\Omega} = \mathbf{\Omega} \hat{\mathbf{z}} \equiv (0, 0, \mathbf{\Omega})$ . The Boussinesq fluid, density  $\rho$ , kinematic viscosity v, has coefficient of thermal expansion  $\alpha$  and thermal diffusivity  $\kappa$ . The fluid is assumed to contain a uniform distribution of heat sources with thermal boundary conditions, which leads to a spherically symmetric temperature exhibiting an adverse radial temperature gradient  $-\beta \mathbf{r}$ .

The basic static equilibrium state just described may be buoyantly unstable. The ensuing fluid motion, velocity  $\mathbf{u}$ , causes temperature perturbations *T* of the basic state (see *Core temperature*), which satisfy the heat conduction equation

$$D_t T = \beta \mathbf{r} \cdot \mathbf{u} + \kappa \nabla^2 T, \tag{Eq. 1a}$$

where  $D_t \equiv \partial/\partial t + \mathbf{u} \cdot \nabla$  is the material derivative: here  $\beta$  is a constant for the case of heating by a uniform distribution of heat sources in a full sphere but may be a function of the radius *r* for more general situations. In turn, the ensuing density variations  $-\alpha\rho T$  drive the motion itself, which is governed by

$$D_t \mathbf{u} + 2\mathbf{\Omega} \times \mathbf{u} = -\nabla(p/\rho) + g\alpha T \mathbf{r} + v \nabla^2 \mathbf{u}$$
  
ith  $\nabla \cdot \mathbf{u} = 0.$  (Eq. 1b)

where p is the fluid pressure, and both  $\rho$  and g are constants. The vorticity equation obtained by taking its curl is

$$D_t \boldsymbol{\zeta} - (2\boldsymbol{\Omega} + \boldsymbol{\zeta}) \cdot \nabla \mathbf{u} = -g\alpha \mathbf{r} \times \nabla T + v \nabla^2 \boldsymbol{\zeta}, \qquad (\text{Eq. 1c})$$

where  $\zeta \equiv \nabla \times \mathbf{u}$  is the relative vorticity (2 $\Omega + \zeta$  is the absolute vorticity). Generally the inner and outer spherical boundaries are regarded as isothermal (T = 0) and impermeable ( $\mathbf{r} \cdot \mathbf{u} = 0$ ), whereas both the cases of stress-free and no-slip boundaries are often considered separately.

The physical system is characterized by four dimensionless numbers, namely the aspect ratio  $\eta$ , the Ekman number, the Prandtl number, and the Rayleigh number:

$$\eta = r_{\rm i}/r_{\rm o}, \quad E = v/2\Omega r_{\rm o}^2, \quad P = v/\kappa, \quad R = g\alpha\beta r_{\rm o}^6/\kappa v \quad ({\rm Eq. 2})$$

These parameters arise naturally for the linear convection that occurs at the onset of instability. For a given system such as the Earth's core, we must regard  $\eta$ , *E*, and *P* as given. Interest then focuses on what happens with increasing *R*. The initial bifurcation occurs at the socalled critical Rayleigh number  $R_c$ . The strength of the finite amplitude that ensues is measured by some convenient parameter such as the Rossby number  $U_0/r_o\Omega$  based on a typical velocity  $U_0$ .

#### The onset of instability

w

The linear problem for the onset of instability has a long history. The early studies (Chandrasekhar, 1961) focused on axisymmetric convection. Later it was realized (Roberts, 1968) that, in the geophysically interesting limit of small Ekman number ( $E \ll 1$ ), the onset is characterized by nonaxisymmetric wave-like modes proportional to exp  $i(m\phi - \omega t)$  with  $m = \mathcal{O}(E^{-1/3})$  and  $(r_o^2/\nu)\omega = \mathcal{O}(E^{-2/3})$ ; they occur when  $R = \mathcal{O}(E^{-4/3})$ .

Since the rotation (as measured by the smallness of *E*) is so rapid, the flow is almost geostrophic;  $2\mathbf{\Omega} \times \mathbf{u} \approx \nabla(p/\rho)$  (see Eq. (1b)). True geostrophic flow satisfies the *Proudman-Taylor theorem* (*q.v.*) and is independent of *z*, i.e.,  $2\mathbf{\Omega} \cdot \nabla \mathbf{u} = 0$  (see Eq. (1c)). In a spherical shell, geostrophic flow is purely azimuthal and not convective. The system overcomes this difficulty by occurring on the small  $\mathcal{O}(E^{1/3}r_o)$  azimuthal length scale upon which it is quasigeostrophic (i.e., independent of *z* on the  $\mathcal{O}(E^{1/3}r_o)$  length scale of the convection but dependent on *z* on the  $\mathcal{O}(r_o)$  length scale of the core radius):

$$p \approx -2\rho\Omega\Psi, \quad \mathbf{u} \approx \nabla \times \Psi \hat{\mathbf{z}} + W \hat{\mathbf{z}}, \quad \boldsymbol{\zeta} \approx -(\nabla_{\perp}^2 \Psi) \hat{\mathbf{z}} + \nabla \times W \hat{\mathbf{z}},$$
  
(Eq. 3)

where  $\nabla_{\perp}^2 \equiv \nabla^2 - \partial^2 / \partial z^2$ . Note that  $\nabla \cdot \mathbf{u} = 0$  does not imply that  $\partial W / \partial z = 0$ . Instead it simply means that there are small extra components of  $\mathbf{u}$ , orthogonal to  $\hat{\mathbf{z}}$ , of order  $E^{1/3}W$  ignored in Eq. (3). Similar remarks

apply to the representation of  $\zeta$ . Within the framework of these approximations, the linearized form of the *z*-components of the vorticity Eq. (1c) and the equation of motion (1b) are

$$(\partial_t - v\nabla_{\perp}^2)\nabla_{\perp}^2 \Psi + 2\Omega \partial_z W = g \alpha \partial_{\phi} T$$
 (Eq. 4a)

$$(\partial_t - v\nabla_{\perp}^2)W - 2\Omega\partial_z \Psi = g\alpha z T, \qquad (\text{Eq. 4b})$$

respectively, where  $\partial_t \equiv \partial/\partial t$  etc. The corresponding form of the heat conduction Eq. (1a) is

$$(\partial_t - \kappa \nabla_{\perp}^2)T = \beta(\partial_{\phi} \Psi + zW).$$
 (Eq. 4c)

Correct to leading order it is sufficient to solve the system (4) subject to the impermeable boundary condition

$$\mathbf{r} \cdot \mathbf{u} \approx \partial_{\phi} \Psi + zW = 0$$
 on  $r = r_{i}$  and  $r_{o}$ , (Eq. 5)

namely the inner and outer boundaries.

In the early solutions of Eq. (4) for a full sphere, it was assumed that motion is localized in the vicinity of some cylinder  $s = s_c$  on a short radial scale, yet long compared to the azimuthal length scale  $\mathcal{O}(s_c E^{1/3})$ . Accordingly, the approximation  $\nabla_{\perp}^2 = s^{-2} \partial_{\phi}^2$  was also made (Roberts, 1968; Busse, 1970). The localized convection has a columnar structure, for which the evolution of its axial vorticity  $-\nabla_{\perp}^2 \Psi$  is governed by Eq. (4a). The buoyancy torques  $-g\alpha \partial_{\phi} T$  that drive motion are most effective near the equator, where the radial component of gravity is strongest. Nevertheless, the large tilt of the boundaries at the ends of the column necessarily break the constraints of the Proudman-Taylor theorem and inhibit motion. This effect is quantified by the term  $2\Omega \partial_z W$ , which describes the stretching of absolute vorticity and is minimized at the poles where the boundary tilt vanishes. In consequence, the preferred location of the convection is at mid latitudes, where  $s_c/r_o$  is roughly a half.

A heuristic appreciation of the solution is obtained by making the geostrophic ansatz that  $\Psi$  and *T* are independent of *z* (i.e., assume Eq. (4b) is simply  $2\Omega \partial_z \Psi = 0$ ) and that *W* is linear in *z*, which according to the boundary condition (5) implies  $W = -(z/h^2)\partial_{\phi}\Psi$ , where  $h = (r_0^2 - s^2)^{1/2}$  is the column half height. Linked to these heuristic assumptions is the neglect of *W* in Eq. (4c), which then leaves the model equations (Busse, 1970)

$$(\partial_t - v\nabla_{\perp}^2)\nabla_{\perp}^2 \Psi - 2(\Omega/h^2)\partial_{\phi}\Psi = g\alpha\partial_{\phi}T, \qquad (\text{Eq. 6a})$$

$$(\partial_t - \kappa \nabla_\perp^2) T = \beta \partial_\phi \Psi \tag{Eq. 6b}$$

In the absence of viscosity v = 0 and buoyancy forces  $g\alpha\beta = 0$ , Eq. (6a) possesses eastward propagating Rossby wave solutions, which under the long radial length assumption  $\nabla_{\perp}^2 = s^{-2}\partial_{\phi}^2$  have frequency  $\omega = 2\Omega s^2/h^2 m$ . When dissipation and buoyancy are reinstated, the dispersion relation becomes

$$(P\tilde{\omega} + i\kappa^2)[(\tilde{\omega} + i\kappa^2) - E^{-1}\tilde{s}(1 - \tilde{s}^2)^{-1}/k + \tilde{s}^2R = 0, \quad \text{(Eq. 7)}$$

where we have introduced the dimensionless parameters  $\tilde{\omega} = r_o^2 \omega / v$ ,  $k = r_o m/s$  and  $\tilde{s} = s/r_o$ . The onset of convection occurs at the minimum value of *R* over  $\tilde{s}$  and *k* subject to the constraint that  $\tilde{\omega}$  is real. This recovers our earlier critical value estimates  $\tilde{s}_c \approx 0.5$ ,  $\tilde{k}_c = \mathcal{O}(E^{-1/3})$ ,  $\tilde{\omega}_c = \mathcal{O}(E^{-2/3})$ , and  $R_c = \mathcal{O}(E^{-4/3})$  (Busse, 1970). The marginal waves, like the Rossby waves travel eastward, and indeed have the Rossby wave character (not to be confused with an alternative class of solutions, namely the equatorially trapped inertial waves discussed later) in the small Prandtl number limit. For that reason, the waves that occur at finite *P* are referred to as thermal Rossby waves.

76

Though the system (6) only constitutes model equations in relation to the rotating self-gravitating sphere, they are correct for an ingenious rapidly rotating annulus model (Busse, 1970). The idea is that the annulus rotates so fast that the centrifugal acceleration produces an effective gravity in the radial s-direction. The top and bottom boundaries are slightly tilted to produce small axial velocities of exactly the form proposed in the heuristic model. This configuration provides the basis of many laboratory investigations (e.g., Busse and Carrigan, 1976; Carrigan and Busse, 1983; but see also Fluid dynamics experiments). The local solutions of both the full-sphere system (4) and annulus system (5) certainly illuminate the physical processes involved but they fail to capture the radial structure, whose resolution is essential for the proper solution of the eigenvalue problem. The correct asymptotic theory was first developed for a model system of annulus type (Yano, 1992) and later for the full-sphere Eqs. (4) and (5) (Jones et al., 2000). The essential difficulty lies in the character of the local dispersion relation  $\omega = \omega(s)$  at given *m* with all other physical parameters fixed. Since  $\omega$ , now complex in general, varies with position, the angular phase velocity  $\omega/m$  varies with radius s. As a result the convection rolls, which the theory assumes are elongated in the radial s-direction (to obtain the relatively long radial length scale), are in fact twisted in a prograde sense because of their tendency to propagate eastward faster with increasing s (Busse and Hood, 1982; Carrigan and Busse, 1983). A balance is in fact achieved at a finite angle of twist which asymptotic theory can predict (Jones et al., 2000) together with the true critical Rayleigh number, which is larger than that obtained by simply minimizing over local values as in the Roberts-Busse theory. In the case of a spherical shell, the Jones et al. asymptotic theory continues to apply provided the convection is localized outside the tangent cylinder  $s = r_i$  of the inner sphere, which it will be for parameter values of the Earth's core. For planets with large inner cores, however, that will no longer be true. Then convection generally occurs outside but adjacent to the inner sphere tangent cylinder at critical values predicted by local theory (Busse and Cuong, 1977). A systematic theory of this inner core tangent cylinder (q.v.) convection (Dormy et al., 2004) also shows that, with alternative heating profiles exhibiting *r*-dependent  $\beta$ , such convection may occur irrespective of the inner core size.

The asymptotic theories described effectively apply to stress-free boundaries for which there are no strong additional boundary layers (see *Core, boundary layers*). When the boundaries are rigid, an Ekman layer forms on the boundary and the analysis of the system (4) applies outside the Ekman layer. The Ekman pumping condition on the outer sphere that replaces the impermeable condition is  $\mathbf{r} \cdot \mathbf{u} \approx -(Er_0/2h)^{1/2}\mathbf{r} \cdot \boldsymbol{\zeta}$ on  $r = r_0$  (Greenspan, 1968) and this leads to a correction to the Rayleigh number smaller by a factor  $\mathcal{O}(E^{1/6})$ . Numerical results (Zhang and Jones, 1993) suggest that this correction is positive (negative) for small (large) Prandtl number, with a switch over when *P* is roughly unity. There are other even smaller corrections arising from weak thermal boundary layers.

The validity of the asymptotic theories presented is not so clear in the limit of small Prandtl number and the double limit  $E \rightarrow 0$ ,  $P \rightarrow 0$  is not yet properly resolved. Nevertheless, numerical studies suggest that at fixed small E the onset of instability in the limit  $P \rightarrow 0$  occurs in the form of equatorially trapped inertial waves with  $m = \mathcal{O}(1)$  rather than as finite latitude Rossby waves with  $m \gg 1$ . Asymptotic theory indicates that, for  $\kappa/2\Omega r_o = P^{-1}E \ge \mathcal{O}(1)$ , the critical Rayleigh number  $R_c$  for this inertial wave convection is sensitive to the kinematic boundary conditions: for stress-free conditions  $R_c = \mathcal{O}(1)$  (Zhang, 1994); for no-slip conditions  $R_c = \mathcal{O}(E^{-1/2})$ (Zhang, 1995).

#### The nonlinear development

An early attempt at a nonlinear asymptotic theory (Soward, 1977) suggested that finite amplitude solutions existed close to the local critical Rayleigh number, which is somewhat smaller than the true (or global) critical value. There is recent evidence that such solutions exist but are unstable. The asymptotic theory depends strongly on the large azimuthal wave number m of the convective mode. As a consequence, the nonlinearity only generates large axisymmetric perturbations of T and  $\mathbf{u}$ , manifest dynamically in large azimuthal geostrophic flows and *thermal winds* (q.v.). These interact with the assumed convective mode and the generation of higher harmonics is ignored. Recent investigations, similar in spirit, taken well into the nonlinear regime have adopted Busse's annulus model with constant tilt boundaries (Abdulrahman *et al.*, 2000), as well as nonlinear versions of Eq. (6) adopting spherical boundaries (Morin and Dormy, 2004).

Most of the earlier numerical work on nonlinear convection at small but finite E (as opposed to the perceived asymptotic limit  $E \rightarrow 0$  of the previous paragraph) was based on Busse's annulus model. The bifurcation sequence has been traced in a series of papers (see Schnaubelt and Busse, 1992, which should be contrasted with Abdulrahman et al., 2000). An important primary instability is the so-called mean flow instability discussed recently in the review (Busse, 2002). The corresponding studies in spherical shells following the pioneering linear investigations (see, for example, Zhang and Busse, 1987; Zhang, 1992) are now extensive and described in review articles (Busse, 1994, 2002). As the Rayleigh number R is increased, a typical scenario is that vacillating convection develops, followed by spatial modulation and a breakdown towards chaos. Surprisingly, with further increase of R more orderly relaxation oscillations are identified (Grote and Busse, 2001). It would seem that the strong shear produced by the convection actually suppresses the convection. There is then a long period over which the shear decays slowly due to viscous damping. After this relaxation, convection begins again becoming vigorous in a relatively short time and the cycle is repeated. There is recent evidence that, for annulus type model systems (Morin and Dormy, 2003), this relaxation oscillation can occur at Rayleigh numbers close to critical in the asymptotic limit  $E \rightarrow 0$ .

## CORE COMPOSITION

Primary planetary differentiation produced a metallic core and silicate shell surrounded by a thin hydrous and gaseous envelope. Emil Wiechert proposed this simple first order picture of the Earth at the end of the 19th century, while in 1914 Beno Gutenberg, Wiechert's former PhD student, determined that the depth to the core-mantle boundary at 2900 km (c.f., the present day value is  $2895 \pm 5$  km depth, Masters and Shearer, 1995). Establishing a more detailed picture of the Earth's core has been a considerable intellectual and technological challenge, given the core's remote setting. The composition of the Earth's core is determined by integrating observations and constraints from geophysics, cosmochemistry, and mantle geochemistry; a unilateral approach from any of these perspectives cannot produce a significant compositional model.

Geophysical methods provide the only direct measurements of the properties of the Earth's core. The presence and size of the core and its material properties are revealed by such studies. Foremost among these observations include (1) its seismic wave velocity and the free oscillation frequencies, (2) the moment of inertia (both of these observations plus the Earth's mass collectively define a density profile for the core and mantle that is mutually and internally consistent (Dziewonski and Anderson, 1981), (3) the distribution and secular variation in magnetic field, and (4) laboratory data on mineral physics (e.g., equation of state (EOS) for materials at core appropriate conditions). When combined with the element abundance curve for the solar system and compositional models for the Earth's mantle (McDonough and Sun, 1995) these observations give us constraints on the mineralogical and chemical constituents of the core and mantle. Washington (1925), Birch (1952), and more recent studies (see McDonough (2004) for a recent update and literature review) have used these constraints to develop compositional models for the Earth and the core. These models consistently converge on the result that the core contains approximately 85% Fe, 5% Ni, and  $\leq 10\%$  of minor lighter components (in weight %, or about 77% Fe, 4% Ni, and 19% other in atomic proportions).

The minor component in the core is an alloy of lower atomic mass that accounts for the core's lower density when compared with that of liquid Fe at core conditions. Washington (1925), drawing upon analogies with phases in iron meteorites, recognized that the core contained a minor amount of an atomically light component (e.g., sulfide, carbide, phosphide). Birch (1964) suggested that this light component represented some 10% of the core's mass and offered a suite of candidate elements (e.g., H, C, O, Si, or S). Anderson and Isaak (2002) more recently reviewed the relevant literature and concluded that only  $\sim$ 5% of this light component is needed. More recently, however, Masters and Gubbins (2003) show that the density increase for the liquid outer core to the solid inner core is much greater than previously considered and Lin et al. (2005) found that Birch's law (a linear relationship between sound velocity and density) does not hold at core pressures. Both findings have implications for the bulk core composition and imply potentially greater amounts of a light component in the outer core. The nature and proportion of the elements that make up this alloy are controlled by three main factors: (1) the behavior of elements during metal-silicate segregation, (2) the integrated pressures and temperatures experienced during core formation, and (3) whether or not there is (or has been) mass transfer across the core-mantle boundary since core formation. Studies of meteorites identify the behavior of the elements in the early solar nebula and during planetismal formation, thus identifying elements that are likely concentrated in the core. Analyses of mantle samples constrain the composition of the Earth's primitive mantle (the combined crust plus mantle) and from this one ascertains the volatile element inventory for the planet. Studies of the secular variation of the mantle composition define the extent of core-mantle mass exchange. However, there is the proviso that we must sample this change; chemical changes occurring at the core-mantle boundary that remain isolated at the base of the mantle can only be speculated upon, but not demonstrated. Collectively, these data establish a bulk planetary composition; subtracting the primitive silicate mantle composition from this reveals the core composition.

The compositional diversity of the planets in the solar system and that of chondritic meteorites (primitive, undifferentiated meteorites) provide a guide to the bulk Earth composition. However, this diversity of samples presents a problem in that there is no unique meteorite composition that characterizes the Earth. The solar system is compositionally zoned from volatile-poor planets closer to the sun to volatilerich gas giants further out. Relative to the other planets, the Earth has a relatively intermediate size-density relationship and volatile element inventory and is more depleted in volatile components than CI chondrites, the most primitive of all of the meteorites. The bulk Earth's composition is more similar to that of some carbonaceous chondrites and less so the ordinary or enstatite chondrites (Figure C21), especially in regard to the four most abundant elements (Fe, O, Si, and Mg; in terms of atomic proportions these elements represent 95% of the inventory of elements in chondrites and the Earth) and their ratios. Thus, we need to establish the absolute abundances of the refractory elements in the Earth and the signature of the volatile element depletion pattern.

The silicate Earth, or primitive mantle, encompasses the solid Earth minus the core. There is considerable agreement at the major and minor element level for the composition of the primitive mantle. The relative abundances of the lithophile elements (e.g., Ca, Al, Ti, REE

(rare earth elements), Li, Na, Rb, B, F, Zn, etc) in the primitive mantle establish both the absolute abundances of the refractory elements in the Earth and the planetary signature of the volatile element depletion pattern. The volatile lithophile elements, those with half-mass condensation temperatures <1200 K (i.e., a reference temperature at which half the mass of a specific element condenses into a mineral from a cooling solar nebular under a given oxygen partial pressure) and excluded from the core, have CI chondrite relative abundances that systematically decrease with condensation temperature.

A compositional model for the Earth, the core, and mantle is presented in Table C1. The model core composition is derived from the above constraints and has a light element component that is consistent with existing geophysical requirements. Significantly, along with Fe

**Figure C21** Atomic proportions of oxygen, silicon, iron, and magnesium in carbonaceous chondrites, the Earth, enstatite chondrites, and ordinary chondrites.

and Ni the core contains most of the planet's sulfur, phosphorous, and carbon. It contains little or no gallium, an element widely found in iron meteorites, and is devoid of radioactive elements.

#### Light elements in the core

Given an outer core density deficit of 5%–10%, a host of elements (e.g., H, C, O, Si, P, S) can potentially be present. Commonly, metallurgical or cosmochemical arguments, coupled with meteoritical analogies (e.g., reduced metals, such as silicides in enstatite chondrites) are used to argue for one's preferred candidate element. There is sufficient evidence to suggest that some, but not all, of this density deficiency is due to the presence of sulfur (McDonough, 2004). However, beyond this, we are still working to place further constraints on this issue and a number of elements in the mix (particularly H, C, O, Si) are considered viable for explaining the core's density deficit.

The Earth's volatility curve can be established from the relative abundances of the lithophile elements, which are elements that (1) are excluded from the core and concentrated in the mantle, (2) have different condensation temperatures, and (3) widely vary in their chemical characteristics (McDonough, 2004). A comparison of the Earth's volatility curve with that of chondritic meteorites shows that the sulfur content of the core is restricted to 1.5-2 wt% due to its volatility. In addition, the planetary volatility curve reveals that the proportions of Si and O in the Earth, both of which have half-mass condensation temperatures <1200 K, cannot be readily established from chondritic observations.

There are a number of issues that need to be evaluated when considering mixed alloying elements to account for the core's density deficit. In calculating the density deficit one needs to know the thermal gradient in the deep Earth and the EOS for appropriate alloys at core conditions. Such data are still lacking for many of these alloys at core

conditions. Likewise, the mutual compatibility of different alloying element pairs has yet to be established for many of these elements. There appears to be good evidence showing that alloys of Si-O and Si-S are not compatible because of contrasting solubility (see recent review of Li and Fei, 2004). Thus, based on a model of heterogeneous accretion for the Earth (i.e., a secular variation in the composition of material that contributed to the growing Earth), the  $\sim 2\%$  (by mass) sulfur in the core is mixed with either silicon or oxygen as the other dominant alloying element in the outer core. From this perspective two competing models for the composition of the core are offered in Table C2, which contain either Si or O, but not both. Other light elements contribute to the density deficit in the core, including H, C, and P (see Table C1), but these elements are in significantly lower proportions due to their partitioning into other parts of the Earth and the markedly lower condensation temperatures for H and C. Such a diverse array of light elements may well be mutually compatible in iron liquids, particularly if liquid segregation occurs at high pressure (ca. 10-25 GPa).

#### Radioactive elements in the core

The existence of radioactive elements in the Earth's core is usually invoked to offer an explanation for the power needed to run the geodynamo (Labrosse *et al.*, 2001) and/or as a way to increase the volatile element content of the Earth. An alternative model for the core's power budget was offered by Christensen and Tilgner (2004) who showed that ohmic losses by the core's geodynamo are sufficiently large enough to remove the need for radioactive heating in the core. Arguments for potassium in the core are based on three lines of evidence: (1) cosmochemical—potassium sulfide is found in some meteorites, (2) high pressure s-d electronic transition, and (3) solubility of K in Fe-S (and Fe-S-O) liquids at high pressure.

The cosmochemical argument for K in the core is based on the observation that a potassium-bearing sulfide (djerfisherite) is found in trace quantities in enstatite chondrites (Lodders, 1995). However, this *ad hoc* hypothesis overlooks the fact that enstatite chondrites

also contain a myriad of other sulfides that are more abundant than djerfisherite, including oldhamite (CaS), ferroan alabandite ((Mn,Fe)S), and niningerite ((Mg,Fe)S), and that alkali sulfides like djerfisherite are typically found in trace quantities as replacement or alteration phases (Brearley and Jones, 1998). Incorporating the more common, higher temperature sulfide phases, which contain REE and other refractory lithophile elements in nonchondritic proportions, would grossly and adversely change both the elemental and isotopic abundances of the Sm/Nd, Lu/Hf, and Th/U isotopic systems. Given an absence of fractionation of these isotopic and elemental systems, one can also conclude that there are negligible quantities of K sulfide in the core. At high pressure s-orbital electrons in alkali metal can be compressed into d-orbital electronic states. For K this electronic transition is theoretically possible, but this effect is likely to be even greater for Rb and Cs. Whereas an argument can be made for Cs in the core, it cannot be so for Rb (McDonough, 2004). Moreover, the coherent depletion pattern of the volatile lithophile elements is not restricted to just the alkali metals and thus the pattern cannot be dismissed as "being stored in the core" based on pressure induced s-d electronic transitions. Finally, Gessmann and Wood (EPSL, 2002) demonstrate that K is soluble in Fe-S and Fe-S-O liquids at high pressure and suggested that K can therefore be sequestered into the core. However, Ca is also incorporated into the metallic liquid and having Ca in the core creates problems given that the mantle's Ca content is in chondritic proportions. Other recent models (Rama Murthy et al., 2003; Lee and Jeanloz, 2003) proposing K in the Earth's core, however, also are accompanied by geochemical consequences that limit their acceptability (see McDonough, 2003 for a further review). Overall, it is unlikely that there is any K in the core, although much debate continues.

#### Timing of core formation

Defining the age and duration of core formation depends on having an isotope system in which the parent-daughter isotope pair are fractionated by core sequestration over a time interval within the functional period of the system's half-life. Fortunately, recent analytical advances in the W-Hf isotope system provide us with a tool to gauge the timing of core formation. Both Hf and W are refractory elements (lithophile and siderophile, respectively) having chondritic relative concentrations in the Earth, with ~90% of the Earth's budget of W being hosted in the core and the entire planet's Hf budget in the silicate Earth. Recent studies (Yin *et al.*, 2002; Kleine *et al.*, 2002; Schoenberg *et al.*, 2002) found that the Earth's W-isotopic composition is higher than that of chondrites, indicating that core separation had to have been completed by ~30 Ma after t<sub>0</sub> (4.56 Ga ago).

#### The inner core and core-mantle exchange

Based on geophysical data the inner core comprises  $\sim$ 5% of the core's mass. Its existence is not disputed, although there is much speculation about when the inner core began to crystallize, the extent of element fractionation between the inner and outer core and the role it plays in models of core-mantle exchange. Recently, Labrosse et al. (2001), examining the power budget for the core, suggested that inner core crystallization began in the latter half of Earth's history (ca. 1-2 Ga) and that some amount of radioactive heating is necessary. In contrast, however, support for early inner core crystallization comes from the Os isotopic compositions of some Hawaiian basalts, which has been explained by parent-daughter isotope fractionation due to core differentiation followed by core contributions to the Hawaiian magma source region. The origin of this Os isotopic signature in these basalts is interpreted to be due to exchange across the core-mantle boundary (with the base of the mantle being the putative source of these basalts) of a radiogenic Os isotopic component that was generated by inner core crystallization, which incorporated Os and to a lesser extent, Re and Pt (Brandon et al., 2002). The extent of core-mantle exchange can be monitored, albeit 80

on a less sensitive scale, from studies of peridotites and basalts. Ratios of Mg/Ni and Fe/Mn in the mantle have been fixed (i.e.,  $\leq \pm 15\%$ ) for the last 3.8 Ga (McDonough and Sun 1995), which is inconsistent with significant core-mantle exchange, given the proportions of these elements in the core and mantle. Likewise, other sensitive element ratios (e.g., Re/Yb, P/Nd, Mo/Ce, W/Ba) involving siderophile element (e.g., Re, P, Mo, W) and similarly incompatible (i.e., elements readily entering a melt relative to the solid) lithophile elements (e.g., Yb, Ce, Nd, Ba) show that <0.5% of a core contribution can be incorporated into the source regions of mid-ocean ridge basalts or intraplate (plume-derived) basalts. In general, however, models invoking early growth of the inner core are at odds with findings from power budget calculations.

## **CORE CONVECTION**

#### Types of core convection

There exist primarily two different types of convection taking place in the Earth's fluid core. The first type is driven by thermal instabilities. A distribution of heat sources from radioactive elements in the core can produce a radial temperature gradient dT(r)/dr, where *T* is the temperature and *r* is the distance from the core centre. Thermal convection may occur when the temperature in the core decreases more rapidly than that of the adiabatic gradient,

$$\frac{\mathrm{d}T}{\mathrm{d}r} < \left(\frac{\mathrm{d}T}{\mathrm{d}r}\right)_{\mathrm{adiabatic}} = \frac{\alpha gT}{\rho C_P},\tag{Eq. 1}$$

where  $\rho$  is the density of the core, g is the acceleration of gravity,  $\alpha$  is the thermal expansion coefficient, and  $C_P$  is the specific heat at constant pressure. The adiabatic gradient in the core is about -0.1 K/km. The unstable stratification described by Eq. (1) offers buoyancy forces that may drive thermal convection in the fluid core. This is a necessary condition for thermal instability, which is usually referred to as Schwarzschild's criterion (or the Adams-Williamson condition) (for example, Gubbins and Roberts, 1987). The actual temperature gradient in the core decreases on approaching the core-mantle boundary because the gradient required to conduct a given amount of heat reduces with radius. Except possibly at the top of the core where the adiabatic gradient is steep as a result of higher g and lower  $\rho$ , Schwarzschild's instability condition is likely to be satisfied in the whole fluid core. In general, the condition for core convection is that its Rayleigh number R defined as

$$R = \frac{\alpha \beta g r_0^4}{\nu \kappa}, \qquad (Eq. 2)$$

where v is the kinematic viscosity of the fluid,  $r_0$  is the radius of the fluid core,  $\kappa$  is the thermal diffusivity, and  $\beta$  is the superadiabatic temperature gradient  $(dT/dr - (dT/dr)_{adiabatic})$  in the core, must be sufficiently large. In other words, Schwarzschild's criterion does not represent a sufficient condition for thermal convection because of viscous and magnetic damping in the fluid core. Gubbins (2001) estimated that the Rayleigh number for thermal convection in the Earth's core is enormously large,  $R = 10^{29}$ , when molecular diffusivities are used, while turbulent diffusivities give a much lower value with  $R = 10^{12}$ . These values of the Rayleigh number exceed the critical value for nonmagnetic thermal convection.

The second type of convection is nonthermal, in connection with slow growth of the solid inner core of the Earth through freezing from the outer core (Gubbins et al., 1979; Labrosse et al., 1997). The density of the outer liquid core is smaller than that of pure iron, being composed of a mixture of iron with lighter elements. During the general cooling of the Earth, the inner core grows and the light constituents excluded from the inner core rise upward buoyantly through the outer core to drive compositional convection (Gubbins et al., 1979; Moffatt and Loper, 1994). Some fraction of the light constituents might survive remixing to create and sustain a stably stratified layer at the top of the core, "the hidden ocean" (Braginsky, 1999). This type of the fluid motion in the core is usually referred to as compositional convection. Gubbins (2001) estimated that the Rayleigh number for compositional convection in the Earth's core is also enormously large,  $R = 10^{38}$ , when molecular diffusivities are used, while turbulent diffusivities give a much lower value with  $R = 10^{15}$ . These values of the Rayleigh number exceed the critical value for nonmagnetic compositional convection.

#### Dynamics of core convection

Core convection, driven by either thermal instability or by the solidification of the inner core or by both, sustains geomagnetic fields through magnetohydrodynamic dynamo processes, which convert the kinetic energy of convection into magnetic energy. The primary dynamics of core convection is controlled by (i) rapid rotation of the Earth, (ii) viscous effects, (iii) thermal or compositional buoyancy, and (iv) convection-generated magnetic fields (Fearn, 1998; Zhang and Gubbins, 2000). Other details such as compressibility, variable rotation, boundary conditions, and the detailed driving mechanism of core convection are of secondary importance. In order that core convection can occur, the dominant Coriolis force must be balanced by five forces at any instant of time:

$$2\mathbf{\Omega} \times \mathbf{u} = -\frac{1}{\rho} \nabla p - \alpha \Theta g_0 \mathbf{r}$$
$$-\frac{\mathbf{D}\mathbf{u}}{\mathbf{D}t} + \frac{1}{\rho\mu} (\nabla \times \mathbf{B}) \times \mathbf{B} + v \nabla^2 \mathbf{u}, \qquad (Eq. 3)$$

where **r** is the position vector,  $\Omega$  is the angular velocity of the Earth,  $\Theta$  is the deviation from the adiabatic or compositional stratification,  $\mu$  is the magnetic permeability, **u** is the velocity field, and **B** is the generated magnetic field. It is important to note that the Coriolis force  $2\Omega \times \mathbf{u}$  can only be balanced in major part by the pressure force  $-\nabla p/\rho$ . All other forces, the buoyancy (thermal or compositional) force  $-\alpha \Theta g_0 \mathbf{r}$ , the magnetic force  $(\nabla \times \mathbf{B}) \times \mathbf{B}/\rho \mu$ , the inertial force  $D\mathbf{u}/Dt$ , and the viscous force  $v\nabla^2 \mathbf{u}$ , play significant roles in core convection. As a consequence of the delicate dynamic balance described by Eq. (3), there exist large disparities both in spatial and temporal scales of core convection, dependent largely upon how the balance between the viscous, Coriolis, and magnetic forces is achieved (Zhang and Gubbins, 2000).

## Structure of core convection

The spatial structure of core convection is likely to vary at different times in the Earth's history. Suppose at one instant that the magnetic field is weak and plays an insignificant role in dynamics. In this case, while the buoyancy force supplies energy to drive convection, the role of viscosity must be inverted from the usual one of inhibiting convection: it provides the necessary frictional forces to offset the part of the Coriolis force  $2\Omega \times \mathbf{u}$  that cannot be balanced by the pressure gradient  $-\nabla p/\rho$ . Moreover, the corresponding convection must be in the form of nearly two-dimensional columnar rolls selecting the symmetry (Roberts, 1968; Busse, 1970; Jones *et al.*, 2000; Zhang and Liao, 2004)

$$(u_r, u_\theta, u_\phi)(r, \theta, \phi) = (u_r, -u_\theta, u_\phi)(r, \pi - \theta, \phi),$$
  

$$\Theta(r, \theta, \phi) = \Theta(r, \pi - \theta, \phi),$$
(Eq. 4)

where  $(r, \theta, \phi)$  are spherical polar coordinates with  $\theta = 0$  at the axis of rotation. With large viscous forces the Rayleigh number *R* required to initiate convection has to be extremely large

$$R = O(E^{-4/3}),$$
 (Eq. 5)

and the horizontal scale L of the rolls must be extremely small

$$L = O(E^{1/3}r_0), (Eq. 6)$$

where  $E = v/2\Omega r_0^2$  is the Ekman number and  $E \le O(10^{-9})$  in the Earth's core. An example of such convection, which shows the convective flow in two different sections, is displayed in Figure C22. The convective motions are the columnar rolls aligned with the axis of rotation and located and localized at higher latitudes with radial phase shifts (Busse, 1970; Zhang, 1992; Jones *et al.*, 2000; Sumita and Olson, 2000).

Suppose at another time that the fluid in the core is permeated by a strong dynamo-generated large-scale magnetic field. With the presence of the strong magnetic field, the dynamical role of viscosity is taken up by the magnetic force  $(1/\rho\mu)(\nabla \times \mathbf{B}) \times \mathbf{B}$ . As a result, core convection becomes more efficient and larger scale, in sharp contrast to

**Figure C22** Structure of weakly nonlinear convection in a rapidly rotating spherical shell at  $E = /2r_0^2 = 2 \times 10^{-6}$  when the effect of magnetic field is weak. Displayed are contours of the radial velocity  $u_s$  in the equatorial plane (*upper panel*) and in a meridional plane (*lower panel*) for the Prandtl number Pr = 1.0. *Solid contours* indicate  $u_s > 0$  and *dashed contours* correspond to  $u_s < 0$ .

nonmagnetic convection shown in Figure C22. By implication, the Rayleigh number R required to initiate convection becomes much smaller:

$$R = O(E^{-1}), \tag{Eq. 7}$$

together with the larger scale of convective motions

$$L = O(r_0). \tag{Eq. 8}$$

In summary, because core convection is critically affected by both the Coriolis and magnetic forces, the huge contrast between the spatial and temporal scales is an important characteristic of core convection.

## CORE DENSITY

#### Introduction

Knowledge of the density distribution inside the core is of interest for several reasons. Perhaps most importantly, the size of the density jump at the inner core boundary controls how important inner core growth is for powering the dynamo. Also of interest is the presence or otherwise of anomalous (e.g., convectively stable) regions in the outer core. This latter problem is more difficult as it requires an evaluation of the density *gradient* and how much this deviates from the Adams-Williamson equation (see below), which is expected to control the density gradient in a vigorously convecting outer core.

The main constraints on density in the core come from measurements of the frequencies of free oscillations of the Earth (Masters and Gubbins, 2003). However, it is also possible to use the sensitivity of reflected body waves to impedance contrasts to infer the density jump at the ICB from the amplitudes of the seismic phase *PKiKP* (Koper and Pyle, 2004; Cao and Romanowicz, 2004). We compare the results of these studies in the following.

#### Background

γ

For a variety of reasons, we believe that most or all of the outer core is convecting vigorously and so will be adiabatic and homogeneous. In such a region, the density distribution will follow the Adams-Williamson equation closely. The Adams-Williamson equation is

$$\left(\frac{\mathrm{d}\rho}{\mathrm{d}r}\right)_{\mathrm{ad}} = \left(\frac{\partial\rho}{\partial\rho}\right)_{\mathrm{s}}\frac{\mathrm{d}p}{\mathrm{d}r} = -\frac{\rho g}{\left(\frac{\partial\rho}{\partial\rho}\right)_{\mathrm{s}}} = -\frac{\rho g}{\phi}$$
(Eq. 1)

where  $\rho$  is density, g is the acceleration due to gravity, s is entropy, and the pressure, p is taken to be hydrostatic.  $(\partial p/\partial \rho)_s$  is often given the symbol  $\phi$  and is called the "seismic parameter" because it can be computed from the velocities of propagation of seismic waves in the Earth. In an isotropic solid, we have

$$\phi = \frac{K_{\rm s}}{\rho} = V_{\rm p}^2 - \frac{4}{3}V_{\rm s}^2$$
 (Eq. 2)

where  $V_p$  and  $V_s$  are the compressional and shear velocity respectively and  $K_s$  is the adiabatic bulk modulus.

The "Bullen parameter,"  $\eta$ , is a measure of departure of the density gradient from the Adams-Williamson condition and is a measure of stability of a region (see Masters, 1979 for a thorough discussion).  $\eta$  is simply given by

$$\eta = -\frac{\phi}{\rho g} \frac{\mathrm{d}\rho}{\mathrm{d}r} \tag{Eq. 3}$$

and so is 1 in a vigorously convecting region. If  $\eta > 1$ , the region is stable—i.e., a radially displaced parcel of material will be negatively buoyant and will oscillate around its initial radius.  $\eta < 1$  implies that a region is convectively unstable though the effects of viscosity and conduction may inhibit convection from occurring. An order of magnitude calculation shows that  $\eta$  is insignificantly less than one in the outer core before convection will start. Note that  $\eta$  will appear to be less than one in the boundary layers of a convecting region where the temperature gradients are strongly superadiabatic. Such boundary layers would be visible in the mantle, but boundary layers in the outer core are expected to be extremely thin because of the low viscosity of this region.

Bullen (1975) made extensive use of an alternative form for  $\eta$ :

$$\eta = \frac{dK_s}{dp} + \frac{1}{g}\frac{d\phi}{dr}$$
(Eq. 4)

by arguing that  $dK_s/dp \equiv (dK_s/dr)/(dp/dr)$  is slowly varying in the Earth (and has a value of about 4) so that departures from the Adams-Williamson state can be determined by looking at the radial gradient of the seismic parameter. In fact, there is every reason to believe that  $dK_s/dp$  will be strongly affected in regions of strong temperature gradient or rapid variation in chemistry so Bullen's approach is somewhat suspect.

## Density models using The Adams-Williamson Equation

Early models of the density within the deep Earth assumed that the Adams-Williamson equation held in the lower mantle and outer core but the development of an extensive data set of degenerate free oscillation frequencies over the last 30 years has given us independent constraints on density, which, in principle, allow us to evaluate departures from the Adams-Williamson state. The resolution of density by this data set has been discussed in detail by Masters and Gubbins (2003). They used a variant of Backus-Gilbert resolving power theory in which linear combinations of the data are taken to localize information about some model property (e.g., density) about some target radius inside the Earth. The resulting "local averages" are relatively precise if averages are sought over large depth intervals but decrease in precision for averages over smaller depth intervals. Some results of this analysis are presented below but first we consider a different approach to constructing density profiles in the core. This approach takes advantage of the fact that the mode data can give precise estimates of the mean density of the whole core and of the outer core alone. Given  $\phi$ , it is then possible to integrate the Adams-Williamson equation in the outer core and inner core and determine a density distribution for the whole core. The result of doing this for five different models of  $\phi$  is shown in Figure C23. Clearly, the resulting density profile is very insensitive to the choice of seismic velocity model and all models have a density jump of about 0.8 Mg/m<sup>3</sup> at the inner core boundary. We also indicate the uncertainty of density in the core which comes primarily from the uncertainty of the estimates of mean density of the outer core

**Figure C23** Five models of density in the core (*top line with error corridor*) made by integrating the Adams-Williamson equation using five different velocity models (*plotted beneath the density models*). The density distribution is insensitive to the particular velocity model chosen. The five velocity models are 1066A and 1066B of Gilbert and Dziewonski (1975), PEMA of Dziewonski *et al.* (1975), isotropic PREM of Dziewonski and Anderson (1981), and AK135 of Montagner and Kennett (1996). The error corridor is determined by how well we can resolve the mean density of the whole core and the outer core.

and the whole core. The value obtained for the density jump at the inner core boundary agrees with the results of Masters and Gubbins (2003) and Cao and Romanowicz (2004) but is larger than the upper bound of 0.45 Mg/m<sup>3</sup> obtained by Koper and Pyle (2004). The reason for this discrepancy is not yet clear.

It is now of interest to ask if there are significant departures from the Adams-Williamson condition. Suppose we relax the constraint of adiabaticity (but keep the assumption of homogeneity—see Masters, 1979, for the general case). Density is a function of temperature and pressure:

$$\frac{\mathrm{d}\rho}{\mathrm{d}r} = \left(\frac{\partial\rho}{\partial T}\right)_{p} \frac{\mathrm{d}T}{\mathrm{d}r} + \left(\frac{\partial\rho}{\partial p}\right)_{T} \frac{\mathrm{d}p}{\mathrm{d}r}$$
(Eq. 5)

The temperature gradient in an adiabatic and homogeneous region is given by

$$\left(\frac{\mathrm{d}T}{\mathrm{d}r}\right)_{\mathrm{ad}} = \left(\frac{\partial T}{\partial p}\right)_{\mathrm{s}} \frac{\mathrm{d}p}{\mathrm{d}r} = -\frac{\alpha gT}{C_p} = -\frac{gT\gamma}{\phi} \tag{Eq. 6}$$

where  $\alpha$  is the coefficient of volume expansion,  $C_p$  is the specific heat, and  $\gamma$  is Grüneisen's ratio, which is a dimensionless number with a value close to 1 for nearly all materials. Let the total temperature gradient be

$$\frac{\mathrm{d}T}{\mathrm{d}r} = \left(\frac{\mathrm{d}T}{\mathrm{d}r}\right)_{\mathrm{ad}} - \tau \tag{Eq. 7}$$

This equation defines the superadiabatic temperature gradient  $\tau$ . Substituting in the above equation and using some thermodynamic identities gives

$$\frac{\mathrm{d}\rho}{\mathrm{d}r} = -\frac{\rho g}{\phi} + \alpha \rho \tau \tag{Eq. 8}$$

and the Bullen parameter becomes

$$\eta = 1 - \frac{\alpha \phi}{g} \tau \tag{Eq. 9}$$

It is extremely unlikely that the bulk of the outer core is significantly superadiabatic but it is possible that a stable (subadiabatic) region exists. The most stable the core could reasonably become in a thermal sense is isothermal, i.e., dT/dr = 0. This leads to a value of  $\eta$ :

$$\eta = 1 + \alpha T \gamma \tag{Eq. 10}$$

The dimensionless combination  $\alpha T \gamma$  is a small quantity inside the Earth (because  $\alpha$  rapidly decreases as pressure increases) and has a value on the order of 0.08 in the core. The consequence of this is that a density model for a core which has a thermally stable region is going to be almost identical to those shown in Figure C23. In fact, even if the whole core is isothermal, the maximum deviation in density from the models shown in Figure C23 is only 1%.

The case of a compositionally stable region in the outer core is discussed by Masters (1979) and it is possible that strong compositional gradients would be observable using the free-oscillation data set. To check this possibility, we performed resolution experiments of the type discussed in Masters and Gubbins (2003). Here, we confine attention to the outer core since resolution of the mode dataset in the inner core is not good enough to detect reasonable departures of the density from the Adams-Williamson state. Figure C24 shows "local averages" of density with errors of 0.5%-1%. These correspond to averages over a radial distance of about 400 km. Though there is apparently some structure in the local averages at a radius of about 2000 km, the local averages follow the Adams-Williamson models quite well and are certainly consistent

**Figure C24** Local averages of density (with 1 sigma error bars) in the outer core computed using the method described by Masters and Gubbins (2003) compared with the models computed using the Adams-Williamson equation. The local averages are for a target error of 0.5% and are averages over about 400 km in radius.

within one standard deviation. Note that we cannot make local averages for target depths closer to the inner core boundary or the outer core boundary since the resulting resolution kernels have significant energy in the inner core or mantle and the local averages are biased.

#### Summary

Given the current observational constraints on the density in the core, we conclude that use of the Adams-Williamson equation is justified and results in a tightly constrained density profile with uncertainties of about 0.5% in the outer core and about 2% in the inner core. The models have a density jump of about 0.8 Mg/m<sup>3</sup> at the inner core boundary. A resolution analysis of the free-oscillation dataset gives local averages of density, which are consistent with the models derived from the Adams-Williamson equation.

# CORE MOTIONS

### Introduction

The geomagnetic field is widely agreed to evolve as a result of selfsustaining geodynamo action, consisting of convective movement of the electrically conducting, liquid iron mixture forming the outer core. Thus we can use magnetic field changes to investigate the flow responsible for the dynamo although, for reasons outlined below (see also *Alfvén's Theorem and the frozen flux approximation*), such studies provide only a limited amount of information. More details of all but the most recent work are given in review articles by Bloxham and Jackson (1991), and Whaler and Davis (1997).

The starting point is a combination of Maxwell's equations and Ohm's Law, in the nonrelativistic limit appropriate for the core:

$$\frac{\partial \mathbf{B}}{\partial t} = \nabla \times (\mathbf{v} \times \mathbf{B}) + \lambda \nabla^2 \mathbf{B}$$
 (Eq. 1)

where **B** is the magnetic field, **v** the velocity, and  $\lambda = 1/\mu_0 \sigma$  is magnetic diffusivity (see *Magnetohydrodynamics* and *Alfvén's Theorem and the frozen flux approximation*). The first term on the right hand side of this equation represents advection, where magnetic field lines are moved around and re-arranged by the flow, and the second represents their creation and destruction, i.e., diffusion; both contribute to temporal changes of the magnetic field, on the left hand side of the equation.

To use Eq. (1) to determine the flow, we need to know the magnetic field and its spatial and temporal derivatives in the core. What we can actually measure are these quantities at the Earth's surface. Extrapolation to the base of the mantle is straightforward in principle if we assume that the mantle is electrically insulating, since then the magnetic field can be described as the gradient of a scalar potential which satisfies Laplace's equation. This potential represents the poloidal part of the field; the toroidal part is confined to the core and cannot be observed directly at the Earth's surface (see Magnetohydrodynamics). The coefficients of the scalar potential, known as spherical harmonic or Gauss coefficients, can be deduced from surface and satellite measurements of the field; techniques for doing so are described in Main Field Modeling. In practice, field extrapolation towards the sources is not a stable procedure, since field coefficients representing short wavelengths, and their uncertainties, are preferentially amplified. Fortunately, regularization techniques can be used to produce magnetic field models at the core-mantle boundary (CMB) in which the uncertain short wavelength features are suppressed (*Core-based inversions*). The weakly conducting mantle ( $\leq 10 \text{ Sm}^{-1}$ ; see Mantle, electrical conductivity, mineralogy) has only a small effect on the downward continued field, so that values extrapolated through

an insulator should not be seriously in error. This process determines the field at the base of the mantle, but only its radial component is guaranteed continuous across the electrical conductivity jump at the CMB (see *Alfvén's Theorem and the frozen flux approximation*). By a boundary layer analysis, Hide and Stewartson (1972) argued that the jump in horizontal components across the CMB should be small (see *Alfvén's Theorem and the frozen flux approximation* and *Core, boundary layers*), but there are additional problems in using the horizontal components of Eq. (1). The presence of a toroidal field component in the core means that, although we know the radial (poloidal) field at the CMB, we cannot estimate its spatial derivatives (required to calculate the diffusion term in Eq. (1)) there, and we have no knowledge of **B** in the bulk of the core.

# The frozen-flux assumption

Fortunately, the high core conductivity means that its magnetic diffusivity is small. If diffusion is neglected, the radial component of (1) becomes

$$\frac{\partial \mathbf{B}_r}{\partial t} = \mathbf{B}_r \nabla_{\mathrm{H}} \cdot \mathbf{v} + \mathbf{v} \cdot \nabla_{\mathrm{H}} \mathbf{B}_r$$
(Eq. 2)

where the subscript H indicates tangential derivatives, i.e.,

$$\nabla_{\mathrm{H}} = \nabla - \hat{\mathbf{r}}(\hat{\mathbf{r}} \cdot \nabla)$$

In fact, the situation is slightly more complicated in that there is a boundary layer adjacent to the CMB across which quantities adjust to match the boundary conditions (see *Alfvén's Theorem and the frozen flux approximation* and *Core, boundary layers*); where we refer to CMB flow and magnetic field in what follows, we actually mean those quantities at the top of the free stream immediately below the boundary layer.

Equation (2) provides one constraint on two unknowns, the tangential components of v—the CMB is a material boundary and thus the radial flow vanishes there. Hence we are unable to determine the flow uniquely, even at the CMB, without making additional assumptions. This nonuniqueness was first pointed out by Roberts and Scott (1965); Backus (1968) gives a clear exposition of exactly what can be determined from Eq. (2). He noted that, just as the CMB flow can be expanded into its toroidal and poloidal components, represented by scalars that integrate to zero over the CMB, so can the product of the flow and the radial field:

$$\mathbf{vB}_r = \nabla_{\mathrm{H}}\chi - \hat{\mathbf{r}} \times \nabla_{\mathrm{H}}\psi. \tag{Eq. 3}$$

Substituting (3) into (2) gives

$$\frac{\partial \mathbf{B}_r}{\partial t} + \nabla_{\mathrm{H}}^2 \chi = 0.$$

This determines  $\chi$  to within a function whose Laplacian vanishes, but does not constrain  $\psi$  at all. Some information on  $\psi$  comes from (3) evaluated on null-flux curves (NFCs). NFCs are contours on which B<sub>r</sub> vanishes, i.e., they separate patches of the core where flux enters from those where it leaves. Setting **B**<sub>r</sub> = 0 in (3) gives

$$\nabla_{\mathrm{H}}\psi=-\hat{\mathbf{r}}\times\nabla_{\mathrm{H}}\chi,$$

determining  $\psi$  to within an arbitrary constant along each NFC. On NFCs, (2) becomes

$$\frac{\partial \mathbf{B}_r}{\partial t} = \mathbf{v} . \nabla_{\mathrm{H}} \mathbf{B}_r$$

from which the component of flow parallel to  $\nabla_{\rm H} \mathbf{B}_r$ , i.e., perpendicular to NFCs,  $v_n$ , can be deduced:

$$\mathbf{v}_n = -\frac{\partial \mathbf{B}_r / \partial t}{|\nabla_{\mathbf{H}} \mathbf{B}_r|} \tag{Eq. 4}$$

 $v_n$  is the only component of the flow that can be determined without further assumptions, and even this requires the frozen-flux hypothesis. Estimates of the magnetic Reynolds number for the core, and the diffusion rate of the dipole field, both suggest that the hypothesis is reasonable on the decade timescale. The assumption can be tested against the data: integrating (2) over a patch of the core bounded by a NFC, and noting that NFCs are material curves, gives

$$\frac{\partial}{\partial t} \iint_{S_i} \mathbf{B}_r dS = 0, \text{ or } \iint_{S_i} \mathbf{B}_r dS = \text{constant},$$
(Eq. 5)

where  $S_i$  is a patch of the core bounded by a NFC (see *Alfvén's Theorem and the frozen flux approximation*). Booker (1969) found that nonregularized CMB field models available at that time were inconsistent with these patch integral constraints, but nevertheless produced maps of the component of flow perpendicular to NFCs given by (4), on the basis that failure to satisfy the constraints may be due to temporal changes in unresolved shorter wavelength components of the magnetic field. More recent tests using regularized CMB field models are equivocal, since uncertainty bounds on the integrals are difficult to determine, and their interpretation depends on the philosophical viewpoint of the inversion practitioner (e.g., Backus, 1988).

In the diffusionless limit in which (2) applies, magnetic field lines are tied to fluid parcels (see *Alfvén's Theorem and the frozen flux approximation*). This means they can be used as tracers of the flow, but individual fluid parcels on a contour of  $\mathbf{B}_r$  cannot be tracked, i.e., there is no information on circulation around a contour. However, the Navier-Stokes equation provides a constraint on the average circulation around NFCs. For an insulating mantle, the radial component of current density vanishes at the CMB, so on NFCs the Lorentz force is purely radial and the horizontal momentum balance thus geostrophic. Then the average circulation speed,  $\bar{v}_c$ , around a NFC satisfies

$$\bar{v}_c L + 2\Omega A_P = \text{constant}$$

where *L* is the length of the NFC and  $A_p$  its area projected onto the equatorial plane. A second piece of flow information that can be deduced without making further assumptions is the amount of horizontal convergence and divergence at points on the CMB where  $\nabla_{\rm H} {\bf B}_r$  vanishes, i.e., at extrema (maxima, minima, and saddle points) of  ${\bf B}_r$ : from (2)

$$\nabla_H \cdot \mathbf{v} = -\frac{\mathbf{B}_r}{\mathbf{B}_r}.$$

### **Toroidal-poloidal decomposition**

Backus' (1968) analysis makes clear the severe nature of the CMB flow nonuniqueness. Several assumptions which reduce it and, like the frozen-flux hypothesis, are testable against the data, have been proposed. Before introducing them, and detailing the extent to which they reduce the ambiguity, it is useful to introduce the standard method for CMB flow modeling. Express the CMB flow as

$$\mathbf{v} = \mathbf{v}_{\mathrm{T}} + \mathbf{v}_{\mathrm{P}} = \nabla \times (T\hat{\mathbf{r}}) + \nabla_{\mathrm{H}}S.$$
(Eq. 6)

The toroidal part,  $\mathbf{v}_{T}$ , represented by the streamfunction, *T*, is divergencefree and represents motion such as solid body rotation and gyres, whereas the poloidal part,  $\mathbf{v}_{P}$ , represented by the velocity potential, *S*, is curl-free and represents tangentially converging and diverging fluid. Expanding T and S as sums of spherical harmonics (qv),

$$T(\theta, \varphi) = c \sum_{l,m} (t_l^{mc} \cos m\varphi + t_l^{ms} \sin m\varphi) P_l^m(\cos \theta)$$
  

$$\equiv c \sum_{l,m} t_l^m Y_l^m(\theta, \varphi)$$
  

$$S(\theta, \varphi) = c \sum_{l,m} (s_l^{mc} \cos m\varphi + s_l^{ms} \sin m\varphi) P_l^m(\cos \theta)$$
  

$$\equiv c \sum_{l,m} s_l^m Y_l^m(\theta, \varphi)$$
(Eq. 7)

where  $\theta$  and  $\varphi$  are colatitude and longitude, respectively, and c is the CMB radius. The flow at any point can be estimated if the coefficients  $\{t_i^m\}$  and  $\{s_i^m\}$  are known. The usual method for determining the coefficients is to substitute for  $\mathbf{B}_r$  and  $\partial \mathbf{B}_r$  / $\partial t$  also expressed as spherical harmonic expansions, together with the spherical harmonic expressions (7) for T and S from (6), into (2), multiply by the complex conjugate of an arbitrary spherical harmonic, integrate over the core surface, and interchange integration and summation. The orthogonality of the spherical harmonics (qv) then isolates a secular variation (SV) coefficient on the left-hand side of (2), whilst the right-hand side can be manipulated into sums of Elsasser and Gaunt (sometimes referred to as Adams-Gaunt) integrals involving the coefficients of the main field, multiplied by the coefficients of T and S respectively. Various selection rules govern which Elsasser and Gaunt integrals are nonzero, and (2) reduces to a finite set of linear equations for the flow coefficients  $\{t_i^m\}$  and  $\{s_i^m\}$  if the sums (7) are terminated at a given spherical harmonic degree and order (see Bullard-Gellman dynamo; Spherical harmonics). In matrix form, we therefore have

$$\dot{\mathbf{g}} = (\mathbf{E}(\mathbf{g}) : \mathbf{G}(\mathbf{g})) \begin{pmatrix} \mathbf{t} \\ .. \\ \mathbf{s} \end{pmatrix}$$
(Eq. 8)

where  $\dot{g}$  is a vector of SV spherical harmonic coefficients, **E** and **G** are matrices whose elements are linear combinations of main field spherical harmonic coefficients (represented by the vector **g**) multiplying Elsasser and Gaunt integrals respectively, and **t** and **s** are vectors of spherical harmonic coefficients of the streamfunction and velocity potential respectively. In early studies such as that of Kahle *et al.* (1967), the flow coefficients were estimated from (8) using standard least squares analysis, without appreciating the ambiguity in the flow. In fact, most of the ambiguity-reducing assumptions discussed below can be incorporated into an estimation of the flow coefficients based on Eq. (8).

### Ambiguity-reducing assumptions

The commonly adopted ambiguity-reducing assumptions are that the flow is purely toroidal (Whaler, 1980), tangentially geostrophic (Hills, 1979; Le Mouël, 1984), steady (Voorhies, 1986), or helical (Amit and Olsen, 2004); in several cases, the assumptions have been combined. Perhaps the easiest assumption conceptually is that the CMB flow is purely toroidal. Then the velocity potential is identically zero and (8) reduces to

 $\dot{\mathbf{g}} = \mathbf{E}(\mathbf{g})\mathbf{t}.$ 

Under this assumption, the first term on the right-hand side of (2) vanishes, and thus the component of the flow perpendicular to contours of  $\mathbf{B}_r$  can be estimated almost everywhere. Equation (4) now applies for all contours of  $\mathbf{B}_r$ , not just the NFCs. Flow around nonzero contours of  $\mathbf{B}_r$  is unconstrained. At extrema of  $\mathbf{B}_r$ , (2) shows that  $\dot{\mathbf{B}}_r$  must vanish, i.e., contours of zero radial SV must pass through them.

A more general test, analogous to that for frozen-flux, is provided by integrating (2) over patches of the CMB, but now those bounded by any contour of  $\mathbf{B}_r$ . Using the divergence theorem in a plane, with the radial flow at the CMB vanishing, we can show that (5) holds for patches  $S_i$  bounded by any nonzero contour of  $\mathbf{B}_r$ . Tests indicate that this condition is as well satisfied as that for patches bounded by NFCs, so that if we are willing to accept the frozen-flux hypothesis, we should also be willing to accept the purely toroidal flow hypothesis. If the flow is incompressible, horizontal flow convergence and divergence at the CMB,  $\nabla_H \cdot \mathbf{v} \equiv \nabla_H \cdot \mathbf{v}_T$ , equates to upwelling and downwelling flow which would be absent if the core was stably stratified adjacent to the CMB (see *Higgins–Kennedy paradox*).

Assuming that a toroidal flow is also steady significantly reduces the ambiguity. At two different epochs, the normal to a contour of  $\mathbf{B}_r$  will in general point in a different direction, allowing two different components of the steady flow to be determined from (4). By combining them vectorially, using the fact that the flow is identical at the two epochs, the full flow is obtained everywhere except at those locations where the normal to the contour does not change direction. This concept can be extended to a steady general flow; magnetic field information is required at three epochs rather than two, and the flow is unique except where

$$\Delta = \hat{\mathbf{r}} \cdot [\mathbf{B}_0(\mathbf{b}_1 \times \mathbf{b}_2) + \mathbf{B}_1(\mathbf{b}_2 \times \mathbf{b}_0) + \mathbf{B}_2(\mathbf{b}_0 \times \mathbf{b}_1)] = 0$$
(Eq. 9)

where  $\mathbf{b}_i = \nabla_H \mathbf{B}_r(\theta, \phi, t_i)$ ,  $\mathbf{B}_i$  is the radial field component at  $t_i$ , and 0, 1, and 2 are the three epochs between which the flow is assumed steady. However, uncertainties on magnetic field components at the CMB, which are amplified when its spatial derivatives are taken, mean that  $\Delta$  is not significantly larger than its uncertainty for time spans short enough for the steady flow assumption to be reasonable, i.e.,  $\Delta$  is difficult to distinguish from zero. In most practical determinations of the flow, steadiness is implicit over the period used to derive the SV. Steady flows are normally calculated by solving simultaneously sets of equations of condition (8) at different epochs (at least three) for a single set of flow coefficients, which defines a linear system. An alternative method is to embody the steady flow assumption in a nonlinear system, which can be solved iteratively.

The tangentially geostrophic (TG) flow assumption is a dynamical constraint making use of the Navier–Stokes equation with the approximation that the essential force balance at the CMB is between Coriolis and buoyancy forces, neglecting Lorentz forces (Bloxham and Jackson, 1991, discuss its validity). Curling the Navier–Stokes equation gives the thermal wind equation, whose radial component is

$$\nabla_H(\mathbf{v}\cos\theta) = 0. \tag{Eq. 10}$$

This equation provides a second constraint on the flow, which then becomes uniquely determined except in so-called ambiguous patches, which are areas of the CMB bounded by contours of  $\mathbf{B}_r/\cos\theta$  that do not cross the equator. Within the ambiguous patches, the component of flow around contours of  $\mathbf{B}_r/\cos\theta$  cannot be determined, but the flow is fully resolved over the rest of the CMB. The test of consistency with the TG assumption is that (5) must hold over patches bounded by contours of  $\mathbf{B}_r/\cos\theta$ . Again, tests indicate that this condition is as well satisfied as that for NFC patch integrals. TG flows can be estimated either by imposing (10) as a side constraint during inversion of (8), or by setting up a geostrophic basis for the flow, and solving for its coefficients. In terms of the geostrophic basis, the flow is

$$\mathbf{v} = \sum_{l,m} z_l^m \boldsymbol{\omega}_l^m \tag{Eq. 11a}$$

where the  $\{z_l^m\}$  are the unknown coefficients and

$$\boldsymbol{\omega}_{l}^{m} = \begin{cases} \mathbf{T}_{l}^{0} & m = 0\\ \mathbf{S}_{l}^{m} + a_{l-1}^{m} \mathbf{T}_{l-1}^{m} + b_{l+1}^{m} \mathbf{T}_{l+1}^{m} & m \neq 0 \end{cases}.$$
 (Eq. 11b)

In (11b),  $\{a_l^m, b_l^m\}$  are known functions, and

$$\mathbf{T}_l^m = \mathbf{r} \times \nabla Y_l^m$$
$$\mathbf{S}_l^m = r \nabla_H Y_l^m.$$

The geostrophic basis is complete, but it requires careful implementation in any numerical scheme where the expansion (11a) must be terminated, due to the coupling between successive spherical harmonics embodied in (11b).

Amit and Olson (2004) assume that CMB flow convergence and divergence,  $\nabla_H \cdot \mathbf{v} = \nabla_H^2 S$ , and its radial vorticity,  $\varsigma = \hat{\mathbf{r}} \cdot (\nabla \times \mathbf{v}) = \nabla_H^2 T$ , are proportional, i.e.,

$$\nabla_H^2 S = \mp k_0 \nabla_H^2 T, \tag{Eq. 12}$$

where  $k_0$  is a positive constant. The minus sign is associated with  $k_0$  in the northern hemisphere, and the plus sign in the southern hemisphere. Helicity,  $H = \varsigma \cdot \mathbf{v}$ , vanishes at the CMB, but a nonzero value in the bulk of the core indicates a correlation between vorticity and velocity, and hence (12) is referred to as the helical flow assumption. The size of  $k_0$  determines whether helicity is strong or weak. Amit and Olson (2004) also introduce what they refer to as columnar flow, where the toroidal and poloidal flow components are coupled through the adjustment of "Busse roll" flow to the core's spherical boundaries (see *Convection, nonmagnetic rotating*). The constraint is very similar to that for TG flows: (10) can be rewritten

$$\nabla_H \cdot \mathbf{v} = \frac{\tan\theta}{c} \mathbf{v}_{\theta}$$

whereas the columnar flow constraint is

$$\nabla_H \cdot \mathbf{v} = \frac{2\tan\theta}{c} \mathbf{v}_{\theta}.$$
 (Eq. 13)

A general constraint on upwelling is obtained by taking a linear combination of (12) and (13), with specific values of the combination constants giving helical, toroidal, TG, or columnar flows. Helical, TG flows are unique, and a necessary condition for the flow to be of this form is that (5) must be satisfied, where now the patches are bound by contours of  $\Gamma$  which satisfy the elliptic equation

$$\left( \frac{\partial \mathbf{B}_r}{\partial \phi} \pm k_0 \sin \theta \frac{\partial \mathbf{B}_r}{\partial \theta} \right) \frac{\partial \Gamma}{\partial \theta} - \left( \frac{\partial \mathbf{B}_r}{\partial \theta} + \mathbf{B}_r \tan \theta \mp k_0 \frac{1}{\sin \theta} \frac{\partial \mathbf{B}_r}{\partial \phi} \right) \frac{\partial \Gamma}{\partial \phi}$$
$$= \pm k_0 \mathbf{B}_r c^2 \sin \theta \nabla_H^2 \Gamma.$$

A comparison of flows produced by the steady, toroidal, and TG assumptions calculated from the same data set shows that steady flows are *predominantly* toroidal and TG, although Bloxham and Jackson (1991) argue that the flow cannot be *purely* so. Modeling SV data obtained from observatory records (rather than spherical harmonic SV models) by a purely toroidal flow gives a good, but statistically inadequate, fit. Steady flows also fit the gross features of the SV record, and thus can model it over long periods with a very small number of parameters. Holme and Whaler (2001) extended the concept to calculate steady flows in a reference frame drifting with respect to the mantle. This maintains the numerical advantage of needing to estimate only a small number of parameters, but reproduces more of the detail of the SV. TG flows are attractive because they allow the flow to be deduced in the interior of the core (see below).

# Flow construction

Most flows are calculated using a spectral approach, i.e., calculating coefficients of a global expression for v. Most commonly, the coefficients of the velocity potential, S, and streamfunction, T, are solved for, but TG flows have been constructed by estimating the geostrophic basis coefficients in (11a). Typically, inversions for the coefficients are regularized to ensure flows are not dominated by small-scale, poorly constrained motion. A number of regularization constraints have been proposed, the most commonly employed being minimizing the rootmean-square (rms) energy in the flow, or minimizing the rms of its second spatial derivatives. Alternatively, the flow minimizing the rms radial SV generated by advection of the main field can be sought; like the constraints on the flow itself, this is a quadratic norm of v. Time dependence can be introduced by parameterizing the coefficients of the streamfunction and velocity potential, e.g., through cubic B-splines, in much the same way as time-dependent models of the magnetic field itself have been constructed. During regularized inversion, the quantity minimized to find the flow coefficients is a linear combination of the sum of squares of residuals between the SV spherical harmonic coefficients (or occasionally, the SV values at points on the Earth's surface) and their predictions by the flow, and a quadratic norm of the flow. This imposes a practical uniqueness on the flow, regardless of the inherent ambiguity. In this linear inverse problem, the numerical value of the Lagrange multiplier is chosen to achieve the required balance between fitting the SV coefficients and the roughness of the flow. If required, the TG constraint (10) can be included with a second Lagrange multiplier.

Chulliat and Hulot (2000) and Amit and Olson (2004) chose instead to calculate local solutions. Chulliat and Hulot (2000) calculated what they called the "geostrophic pressure"—the CMB overpressure associated with a TG flow—outside the ambiguous patches. Amit and Olson (2004) used a finite difference method on a regular grid covering the CMB to calculate flows including helicity and columnar constraints. Near the equator, helical flows are dominated by the TG assumption, and poloidal flow sources are located in regions of meridional flow; away from the equator, flows are dominated by helicity, and poloidal flow sources coincide with vortex centers.

The most common features of CMB velocity maps, regardless of the ambiguity-reducing assumptions imposed, are a band of westward flow centered on the equator extending from about  $90^{\circ}$ E to  $90^{\circ}$ W, an anticlockwise gyre beneath the south-western Indian Ocean, a jet from the North (and to a lesser extent, South) pole approximately along the  $90^{\circ}$ E meridian, and slower flow beneath the hemisphere centered on the  $180^{\circ}$ E meridian (see Figure C25). The band of westward flow produces the westward drift of the geomagnetic field in the hemisphere centered on the Greenwich meridian, known since the time of Halley to be a first-order feature of the SV. Likewise, we would expect slower flow beneath the Pacific because the magnetic field there changes much more slowly, a feature of the palaeomagnetic as well as geomagnetic observational record.

SV can be interpreted in terms of wave motion (see *Magnetohydro-dynamic waves*). There is evidence from time dependent CMB field models of westward drifting waves, both at mid-latitudes, and centered on the equator (with wavenumber 5, period 270 years, drifting westward at 17 km/year; Finlay and Jackson (2003)). If a stably stratified layer exists adjacent to the CMB, short-term SV variations could propagate through it by horizontally-polarized MAC waves (rather than be screened by the layer's skin depth).

### Torsional oscillations and extrapolation into the core

The response of the core to a torque applied from the mantle is to set up torsional oscillations. These are oscillations of cylinders coaxial with the rotation axis, and thus the flow is constant on their surfaces. Torsional oscillations are responsible for changes in angular momentum of the core thought to maintain the angular momentum budget of the Earth system on the decade timescale (see *Length of day variations, decadal*).

Figure C25 Typical steady flow for the period 1960–1980 inferred from the secular variation at the core–mantle boundary, illustrating features mentioned in the text. Continents are shown only for reference.

For such motions, the CMB flow is symmetric about the equator, and about the center of the Earth. About 80% of the CMB flow energy in unconstrained flows is symmetric about the equator. Assuming the symmetries required for TG flow on these coaxial cylinders reduces the number of independent velocity parameters by a factor of eight, but does not degrade the misfit to the SV significantly. The axial component of the core's angular momentum depends on just two coefficients of (7),  $t_1^0$  and  $t_3^0$ , of a TG flow (neglecting the effect of the inner core). If the flows are realistic, its time changes should match the axial component of angular momentum changes in the mantle, which can be deduced from changes in the length-of-day. There is good agreement between the length-of-day signal and that predicted by timevarying TG CMB flow over the 20th century. Holme and Whaler (2001) found that, if they interpreted the drift of the core reference frame with respect to the mantle as representing solid body rotation, its time dependence also matched the observed length-of-day changes. Decadal changes in length-of-day indicate that the core flow is not steady, but the steady flow assumption remains a useful approximation in many circumstances.

Zatman and Bloxham (1997, 1999) used torsional waves as a means of extrapolating into the interior of the core. Modeling the SV by a steady CMB flow plus two torsional oscillations reproduces many features of observed geomagnetic impulses or "geomagnetic jerks" signal (see *Geomagnetic jerks*) well (Bloxham *et al.*, 2002). If *s* is distance from the rotation axis, the excitation and damping of these oscillations depends on  $B_s$  averaged over a cylinder centered on the rotation axis,  $\bar{B}_s$ . This relationship can be inverted for  $\bar{B}_s$  as a function of *s*.

### Summary

CMB flows can be deduced from geomagnetic observations and the frozen-flux induction equation using regularized inversion combined with additional assumptions on the nature of the flow, including that it is steady, toroidal, tangentially geostrophic, helical, and/or columnar. The extent to which the additional assumptions reduce the inherent ambiguity can be characterized, and the validity of the assumptions tested against the data, commonly through examining the time stationarity of surface integrals of  $B_r$  over patches of the CMB bounded by contours of specific functions of  $B_r$ . The main features of the flows are robust, regardless of the assumptions made concerning the nature of the flow. They have westward drift in an equatorial band in the western hemisphere, an anticlockwise gyre beneath the south-western Indian Ocean, and many have slower flow beneath the Pacific Ocean. Interpreting the flow in terms of torsional oscillations allows some extrapolation into the core. Time-varying flows predict angular

momentum changes of the core which compensate for those of the mantle deduced from length-of-day variations.

# CORE ORIGIN

All major bodies of the inner solar system, including the Earth, are composed primarily of iron and silicates. Due to its high density, the iron component-the core-is invariably found at the center of the body. In addressing the origin of the Earth's core, four main questions arise. Firstly, composition: of what does the core consist? Secondly, accretion: how and when was this material assembled? Thirdly, differentiation: how and when did the Earth develop a recognizable core at its center? And finally, evolution: how did the core change subsequent to its formation? The first of these questions is dealt with elsewhere (see Core composition; Inner core composition), and will be only briefly summarized below. The other questions form the bulk of this article. Although the focus of the article will be the Earth's core, where possible these questions will also be discussed for other terrestrial planets. The answers to these questions are in many cases poorly understood, especially for planets for which few or no samples are currently available.

### Composition

Because the solar photosphere and primitive (chondritic) meteorites have similar ratios of most elements, it is a reasonable supposition that these elements are present in the same ratios in the bulk Earth (and other terrestrial planets) (Taylor, 1992). The chondritic Si:Fe atomic ratio of 1.2:1 suggests that terrestrial planets should have roughly comparable core and mantle masses. The actual ratios of core to mantle mass are 85:15, 33:67, 15:85, and 2:98 for Mercury, Earth/Venus, Mars, and the Moon (Lodders and Fegley, 1998). This rather wide range of values is probably a result of late-stage impacts, as discussed below.

The composition of planetary cores depends partly on what elements were present at the time of core formation. Simple models of solar system formation suggest that elements with relatively low condensation temperatures (i.e., volatiles) are likely to have been more abundant at greater distances from the Sun. The terrestrial planets and meteorites appear to be depleted in elements with condensation temperatures  $< \sim 1000$  K, compared to the initial solar nebula (Taylor, 1992). Whether there are gradations in volatile content between the terrestrial planets is currently unclear. Potassium isotope data (Humayun and Clayton, 1995) are a strong argument against such gradients occurring as a result of fractionating processes. Furthermore, any initial gradation will have been reduced by mixing of bodies from different solar distances during the accretion process.

For the Earth, more information is available because of seismological constraints on its interior structure, and constraints from samples on its bulk composition. As discussed elsewhere (*Core composition; Inner core composition*), the core consists of Fe plus about 10 wt% of one or more light elements, probably either S, Si, or O. These light elements are more concentrated in the liquid outer core and can significantly reduce the melting temperature of the liquid (see *Melting temperature of iron in the core, theory; Ideal Solution theory*). If core solidification occurs at the center of the planet, expulsion of the light elements during freezing can drive compositional convection (see *Convection, chemical; Geodynamo, energy sources*).

Because alkali element abundances are depleted with respect to the solar nebula, it is likely that potassium was mostly lost as a volatile during Earth's formation. Nonetheless, the remaining potassium is a potentially significant constituent of the core. Recent experimental evidence and theoretical arguments both suggest that potassium may partition into the core, especially if sulfur is a major constituent (see *Radioactive isotopes, their decay in mantle and core*). Radioactive decay of potassium-40 may help to power the terrestrial geodynamo (see *Geodynamo, energy sources*; Nimmo *et al.*, 2004) and could also be important on other planets. The presence of these secondary elements is presumably determined by their overall availability and the conditions that applied the last time the iron was in equilibrium with its surroundings.

There are few constraints on the detailed compositions or states of other planetary cores (see Taylor, 1992 and Nimmo and Alfe, 2006 for summaries). The Moon is very depleted in volatile elements and has a small core; these observations can be explained if it accreted at high temperatures from debris left over after a Mars-sized object collided with the Earth (e.g., Canup and Asphaug, 2001). Analyses of meteorites thought to have come from Mars have been used to deduce a planet that is richer in S and Fe than the Earth. The response of Mars to solar tides has been used to argue that the core of Mars is at least partially liquid. Similar observations have also been made for the Moon, Mercury, and Venus. Since most of these bodies are small and cool rapidly, these observations strongly suggest the presence of substantial amounts ( $\sim 10 \text{ wt }\%$ ) of S in the outer cores of these bodies. Because S is not incorporated into the solid core at low pressures, it becomes progressively harder to freeze the remaining liquid as solidification progresses. Whether the presence of large quantities of S is likely at Mercury's orbit, or following a high energy impact, remains an unanswered question.

### Solar system accretion

The process of accretion is now reasonably well understood, at least in outline (see Weidenschilling (2000) and Chambers (2004) for summaries of the likely timescales and processes). The solar system began when a nebular cloud of dust and gas became gravitationally unstable, and collapsed in on itself, forming a star surrounded by the orbiting remnants of the original cloud. Models suggest that the accumulation of these cloud remnants into Mars-sized planetary embryos was a rapid process, taking  $O(10^5$  years) in the inner solar system and somewhat longer at greater distances from the Sun. The final stage of accretion, in which these planetary embryos collided in high-energy impacts, was much slower, taking  $O(10^8 \text{ years})$ . The early formation of Jupiter is presumed to have frustrated planet formation within the asteroid belt (see Chambers, 2004).

Presumably, each planetary embryo began as a relatively homogeneous object, similar to the undifferentiated asteroids observed today. However, collisions between different embryos caused these bodies to increase in temperature as they grew (e.g., Stevenson, 1989). Furthermore, bodies, which formed early, may also have been heated by the decay of now-extinct radioactive elements, especially <sup>26</sup>Al (half-life 0.73 Myr). Thus, at some critical size, the planetary embryo will have begun to melt and (as discussed below) core formation is likely to have proceeded rapidly thereafter. This critical size probably varied in both time and space; for instance, Ceres, the largest asteroid (present-day diameter D = 913 km) appears not to have differentiated at all, while Vesta (D = 520 km) underwent widespread melting, which certainly involved core formation.

The process of differentiation is discussed in more detail below. Of more interest, from the point of view of accretion, is the timescale over which differentiation occurs. This timescale may be obtained from hafnium-tungsten (Hf/W) isotopic observations, as follows (see Harper and Jacobsen, 1996 for a summary).

Core differentiation leads to fractionation between Hf and W, with Hf going preferentially into the silicate phase and about 80% of the W into the core. The unstable isotope of Hf, <sup>182</sup>Hf, decays to <sup>182</sup>W with a half-life of 9 Ma. If differentiation happens before all the <sup>182</sup>Hf is exhausted, then the mantle will show an excess of <sup>182</sup>W over stable <sup>180</sup>W relative to an undifferentiated (chondritic) sample. The amount of the <sup>182</sup>W excess depends on the initial <sup>182</sup>Hf/<sup>180</sup>Hf ratio and the timing of differentiation. Since the former is known, observations of the <sup>182</sup>W/<sup>180</sup>W ratio have been used to constrain core formation time-scales.

If core formation is assumed to occur instantaneously, then the times after solar system formation at which core formation took place are (Kleine *et al.*, 2002): 4 Ma, 13 Ma, 33 Ma, and 26–33 Ma for Vesta, Mars, the Earth, and the Moon, respectively. These timescales indicate that planetary accretion and differentiation is a relatively rapid process. Core formation, as discussed below, occurs most rapidly if the iron is liquid. Vesta's early core formation age and small size suggest that heating either by  $^{26}$ Al or large impacts was probably important. For larger bodies like the Earth, core melting would have occurred simply due to the gravitational energy of accretion (Stevenson, 1989; see below).

In practice, accretion is likely to occur over a long timescale (tens of million years for an Earth-sized body; Chambers, 2004). Furthermore, for bodies the size of the Earth, it is likely that many of the accreting planetary embryos had themselves already undergone differentiation. Thus, the interpretation of the apparent core age is not straightforward. For instance, the increase in apparent core age with object size (Figure C26) is probably a reflection of a more prolonged accretion process for the larger bodies. An additional problem in the interpretation of Hf/W data is that the degree to which incoming bodies re-equilibrate with the planet's mantle is uncertain, and probably depends on the size of the impactor and the state of the mantle (magma ocean or solid) (Harper and Jacobsen 1996). The Moon-forming impact almost certainly produced a magma ocean on Earth and may also have partially or completely re-set the isotopic Hf/W clock.

Similar issues arise when considering the concentrations of siderophile (iron-loving) elements in the mantle (see Righter (2003) for a review). On Earth, these concentrations are significantly higher than those expected for equilibration at low pressures and temperatures. A possible solution is that equilibration took place at the bottom of a deep ( $\sim 1000 \text{ km}$ ) magma ocean. Interestingly, siderophile abundances estimated for the Martian mantle, based on Martian meteorite compositions, are more consistent with equilibration at lower temperatures and pressures (Righter, 2003). Although highly modeldependent, these observations suggest that Mars lacked a deep magma ocean. These conclusions are consistent with the expectation that larger bodies have higher internal temperatures owing to their greater gravitational potential energy.

### Differentiation

As described above, small planetary embryos (or planetesimals) probably consisted of a homogeneous mixture of metallic, silicate, and volatile components. However, as the planetesimals grew, collision velocities and thus the heat energy of each impact increased. Simultaneously, radioactive decay within the planetesimals further increased their internal temperature, especially if short-lived species such as <sup>26</sup>Al were still active at this point. At some particular size, probably depending on the rate of growth, the interior of the planetesimal started to melt. As described below, melting permits the denser components of the planetesimal to migrate towards the center of the body, thus achieving the process of differentiation. The following description is based largely on Stevenson (1990) and Solomon (1979) (see also Figure C27).

In general, metallic iron melts before end-member mantle silicates. Thus, differentiation can potentially occur either by the core liquid migrating through a solid silicate matrix or by liquid core droplets settling in a silicate liquid. The latter process is appropriate, for example, to the kind of magma ocean that is formed after giant impacts and results in rapid core formation. Based on the balance between viscous and surface tension forces in a convecting magma ocean, the likely

**Figure C26** Model single-stage core formation age after solar system formation compared with present-day radius of body. From Kleine *et al.* (2002).

**Figure C27** Mechanisms of core differentiation, after Stevenson (1990). is the dihedral angle.

iron droplet size is  $\sim 1$  cm. At these length scales, chemical equilibration with the surrounding mantle material is likely to be complete.

The former process, core liquid migrating through a solid silicate matrix, is controlled largely by the dihedral angle, the characteristic angle formed at an interface between solid grains and an interstitial melt. For large dihedral angles, typical of iron-silicate interfaces at low pressures, melt percolation is inefficient because the iron droplets accumulate in disconnected pockets. Percolation is much more rapid if the dihedral angle is smaller (<60°), the melt fraction is large (>~10%), or large shear stresses occur. The dihedral angle typically decreases with pressure, so that large variations in permeability with depth may have occurred within accreting planets. For dihedral angles <60°, transit timescales through the mantle for individual iron particles are typically 10<sup>4</sup>–10<sup>5</sup> y. For dihedral angles >60°, an alternative mechanism for differentiation is the accumulation of large bodies of iron which then migrate downwards as diapirs.

Once differentiation begins, it is likely to go rapidly to completion: the downwards motion of the dense iron results in a release of gravitational potential energy, leading to local heating, viscosity reduction, and an increase in the rate at which differentiation proceeds. This runaway effect is larger for larger bodies, but even for Mars-sized objects the energy of core differentiation is sufficient to raise the temperature of the entire planet by 300 K (Solomon, 1979).

### Evolution and inner core growth

Once the bulk of differentiation has ended, subsequent evolution of planetary cores is more leisurely. Core cooling is controlled by the rate at which the overlying mantle can remove heat (see *Core-mantle boundary, heat flow across; Interiors of planets and satellites*). Reactions between the core and mantle may take place, but are likely to be relatively slow (see D'', *Composition*). Partly because of the energy released during differentiation, the cores are initially likely to be both hot and convecting, and in many cases (e.g., Mars, Earth, the Moon?) develop early dynamos (see *Dynamos, planetary and satellite; Magnetic field of Mars;* Nimmo and Alfe, 2006).

Over the longer term, the core will cool and core solidification will set in, acting as another energy source for the dynamo (see Geodynamo, energy sources). Only for the Earth is the existence of a solid inner core certain (see Inner core composition). Similar inner cores may exist for the other terrestrial planets, depending on the slopes of the core adiabat (see Core, adiabatic gradient) and melting curve, and the core sulfur content (Nimmo and Alfe, 2006). The age of the inner core depends on the rate at which the mantle is extracting heat from the core. Current estimates (see Core-mantle boundary, heat *flow across*) suggest an inner core age of only  $\sim$ 1 Ga. Although the uncertainties in this value are still quite large, a cooling rate sufficient to maintain the terrestrial dynamo implies an inner core significantly younger than the age of the Earth (Nimmo et al., 2004). Prior to the formation of the inner core, the terrestrial dynamo was driven mainly by cooling of the liquid core, with possible assistance from radioactive decay (see Radioactive isotopes, their decay in mantle and core).

# **CORE PROPERTIES, PHYSICAL**

This is an overview of properties, many of which have individual entries in this encyclopedia [see *Core composition; Core properties, theoretical determination;* D" as a boundary layer; Grüneisen's parameter for iron and Earth's core; and *Core viscosity*]. Some properties are very well determined, notably density and elasticity, but others are hardly more than guesses and for some there is significant disagreement, as in the case of the Grüneisen parameter. Values given here are selected, as far as possible to make a self-consistent set, constrained by relevant thermodynamic relationships. Table C3 summarizes them for the top and bottom of the outer core and the top of the inner core.

# Elasticity and the equation of state

The most secure data on the core that we have are obtained from seismology and are presented in the digested form of Earth models. The most widely used of these is PREM (Preliminary Reference Earth Model—Dziewonski and Anderson, 1981). PREM is a parameterized model in the sense that density and the speeds of P and S waves are

Property	Outer core at CMB	Outer core at ICB	Inner core at ICB
Density, $\rho(\text{kgm}^{-3})$	9902	12163	12983
Bulk modulus, $K_S$ (GPa)	645.9	1301.3	1303.7

Table C3 Physical properties of the core: a summary. Numbers are constrained to give a self-consistent set, retaining digits beyond the level of absolute accuracy

presented as polynomials in radius, over different ranges. In the case of the outer core they are third order polynomials. This makes the model convenient to use for many purposes and it represents well the broad scale of properties, density (and therefore gravity and pressure), as well as elasticity. However, there is a limitation. When we consider derivative properties, especially the pressure derivatives of bulk modulus, *K*, that is K' = dK/dP and  $K'' = d^2K/dP^2$ , the model parameterization gives unrealistic variations. The dimensionless derivatives K'and KK'' are essential parameters of an equation-of-state (EoS) so it is necessary to constrain them by imposing an EoS and using PREM to fit EoS parameters. This means that we decide on the form of the EoS before fitting model data and the bias of this decision influences the conclusions. The result is a divergence of inferences about properties according to the favored equations.

It must be noted that the bulk modulus observed seismologically is the adiabatic value,  $K_S$ , which applies to the compression of thermally isolated material. It is related to the isothermal modulus,  $K_T$ , describing the compression of material held at constant temperature, by the identity

$$K_S = K_T (1 + \gamma \alpha T)$$

 $\gamma$  being the Grüneisen parameter and  $\alpha$  the volume expansion coefficient, which are discussed below and listed in Table C3. In common parlance, "bulk modulus" means  $K_T$  unless otherwise specified. In the core  $K_S$  and  $K_T$  differ by 7%–10%. We must also be careful to specify that in the outer core the depth dependence of  $K_S$  is given by its adiabatic derivative,  $K'_S \equiv (\partial K_S / \partial P)_S$ , because the temperature gradient is adiabatic. Similarly,  $K''_S \equiv (\partial K'_S / \partial P)_S$ .

The status and acceptability of current rival equations are reviewed by Stacey and Davis (2004). The situation has improved noticeably since about 2000 with new thermodynamic constraints that restrict the acceptable equations to those that are specifically written as equations for K'. One of these, which we refer to as the "reciprocal K-primed equation," was used to obtain the EoS parameters in Table C3:

$$\frac{1}{K'} = \frac{1}{K'_0} + \left(1 - \frac{K'_\infty}{K'_0}\right) \frac{P}{K}$$

where subscripts zero and infinity indicate the zero and infinite pressure extrapolations of K'. A particular advantage of an equation of this form is that it makes use of an identity (common to all of the rival equations, but not recognized)

$$K'_{\infty} = 1/(P/K)_{\infty}$$

In the case of the core,  $K'_{\infty}$  is quite tightly constrained by the observation of inner core rigidity, so this identity provides a fixed infinite pressure end point to the EoS.

The need for a theoretical constraint on the EoS is obvious also in consideration of the rigidity modulus,  $\mu$ , of the inner core, which is not well observed seismologically. PREM gives a satisfactory average value but a gradient such that the ratio  $\mu/K$  increases with depth, which is incompatible with homogeneous material. We have a relationship first developed for application to the inner core but shown to fit lower mantle data precisely

$$\frac{\mu}{K} = \left(\frac{\mu}{K}\right)_0 - \left[\left(\frac{\mu}{K}\right)_0 - \left(\frac{\mu}{K}\right)_\infty\right] K'_\infty \frac{P}{K}$$

In fact it is not only  $\mu'$  that is anomalous in the inner core by PREM, but also K'. Both can be adjusted to agree with the above equations without changing the profile of  $(K + 4/3\mu)$  which is reliably observed from the P wave speed. Now,  $\mu/K$  in the inner core is quite small, so that there is little scope for extrapolation of the  $\mu/K$  equation above.  $\mu/K$  must fall below the inner core value, but cannot vanish, that is  $(\mu/K)_{\infty} = 0$  gives an extreme upper bound to the P/K scale and therefore a lower bound on  $K'_{\infty}$ . The result is a very restricted range of possible values:  $K'_{\infty} = 3.0 \pm 0.1$ . When the reciprocal K' equation is applied to the core even this range is seen to be too wide; the value 2.9 is implausible. So, we now have a firm basis for adjusting the PREM tabulation for the core and the values in Table C3 were

obtained in this way. Details of fitting and a complete tabulation are given by Stacey and Davis (2004).

### Specific heat

At the high temperatures of the core the lattice component of specific heat,  $C_{\ell}$ , can differ little from the classical (Dulong-Petit) value, 3R (per mole). With the estimated mean atomic weights in Table C3, this means 519 JK<sup>-1</sup>kg<sup>-1</sup> for the outer core and 475 JK<sup>-1</sup> kg<sup>-1</sup> for the inner core. Added to this is an electron component,  $C_e$ , arising from the thermal excitation of conduction electrons. At specified volume,  $C_e$  is proportional to temperature, T, because both the number of electrons that are thermally excited and the level to which they are excited are proportional to T, making the electron thermal energy proportional to  $T^2$ . The proportionality constant depends on the density of electron states from which electrons may be thermally excited and this decreases with compression by an increasing energy spread of the bands of energy levels. As a convenient analytical representation of the results of a numerical band structure calculation, Boness *et al.* (1986) wrote the electron specific heat of iron at density  $\rho$  as

$$C_e = (A\rho_0/\rho - B)T$$

 $\rho_0$  being the zero pressure density (at 290 K). Allowing for the dilution by lighter elements, we can use this expression for outer core alloy with  $A = 0.12709 \text{ JK}^{-2}\text{kg}^{-1}$  and  $B = 0.02378 \text{ JK}^{-2}\text{kg}^{-1}$ , making the total specific heat at constant volume

$$C_V = C_\ell + C_\epsilon$$

This is converted to  $C_P$ , specific heat at constant pressure, as listed in Table C3, by the identity

 $C_P = C_V (1 + \gamma \alpha T)$ 

which is similar to the relationship (above) between  $K_S$  and  $K_T$ .

### Temperature and temperature gradient

Core temperatures in Table C3 are anchored to 5000 K at the inner core boundary. This estimate could be in error by 500 K. It is based on the coexistence at that level of solid and liquid, with the assumption that there is some melting point depression by the solutes, relative to the melting point of pure iron, which is usually estimated to be nearer to 6000 K at ICB pressure. The temperature gradient is calculated from the identity

 $(\partial \ln T / \partial \ln \rho)_s = \gamma$ 

and the temperature at the core mantle boundary is obtained by integrating this gradient with a density dependence of  $\gamma$ , as considered below.

# The Grüneisen parameter and thermal expansion coefficient

The thermodynamic definition of the Grüneisen parameter is

$$\gamma = \frac{\alpha K_T}{\rho C_V} = \frac{\alpha K_S}{\rho C_P}$$

It is a dimensionless number, of order unity, that is a simple combination of four familiar properties. Three of them are subject to independent estimates.  $K_S/\rho$  is obtained from the seismic wave speeds and  $C_P$ , calculated as described above, cannot be far from 800 JK<sup>-1</sup>kg<sup>-1</sup> in the core (Table C3). The thermal expansion coefficient,  $\alpha$ , is the odd one out. Our only effective way of estimating  $\alpha$  is by means of  $\gamma$ . Knowledge of one is equivalent to knowledge of the other and equations for thermodynamic properties of the Earth's interior can be written in terms of either, but since  $\alpha$  is obtained from  $\gamma$  it is usually more convenient to use  $\gamma$  directly. This is essential to calculation of the adiabatic temperature gradient, as above, and hence the thermodynamic efficiency of convection and much other thermal geophysics.

As has been recognized since the early work of E. Grüneisen and J.C. Slater, in principle  $\gamma$  can be represented in terms of elastic moduli and their pressure derivatives, but the theories that do this are not free of doubts and difficulties. Grüneisen defined the parameter named after him in terms of volume dependence of crystal vibration frequencies, making the connection to elasticities obvious. As Stacey and Davis (2004) showed by an application of Einstein's theory of specific heat, the Grüneisen and thermodynamic definitions are equivalent if the mode frequencies are independent of temperature at constant volume. Then, by assuming that the crystal mode frequencies are adequately represented by the seismologically observed moduli, *K* and  $\mu$ , we obtain a formula known as the acoustic  $\gamma$ . This works well for the mantle, but is not applicable to the core. Apart from the problem of applying to the liquid outer core a formula using  $\mu$  and  $\mu'$ , electrons have an important role in metals that is not properly accounted for in the Grüneisen approach.

Another way of looking at  $\gamma$  is to see it as the ratio of thermal pressure to thermal energy. If we raise the temperature of a unit volume of material by  $\Delta T$ , by applying heat  $\rho C_P \Delta T$  at constant *P*, causing thermal expansion  $\alpha \Delta T$ , and then recompress it adiabatically to the original volume, the pressure is increased by  $\alpha K_S \Delta T$ . This is thermal pressure and we see that the ratio of this to the applied heat coincides with the thermodynamic definition of  $\gamma$ . Still considering only atomic vibrations, we can apply this concept to calculate the mean forces between vibrating atoms (and hence pressure) relative to their thermal energy. This leads to a formula of the form

$$\gamma = \frac{(1/2)(dK/dP) - 1/6 - (f/3)(1 - P/3K)}{1 - (2f/3)P/K}$$

where *f* is a factor that depends on how the atoms vibrate (correlations, mutual interactions between bonds, and so on). Rival theories give a wide range of alternatives (f = 0, 1, 2, 2.35) but none is convincing. However, the general form of the equation appears satisfactory and it can be used with a value of *f* selected empirically to match a relevant observation, such as a measured zero pressure value of  $\gamma$ . On the basis of a comparison with the acoustic  $\gamma$  for the lower mantle, Stacey and Davis (2004) suggested f = 1.44, but hesitated to assume that any constant value was acceptable. There is one situation in which we can be confident of this formula. In the limit  $P \to \infty$ , so that  $K'_{\infty} \to (K/P)_{\infty}$ , we have  $\gamma_{\infty} = (1/2)K'_{\infty} - 1/6$ , independently of *f*. We can note that there is no difficulty in applying this equation to a liquid, such as the outer core, and there is no appeal to mode frequencies so that electron pressure is properly included, but that doubt remains about the role of shear modes.

A third approach to the calculation of  $\gamma$  relies on the thermodynamic requirement that its volume derivative,  $q = (\partial \ell n \gamma / \partial \ell n V)_T$ , must decrease strongly with pressure, vanishing in the infinite pressure limit, so that the next derivative,  $\lambda = (\partial \ell n q / \partial \ell n V)_T$ , is at least nearly constant. This method also requires calibration by a known value of  $\gamma_0$ , but uses also the fix on  $\gamma_\infty$  (on which all theories agree). Interestingly, Stacey and Davis (2004) found that when applied to the core the second and third of these approaches gave almost identical values. Thus, although the theory is still incomplete and numerical calculations give higher values [see *Core properties, theoretical determination*] thermodynamic arguments lead to the values in Table C3, which reports values of q as well as  $\gamma$  and also the values of  $\alpha$  that follow from it.

### Electrical and thermal conductivities of the core

As pointed out in the separate entries for these properties, they are closely related. Electrons dominate thermal as well as electrical conduction. Calculation of electrical conductivity,  $\sigma_e$ , is usually a calculation of its inverse, resistivity,  $\rho_e = 1/\sigma_e$ . This is a measure of the impediment to

94

the free motion of electrons by thermal vibration, crystal irregularities, and impurities. It is the impurity resistivity that gives the greatest difficulty, but the overall conductivity is now almost certainly estimated to  $\pm 25\%$ . The precise value does not appear crucial to the dynamo, but the consequent thermal conductivity is more critical because of the drain on core heat by thermal conduction. The conductivities of core alloy appear nicely balanced, being high enough for dynamo action but not so high as to exhaust the energy source by conductive heat loss.

### Magnetic susceptibility and diffusivity

Iron in any of its forms is strongly paramagnetic, that is it responds positively to a magnetic field, but under core conditions the magnetic susceptibility is only about  $5 \times 10^{-6}$ , that is the permeability,  $\mu$ , differs from the vacuum value,  $\mu_0 = 4\pi \times 10^{-7}$  Hm<sup>-1</sup>, by about 5 parts in  $10^6$ . It can have no influence on the dynamo or other properties, including the magnetic diffusivity,  $\eta_m = 1/(\sigma_e \mu)$ .

### Viscosity

The molecular viscosity of the outer core,  $\sim 10^{-2}$  Pa s, is believed to be little different from that of liquid iron at ordinary pressures. It is low enough to cause no geophysical effect. This is even true of the eddy viscosity, arising from turbulence in the magnetically controlled flow, being 1 to  $2 \times 10^4$  Pa s, but anisotropic according to the local orientation of the magnetic field.

# CORE PROPERTIES, THEORETICAL DETERMINATION

### Introduction

The fact that the core is largely composed of Fe was firmly established as a result of Birch's analysis of mass-density/sound-wave velocity systematics. Today we believe that the outer core is about 6%-10% less dense than pure liquid Fe, while the solid inner core is a few percent less dense than crystalline Fe. Before a full understanding of the chemically complex core is reached, however, it is necessary to understand the properties and behavior at high pressure (*P*) and temperatures (*T*) of its primary constituent, namely metallic Fe. Experimental techniques have evolved rapidly in the past years, and today using diamond anvil cells or shock experiments, the study of minerals at pressures up to  $\sim$ 200 GPa and temperatures of a few thousand Kelvin is possible. These studies, however, are still far from routine and results from different groups are often in conflict. As a result, therefore, in order to complement these existing experimental studies and to extend the range of pressure and temperature over which we can model the Earth, computational mineral physics has, in the past decade, become an established and growing discipline.

Within computational mineral physics a variety of atomistic simulation methods (developed originally in the fields of solid state physics and theoretical chemistry) are used. These techniques can be divided approximately into those that use some form of interatomic potential model to describe the energy of the interaction of atoms in a mineral as a function of atomic separation and geometry, and those that involve the approximate solution of Schrödinger's equation to calculate the energy of the mineral species by quantum mechanical techniques. For the Earth sciences, the accurate description of the behavior of minerals as a function of temperature is particularly important and computational mineral physics usually uses either lattice dynamics or molecular dynamics methods to achieve this important step. The relatively recent application of all of these advanced condensed matter physics methods to geophysics has only been made possible by the very rapid advances in the power and speed of computer processing. Techniques, which in the past were limited to the study of structurally simple compounds, with small unit cells, can today be applied to describe the behavior of complex, low symmetry structures (which epitomize most minerals) and liquids. In this entry, we will focus on recent computational studies of Fe, which have been aimed at predicting its geophysical properties and behavior under core conditions. These recent quantum mechanical calculations of the free energy of the solid and liquid phases of Fe have enabled the determination of a number of geophysically significant thermodynamic properties of Fe (Alfè et al., 2001, 2002).

# The structure of Fe under core conditions

Under ambient conditions, Fe adopts a body-centered cubic (bcc) structure that transforms with temperature to a face-centered cubic (fcc) form, and with pressure transforms to a hexagonal close packed (hcp) phase,  $\epsilon$ -Fe. The high *P*/*T* phase diagram of pure iron itself however is still controversial. Various diamond anvil cell (DAC) based studies have been interpreted as showing that hcp Fe transforms at high temperatures to a phase that has variously been described as having a double hexagonal close-packed structure (dhcp) or an orthorhombicly distorted hcp structure. Furthermore, high-pressure shock experiments have also been interpreted as showing a high pressure solid-solid phase transformation, which has been suggested could be due to the development of a bcc phase. Other experimentalists, however, have failed to detect such a post-hcp phase and have suggested that the previous observations were due either to minor impurities or to metastable strain-induced behavior.

Further progress in interpreting the nature and evolution of the core would be severely hindered if the uncertainty concerning the crystal structure of the core's major chemical component remained unresolved. Such uncertainties can be resolved, however, using *ab initio* calculations (e.g., Vočadlo *et al.*, 1999). Spin-polarized simulations have been performed on candidate phases (including a variety of distorted bcc and hcp structures and the dhcp phase) at pressures ranging from 325 to 360 GPa. These reveal that under these conditions only bcc Fe has a residual magnetic moment and all other phases have zero magnetic moments. It should be noted however, that the magnetic moment of bcc Fe disappears at temperatures >1000 K, indicating that even bcc Fe will have no magnetic stabilization energy under core conditions. Static simulations find that at core pressures, the bcc polymorph of iron is mechanically unstable and continuously transforms to

the fcc when allowed to relax to a state of isotropic stress. In contrast, hcp, dhcp, and fcc Fe remain mechanically stable at core pressures, and so it is possible to calculate their phonon frequencies and hence free energies. From such an analysis the hcp phase of Fe is found to have the lowest Gibbs free energy over the whole P-T space thought to represent inner core conditions.

Despite the fact that bcc Fe is mechanically unstable at high pressure and low temperatures (and so not amenable to lattice dynamical modeling), it has been suggested that it may become entropically stabilized at high temperatures (e.g., Matsui and Anderson, 1997). This behavior is found in some other transition metal phases, such as Ti and Zr. Vočadlo *et al.* (2003a) have performed molecular dynamic simulations of bcc Fe and have found that this structure is indeed mechanically stable above ~1000 K at core densities, but in the absence of S or Si, still remains metastable with respect to hcp-Fe.

# Calculated thermodynamic properties of hcp Fe

Alfè *et al.* (2001) have presented a comprehensive set of quantum mechanically derived thermodynamic data for hcp-Fe. Their calculated total constant-volume specific heat per atom  $C_v$  (Figure C28) emphasizes the importance of electronic excitations. In a purely harmonic system,  $C_v$  would be equal to  $3k_{\rm B}$ , and it is striking that  $C_v$  is considerably greater than that even at the modest temperature of 2000 K, while at 6000 K it is nearly doubled. The decrease of  $C_v$  with increasing pressure evident in Figure C28 comes from the suppression of electronic excitations by high compression and to a smaller extent from the suppression of anharmonicity.

The thermal expansivity  $\alpha$  (Figure C29) is one of the few cases where it is possible to compare calculated properties with experimental measurements and both approaches show that  $\alpha$  decreases strongly with increasing pressure. Calculation also shows that  $\alpha$  increases significantly with temperature. The product  $\alpha K_T$  of expansivity and isothermal bulk modulus, which is equal to  $(dP/dT)_{\nu}$ , is important because it is sometimes assumed to be independent of pressure and temperature over a wide range of conditions, and this constancy is used to extrapolate experimental data. Calculated isotherms for  $\alpha K_T$ (Figure C30) indicate that its dependence on P is indeed weak, especially at low temperatures, but that its dependence on T certainly

**Figure C28** Total constant-volume specific heat per atom ( $C_{V_r}$  in units of  $k_B$ ) of hcp Fe as a function of pressure on isotherms T = 2000 K (*continuous curves*), 4000 K (*dashed curves*), and 6000 K (*dotted curves*). Heavy and light curves show results of Alfè *et al.* (2000) and of Stixrude *et al.* (1997), respectively.

cannot be ignored, since it increases by at least 30% as *T* goes from 2000 to 6000 K at high pressures.

The thermodynamic Grüneisen parameter  $\gamma = V(dP/dE)_{\nu} = \alpha K_T V/C_{\nu}$ plays an important role in high-pressure physics because it relates the thermal pressure and the thermal energy. Assumptions about the value of  $\gamma$  are frequently used in reducing shock data from the Hugoniot to an isothermal state. If one assumes that  $\gamma$  depends only on *V*, then the thermal pressure and energy are related by

$$P_{\rm th}V = \gamma E_{\rm th}$$

**Figure C29** The thermal expansivity ( $\alpha$ ) of hcp-Fe as a function of pressure on isotherms *T* = 2000 K (*continuous curves*), 4000 K (*dashed curves*), and 6000 K (*dotted curves*). Heavy and light curves show results of Alfè *et al.* (2000) and of Stixrude *et al.* (1997), respectively. The black circle is the experimental value of Duffy and Ahrens (1993) at *T* = 5200 ± 500 K. Diamonds are data from Boehler (1990) for temperatures between 1500 and 2000 K.

**Figure C30** The product of the expansion coefficient ( $\alpha$ ) and the isothermal bulk modulus ( $K_T$ ) of hcp-Fe as a function of pressure on isotherms T = 2000 K (*continuous curves*), 4000 K (*dashed curves*), and 6000 K (*dotted curves*). Heavy and light curves show results of Alfè *et al.* (2000) and of Stixrude *et al.* (1997), respectively.

the well known Mie-Grüneisen equation of state. At low temperatures, where only harmonic phonons contribute to  $E_{th}$  and  $P_{th}$ ,  $\gamma$  should indeed be temperature independent above the Debye temperature, because  $E_{th} = 3k_{\rm B}T$  per atom, and  $P_{th}V = -3k_{\rm B}T(d\ln\omega/d\ln V) = 3k_{\rm B}T\gamma_{\rm ph}$ , so that  $\gamma = \gamma_{\rm ph}$  (the phonon Grüneisen parameter), which depends only on *V*. But at high temperatures, the temperature independence of  $\gamma$  will clearly fail because of electronic excitations and anharmonicity. Calculated results for  $\gamma$  (Figure C31) indicate that it varies rather little with either pressure or temperature in the region of interest. At temperatures below ~4000 K, it decreases with increasing pressure, as expected from the behavior of  $\gamma_{\rm ph}$ . This is also expected from the often-used empirical rule of thumb  $\gamma = (V/V_0)^q$ , where  $V_0$  is a reference volume and q is a

**Figure C31** The Grüneisen parameter ( $\gamma$ ) of hcp-Fe as a function of pressure on isotherms *T* = 2000 K (*continuous curves*), 4000 K (*dashed curves*), and 6000 K (*dotted curves*). Heavy and light curves results of Alfè *et al.* (2000) and of Stixrude *et al.* (1997), respectively.

constant exponent usually taken to be roughly unity. Since V decreases by a factor of about 0.82 as P goes from 100 to 300 GPa, this empirical relation would make  $\gamma$  decrease by the same factor over this range, which is roughly what we see. However, the pressure dependence of  $\gamma$  is very much weakened as T increases until, at 6000 K,  $\gamma$  is almost constant.

The measured and calculated elastic constants of hcp-Fe are presented in Table C4. Although there is some scatter on the reported values of  $c_{12}$ , overall, the agreement between the experimental and various *ab initio* studies are excellent.

# Rheological and thermodynamical properties of liquid Fe

De Wijs *et al.* (1998) in Alfè *et al.* (2000) have reported the quantum mechanically determined viscosity, diffusion, and thermodynamic properties of Fe in the liquid state. Their simulations cover the temperature range 3000–8000 K and the pressure range 60–390 GPa. Table C5 shows a comparison of the pressures calculated in the simulations with the pressures deduced by Anderson and Ahrens (1994) from a conflation of experimental data, and Figure C32a-e summarizes for liquid Fe the calculated values of density, thermal expansion coefficient, adiabatic and isothermal bulk moduli, heat capacity ( $C_v$ ), and Grüneisen parameter. These values are in close accord with the estimates available in Anderson and Ahrens (1994). It is worth noting that the systematics of the behavior of heat capacity ( $C_v$ ), Grüneisen parameter, etc., for liquids is quite different for those of solids.

Table C6 reports the calculated values for the self diffusion of Fe in liquid Fe, and the viscosity of liquid Fe for the same range of P and T conditions reported above. For the entire pressure-temperature domain of interest for the Earth's outer core, the diffusion coefficient, D, and viscosity,  $\eta$ , are comparable with those of typical simple liquids, D being  $\sim 5 \times 10^{-9} \text{ m}^2 \text{s}^{-1}$  and  $\eta$  being in the range 8–15 mPa s, depending on the detailed thermodynamic state.

### Conclusion

The past decade has seen a major advance in the application of *ab initio* methods in the solution of high pressure and temperature geophysical problems, thanks to the rapid developments in high-performance computing. The progress made means that it is now

**Table C4** A compilation of elastic constants ( $c_{ij}$ , in GPa), bulk (K) and shear (G) moduli (in GPa), and longitudinal ( $v_P$ ) and transverse ( $v_S$ ) sound velocity (in km s<sup>-1</sup>) as a function of density ( $\rho$ , in g cm<sup>-3</sup>) and atomic volume (in Å<sup>3</sup> per atom). In this table  $K = (\langle c_{11} \rangle + 2 \langle c_{12} \rangle)/3$  and  $G = (\langle c_{11} \rangle - \langle c_{12} \rangle + 3 \langle c_{44} \rangle)/5$ , where  $\langle c_{11} \rangle = (c_{11} + c_{22} + c_{33})/3$ , etc. Previous calculated values are from Stixrude and Cohen (1995), Steinle-Neumann *et al.* (1999), Söderlind *et al.* (1996), and Vočadlo *et al.* (2003b). The experimental data of Mao *et al.* (1999) is also presented

possible to calculate from first principles the free energies of solid and liquid phases, and hence to determine both the phase relations and the physical properties of planetary-forming minerals. In the future, with "tera-scale computing," it will be possible to model more complex and larger systems to investigate for example solid-state rheological problems or physical properties such as thermal and electrical conductivity, which are currently beyond current quantum mechanical simulations.

# CORE TEMPERATURE

High-pressure experiments combined with geophysical and geodynamic modeling suggest that the temperature near the bottom of the mantle probably lies between 2500 and 3000 K. There is still uncertainty over the heat flow out of the core and the thermal conductivity of the materials in D" zone, so it is not possible to give a precise estimate of the temperature increase across the thermal boundary layer at the base of the mantle, although it is generally accepted that this may be of the order of 1000 K. Another approach to constraining the temperature of the core is based upon the assumption that the solid inner core is crystallizing from the liquid outer core, and the ICB marks a crystallization interface. Given that the core is iron (alloyed with about 10% of lighter elements), and given that impurities lower the melting point, then the melting temperature ( $T_m$ ) of iron at the pressure of the ICB can be used to place an upper bound on the core's temperature at this

depth. As reviewed elsewhere in this volume (see *Melting temperature* of iron in the core, experimental and *Melting temperature of iron in the* core, theory) estimates for  $T_{\rm m}$  can be obtained from shock melting experiments, by laser-heated diamond-anvil cells studies, and from theory. The experimental measurements are difficult and their interpretation is controversial, with ICB melting temperatures inferred from experiments ranging from ~4850 K (Boehler, 1996) to ~6850 K (Yoo *et al.*, 1993). Values from theory, however, now seem to be more closely clustered, with values of  $T_{\rm m}$  of Fe at 360 GPa of between 6000 and 6400 K (see *Melting temperature of iron in the core, theory*). However, to constrain the temperature at the ICB more tightly, it is essential to infer an estimate of the true composition of the core and to determine the resulting suppression of the melting temperature caused by the light alloying elements.

On the basis of seismology and data for pure Fe, it is considered that the outer and inner core contain some light element impurities (see *Core composition*). Cosmochemical abundances of the elements, combined with models of the Earth's history, limit the possible impurities to a few candidates. Those most often discussed are S, O, and Si (e.g., Poirier, 1994; Allègre *et al.*, 1995), and most studies are, to date, confined to these three alloying elements. Boehler (2000) reviews the high *P* melting studies done on Fe-O and Fe-S systems, and concludes that the *in situ* detection of the solidus in such experiments is difficult because of the small melt fraction produced at the eutectic temperature in a multicomponent system. Nevertheless, he claims that experiments suggest that alloying elements in Fe produce only a small depression in  $T_{\rm m}$ . This contrasts with historical estimates (Stevenson, 1981) of the effect of, for example, S on the  $T_{\rm m}$  of Fe at core pressures, which indicated that a suppression of ~1100 K should be expected.

To address this problem, Alfè et al. (2002 a,b) have recently developed a strategy that uses quantum mechanical molecular dynamics to both constrain seismologically and thermodynamically allowed compositions for the outer and inner core, and to determine the magnitude of alloy-induced suppression of the melting temperature of Fe at the ICB. Their approach is based on the supposition that the solid inner core is slowly crystallizing from the liquid outer core and that therefore the inner and outer cores are in thermodynamic equilibrium at the ICB. This implies that the chemical potentials of Fe and of each impurity must be equal on the two sides of the ICB. If the core consisted of pure Fe, equality of the chemical potential (Gibbs free energy in this case) would tell us only that the temperature at the ICB is equal to the melting temperature of Fe at the ICB pressure of 330 GPa. With impurities present, equality of the chemical potentials for each impurity element imposes a relation between the mole fractions in the liquid and the solid, so that with S, O, and Si there are three such relations. But these three relations must be consistent with the inferred values of the mass densities in the inner and outer core deduced from seismic and free-oscillation data.

The chemical potential,  $\mu_x$ , of a solute *X* in a solid or liquid solution is conventionally expressed as  $\mu_x = \mu_x^0 + k_B T \ln a_x$ , where  $\mu_x^0$  is a constant and  $a_x$  is the activity. It is common practice to write  $a_x = \gamma_x c_x$ , where  $\gamma_x$  is the activity coefficient and  $c_x$  the concentration of *X*. The chemical potential can therefore be expressed as

$$\mu_x = \mu_x^0 + k_{\rm B}T \ln \gamma_x c_x \tag{Eq. 1}$$

which can be rewritten as

$$\mu_x = \mu_x^* + k_{\rm B}T \ln c_x \tag{Eq. 2}$$

It is helpful to focus on the quantity  $\mu_x^*$  for two reasons: first, because it is a convenient quantity to obtain by *ab initio* calculations (Alfè *et al.*, 2002b); second, because at low concentrations the activity coefficient,  $\gamma_x$ , will deviate only weakly from unity by an amount proportional to  $c_x$  and by the properties of the logarithm the same will be true of  $\mu_x^*$ . The equality of the chemical potentials  $\mu_x^l$  and  $\mu_x^s$  in coexisting liquid and solid (superscripts l and s, respectively) then requires that

$$\mu_x^{*1} + k_{\rm B}T \ln c_x^{\rm l} = \mu_x^{*\rm s} + k_{\rm B}T \ln c_x^{\rm s}$$
(Eq. 3)

or equivalently

$$c_x^{\rm s}/c_x^{\rm l} = \exp\left[(\mu_x^{\rm sl} - \mu_x^{\rm ss})/k_{\rm B}T\right]$$
 (Eq. 4)

This means that the ratio of the mole fractions  $c_x^s$  and  $c_x^l$  in the solid and liquid solution is determined by the liquid and solid thermodynamic quantities  $\mu_x^{*l}$  and  $\mu_x^{*s}$ . Although liquid-solid equilibrium in the Fe/S and Fe/O systems has been experimentally studied up to pressures of around 60 GPa, there seems little prospect of obtaining experimental data for  $\mu_x^{*l} - \mu_x^{*s}$  for Fe alloys at the much higher ICB pressure. However, Alfè *et al.* (2002 b) have recently shown that the fully *ab initio* calculation of  $\mu_x^{*1}$  and  $\mu_x^{*s}$  is technically feasible. Thus, the chemical potential,  $\mu_x$ , of chemical component X can be defined as the change of Helmholtz free energy when one atom of X is introduced into the system at constant temperature T and volume V. In ab initio simulations, it is awkward to introduce a new atom, but the awkwardness can be avoided by calculating  $\mu_{\rm X}^* - \mu_{\rm Fe}^*$ , which is the free energy change,  $\Delta F$ , when an Fe atom is replaced by an X atom. For the liquid, this  $\Delta F$  is computed by applying the technique of "thermodynamic integration" to the (hypothetical) process in which an Fe atom is continuously transmuted into an X atom.

Alfè *et al.* find a major qualitative difference between O and the other two impurities. For S and Si,  $\mu_x^*$  is almost the same in the solid and the liquid, the differences being at most 0.3 eV, i.e., markedly smaller than  $k_BT \sim 0.5$  eV; but for O the difference of  $\mu_x^*$  between solid and liquid is ~2.6 eV, which is much bigger than  $k_BT$ . This means that added O will partition strongly into the liquid, but added S or Si will have similar concentrations in both the solid and the coexisting liquid phase.

Their simulations of the chemical potentials of the alloys can be combined with simulations of their densities to investigate whether the known densities of the liquid and solid core can be matched by any binary Fe/X system, with X = S, O, or Si. Using their calculated partial volumes of S, Si, and O in the binary liquid alloys, one finds that the mole fractions required to reproduce the liquid core density are 16%, 14%, and 18% respectively (Figure C33, panel (a) displays the predicted liquid density as a function of  $c_x$  compared with the seismic density). The calculated chemical potentials in the binary liquid and solid alloys then give the mole fractions in the solid of 14%, 14%, and 0.2%, respectively, that would be in equilibrium with these liquids (see Figure C33, panel (b)). Finally, the partial volumes in the binary solids give ICB density discontinuities of 2.7  $\pm$  -0.5,  $1.8 \pm -0.5$  and  $7.8 \pm -0.2\%$ , respectively (Figure C33, panel (c)). As expected, for S and Si, the discontinuities are considerably smaller than the known value of 4.5  $\pm$  -0.5%; for O, the discontinuity is markedly greater than the known value. Alfè et al. conclude that none of the binary systems can account for the discontinuity quantitatively. The density and seismic character of the core can, however, be accounted for by O together with either or both of S and Si. Ab initio calculations on general quaternary alloys containing Fe, S, O, and Si will clearly be feasible in the future, but currently they are computationally too demanding, so for the moment it is assumed that the chemical potential of each impurity species is unaffected by the presence of the others. This led Alfè et al. to estimate that the mole fractions needed to account for the ICB density discontinuity were 8.5  $\pm$  2.5 mole % S (and/or Si) and 0.2  $\pm$ 0.1% O in the inner core and 10  $\pm$  2.5% S/Si and 8  $\pm$  2.5% O in the liquid outer core. This compositional estimate is based on the value of the density discontinuity at the ICB determined by Shearer and Masters (1990). Since then, Masters and Gubbins (2003) have reassessed the free oscillation data set and have determined the density jump at the ICB to be

**Figure C33** Liquid and solid impurity mole fractions  $c_x^l$  and  $c_x^s$  of impurities X = S, Si, and O and resulting densities of the inner and outer core predicted by *ab initio* simulations. *Solid, dashed* and *chain curves* represent S, Si, and O, respectively. (a) Liquid density  $\rho^l$  (kg m<sup>-3</sup>); horizontal *dotted line* shows density from seismic data. (b) Mole fractions in solid resulting from equality of chemical potentials in solid and liquid. (c) Relative density discontinuity ( $\delta \rho / \rho^l$ ) at the ICB; horizontal *dotted line* is the value from free oscillation data.

 $0.82 \pm 0.18$  Mg m<sup>-3</sup>, which is larger than the previous estimates. Using the new density data of Masters and Gubbins leads to a revised core composition of  $7 \pm 2.5$  mole % S/Si and  $0.2 \pm 0.1$ % O for the inner core and  $8 \pm 2.5$ % S/Si and  $13 \pm 2.5$ % O for the outer core. This sensitivity emphasizes the need for very accurate seismic data if the composition of the core is to be constrained more precisely (see also recent studies by Koper and Pyle (2004) and Cao and Romanowicz (2004)). Finally, we should note that Braginsky and Roberts (1995) have considered the effect of S, Si, and O on core convection and the geodynamo. They concluded on the basis of their dynamical studies, however, that silicon or sulfur would be favored over oxygen as the principal light alloying constituent. The conflict between their conclusions and the atomistic-based deductions of Alfè *et al.* is still to be resolved.

Using however the calculated impurity chemical potentials of Alfè *et al.*, it is possible to use the Gibbs-Duhem relation to compute the change in the Fe chemical potential caused by the impurities in the solid and liquid phases. Alfè *et al.* (2002b) show that the shift of melting temperature ( $\Delta T_{\rm m}$ ) due to the presence of the impurities is

$$\Delta T_{\rm m} = k_{\rm B} T_{\rm m} \left( c_{\rm x}^{\rm s} - c_{\rm x}^{\rm l} \right) / \Delta S_{\rm m} \tag{Eq. 5}$$

where  $k_{\rm B}$  is Boltzmann's constant,  $\Delta S_{\rm m}$  is the entropy of melting of the pure Fe, and  $c_x^{\rm s}$  and  $c_x^{\rm l}$  are the concentration of solute atoms in the solid inner core and liquid outer core, respectively. From their calculated

**Figure C34** The calculated melting curve of Fe (*chained line*), the suppressed melting curve of Fe-alloy in the core assuming that  $\Delta T_{\rm m}$  is independent of depth (*dash line*), and the resulting adiabatic temperature profile (*solid line*) for the outer core obtained using Eq. (6).

values it is clear that the suppression of the core melting temperature  $(\Delta T_{\rm m})$  is dominated by the effect of O, and is approximately –900 K depending upon the exact value of the density contrast at the ICB. Using their *ab initio* estimate of the melting temperature of pure Fe (see *Melting temperature of iron in the core, theory*) at core pressure, Alfè *et al.* predict that the Earth's temperature at the ICB to be ~5300 ± 300 K.

There now appears to be an emerging consensus on the temperature of the ICB, as the value inferred from the work of Alfè *et al.* (~5300  $\pm$  300 K) is close to the value of 5700 K inferred by Steinle-Neumann *et al.* (2001) from independently determined *ab initio* calculations on the elastic properties of the inner core and to the values favored by Poirier and Shankland (1993) and that of 5050  $\pm$  300 K suggested by Anderson (2003). It appears now that only the results inferred from diamond anvil cell (DAC) studies (Boehler, 1996, 2000) lie outside this region of agreement, with these experiments suggesting that the temperature at the ICB is less than 4800 K. The origin for the disagreement between melting temperatures inferred from DAC studies and those obtained from shock data and theory is still to be satisfactorily explained.

This notwithstanding, given the temperature of the ICB, it is possible to calculate the temperature of the core at the CMB, assuming that the outer core temperature profile is adiabatic since

$$\partial T/\partial r = \gamma g T/\Phi$$
 (Eq. 6)

where  $\Phi$  is the seismic parameter,  $\gamma$  is the Grüneisen parameter in the liquid outer core, and g is the acceleration due to gravity (see also Figure C34). As with  $T_{ICB}$ , there is an emerging consensus about the value of  $\gamma$  for the liquid core, with *ab initio* values (e.g., Vočadlo *et al.*, 2003) and those inferred from thermodynamic relations (e.g., Anderson, 2003) both finding  $\gamma$  to be virtually constant along the adiabat, with a value of ~1.5 (however, see Stacey and Davis (2004), who favor a lower value of  $\gamma$ ). Using the *ab initio* value and the melting behavior of Fe alloy determined by Alfè *et al.* leads to an entirely *ab initio* estimate of the core temperature at the CMB of between 4000 ± 300 K. Again, this is in excellent agreement with that inferred from thermodynamic arguments (Anderson, 2003), and coincidentally identical to the value inferred by Boehler (1996), although in this case the agreement is fortuitous, as Boehler's assumed outer core adiabat is much shallower than that used in other studies. # CORE TURBULENCE

#### Introduction

Turbulence is a ubiquitous feature of geophysical flows. The challenge in dealing with turbulence is the broad range of spatial and temporal scales. For the Earth's core, the largest scales of motion  $(L \approx 10^6 \text{ m})$ are set by the geometry of the core, whereas the smallest dissipative scales (l < 0.1 m) are determined by the low viscosity and chemical diffusivity of liquid iron alloys (Dobson, 2000; Vocadlo et al., 2000). The range of time scales is even greater (Hollerbach, 2003). Buoyancy-driven inertial oscillations have diurnal periods (Zhang, 1994), whereas changes in the frequency of magnetic reversals occur on time scales of 10<sup>8</sup> years (McFadden and Merrill, 2000). Such a vast range of spatial and temporal scales prohibits direct simulations of the Earth's geodynamo (q.v.). Instead, modelers must confine their attention to the largest scales and deal with the problem of limited spatial resolution by parameterizing processes that operate at subgrid scales. Spatially constant eddy diffusivities or hyperdiffusivities are routinely used to represent the effects of small-scale flow in geodynamo models (Glatzmaier and Roberts, 1995, 1996; Kageyama and Sato, 1997; Kuang and Bloxham, 1997; Kida et al., 1997; Christensen et al., 1998, 1999; Grote et al., 1999; Kono and Sakuraba, 2000). Even though many of these models are capable of reproducing features of the Earth's field (dipole dominance, episodic reversals, etc.), there is little doubt that simple models based on scalar diffusivities are inadequate representations of the small-scale processes (Buffett, 2003). Theoretical studies (Braginsky and Meytlis, 1990; Shimizu and Loper, 1997) and numerical simulations (St. Pierre, 1996; Matsushima et al., 1999) have shown that small-scale motion is likely to be highly anisotropic due to the influence of rotation and a strong, large-scale magnetic field. Turbulence in the core is expected to have a plate-like structure, which affects the transport of heat and momentum at small scales. The influence of this anisotropy on the large-scale flow is presently unknown.

The nature of turbulence in the core differs in several important respects from the types of turbulence that are encountered in other areas of fluid mechanics (e.g., Tennekes and Lumley, 1972). The first distinction involves the role of the Reynolds number (Re) in characterizing the flow. The Reynolds number describes the relative importance of inertia and viscous forces in the momentum equation, so high Re usually means that inertia has a leading-order role in the dynamics. This expectation may not be valid when other forces are present. The value of Re in the Earth's core is thought to be quite large (perhaps as large as 10<sup>8</sup>) by virtue of the low viscosity of liquid iron and the large size of the core. However, the inertial forces are not expected to have a leading-order role in the momentum equation, where the primary force balance includes the Coriolis, Lorentz, and pressure forces. Large Re in the core means that the effect of inertia in the core is large compared with the effects of viscosity, but inertia is still small compared with other forces. This distinction makes the dynamics of turbulence in the core fundamentally different from that in other high-Re flows.

102

One consequence of this difference is manifest in the spatial distribution of dissipation in the core. Flow in the core is driven by thermal and compositional anomalies. These density anomalies are probably distributed over a very broad range of spatial scales. We expect the work done by buoyancy forces (e.g., the input of energy to the flow) to be distributed over an equally broad range of scales. Another expectation, based on current geodynamo models, is that much of the input energy is dissipated at the scale where it is supplied (Olson and Christensen, 1999; Buffett and Bloxham, 2001). This view of convection in the core is strikingly different from high-Re turbulence, where energy is input at large scales and cascades through a range of progressively smaller scales until viscous dissipation becomes appreciable. Transfers of energy between scales still occur in the geodynamo problem. In fact, these interactions are essential for the operation of the geodynamo (Buffett and Bloxham, 2001). The subtlety of energy transfers to and from the small scales make core turbulence an important part of the geodynamo problem.

### **Eddy diffusion**

Eddy diffusion is based on an analogy with molecular transport of heat and momentum in an ideal gas. The continuum approximation for molecular transport works well when the average distance between collisions of molecules,  $\lambda$ , is small compared with the scale of the flow. With the usual assumption that the velocity scale of molecular motion is proportional to the speed of sound *a*, the kinetic theory of gases predicts that the kinematic viscosity of the gas is (Landau and Lifshitz, 1981)

$$v \approx a\lambda$$
. (Eq. 1

The analogy between molecular and turbulent transport implies that the eddy viscosity (or diffusivity) is described by  $v_T \approx vl$ , where vand l are the velocity and size of the unresolved eddies. Although this analogy is conceptually appealing, it has several serious shortcomings. One of these is a lack of separation between the scale of the turbulent transport and the scale of the resolved motions. Normally, the distinction between the turbulent and resolved scales is imposed by the choice of grid spacing in the numerical calculations. Near the scale of truncation the resolved and unresolved scales are comparable, so the analogy breaks down. Interactions between the resolved and unresolved scales are liable to depend on their relative size, so the effective viscosity would need to vary with the scale of the resolved flow in order to reproduce the effect of interactions between the turbulent and resolved flows.

Another challenge for eddy diffusion models in the geodynamo problem arises from the anisotropic structure of small-scale convection (Braginsky and Metlyis, 1990). Eddies are expected to have longer dimensions in the directions of the rotation axis  $\Omega$  and the local magnetic field **B**, and a much shorter dimension in the perpendicular direction (e.g.,  $\mathbf{\Omega} \times \mathbf{B}$ ). Expectations about the magnitude of the eddy diffusivity (e.g.,  $v_T \approx vl$ ) could be extended from a scalar quantity to a tensor using information about the dimensions of the eddies in the three defining directions. However, such an approach would require substantial effort because the size and orientation of eddies may change as **B** evolves. Moreover, the eddies may not be characterized by a single size or shape. It is more likely that eddies exist over a broad range of scales. The absence of any clear separation between the scale of the eddies and the smallest resolved flows returns us to the problem of requiring the eddy viscosity to vary with the scale of the resolved flow. The most comprehensive attempt to include the effects of anisotropic diffusion in geodynamo models is described in a series of papers by Phillips and Ivers (2000, 2001, 2003).

A variant of the eddy diffusion model replaces the derivatives in the dissipative terms with higher-order operators. This approach is called hyperdiffusion because it enhances the damping of motion or the diffusion of heat as the length scale decreases. Hyperdiffusion addresses the need to make the eddy diffusivity dependent on the scale of the flow. However, the imposed dependence is usually ad hoc. One approach to hyperdiffusion replaces the Laplacian operator  $\nabla^2$  with  $-\nabla^4$  or  $\nabla^6$ , which is equivalent to making the eddy diffusion depend on the wavenumber of the motion in the spectral domain. On the other hand, adding higher order derivatives introduces the problem of requiring additional boundary conditions to solve the problem. Most implementations of hyperdiffusion in geodynamo models alter only the horizontal part of  $\nabla^2$  in spherical coordinates, so that the order of the equations for the radial part of the solution is unchanged (and the number of boundary conditions is unchanged). This means that turbulent diffusion is handled differently in the horizontal and radial directions (Grote et al., 2000). An unintended anisotropy may arise from this implementation of hyperdiffusivity, which is unrelated to the effects of rotation and large-scale magnetic fields.

Eddy diffusion and hyperdiffusion models are computationally simple, but they do a poor job of representing the effects of small-scale turbulence in magnetoconvection calculations (Buffett, 2003). Several alternative strategies have developed in recent years for other applications (see Lesieur and Metais, 1996; Meneveau and Katz, 2000 for recent reviews). Of particular interest is the scale-similarity model, and its variants, because these models have the potential to reproduce the anisotropy of core turbulence. These approaches have grown out of a conceptual framework known as large-eddy simulations. This framework is useful because it defines the modifications to the governing equations when the fields are not resolved. Unfortunately, it does not specify how these additional terms should be evaluated. Another promising approach, based on Lagrangian averaging, is briefly described in the concluding remarks.

# Large-Eddy simulations

Large-eddy simulations use spatial filtering to eliminate scales that are smaller than the grid spacing  $\Delta$ . Each field in the calculation (velocity **V**, for example) is convolved with a filter function  $G(\mathbf{x})$  to define the large-scale fields, e.g.,

$$\widetilde{\mathbf{V}}(\mathbf{x},t) = \int G_{\Delta}(\mathbf{x} - \mathbf{x}') \mathbf{V}(\mathbf{x}') d\mathbf{x}'$$
(Eq. 2)

Analogous expressions define the large-scale temperature  $\tilde{T}$  and magnetic field  $\tilde{B}$ . Applying the filter to the governing equations yields a set of equations for the large-scale fields. To illustrate, we filter the energy equation for an incompressible fluid

$$\frac{\partial T}{\partial T} + \nabla \cdot (\mathbf{V}T) = \kappa \nabla^2 T \tag{Eq. 3}$$

to obtain

$$\frac{\partial \tilde{T}}{\partial t} + \nabla \cdot (\tilde{\mathbf{V}}\tilde{T}) = \kappa \nabla^2 \tilde{T} - \nabla \cdot \mathbf{I}^\Delta, \qquad (\text{Eq. 4})$$

where

$$I_i^{\Delta} = \widetilde{V_i T} - \widetilde{V}_i \widetilde{T}$$
(Eq. 5)

is the subgrid-scale (SGS) heat flux;  $\mathbf{I}^{\Delta}$  represents a correction for the omitted correlations between **V** and *T* when the large-scale heat flux is calculated from  $\tilde{V}_i \tilde{T}$  instead of  $\tilde{V}_i \tilde{T}$ . Other SGS terms arise from the other nonlinear terms in the relevant governing equations. For the problem of convection in the Earth's core, these additional terms include

the SGS momentum flux (or Reynolds stress), the SGS Maxwell stress and the SGS induction term (see Buffett, 2003 for details).

The scale-similarity model makes a direct attempt to estimate (5) using only the resolved part of the fields (Bardina *et al.*, 1980; also see Leonard, 1974). Suppose that we filter the complete (and unknown) fields **T** and **V** using a wider filter, say  $G_{2\Delta}(\mathbf{x})$ , to define the fields **T** and **V**. It follows that the SGS heat flux on the coarser grid (with resolution  $2\Delta$ ) is defined by

$$I_i^{2\Delta} = \overline{V_i T} - \overline{V_i} \overline{T}$$
(Eq. 6)

When the amplitude of the fields with scales between  $2\Delta$  and  $\Delta$  are large compared with the amplitudes at scales below  $\Delta$ , we can approximate  $V_i$  and T in Eq. (6) using  $\tilde{V}_i$  and  $\tilde{T}$ . This substitution yields an approximation for  $I_i^{2\Delta}$ . The scale-similarity method supposes that  $I_i^{2\Delta}$  is similar to  $I_i^{\Delta}$ . Specifically, the spatial pattern is the same, but the amplitude may differ. The modeled SGS heat flux becomes [Germano, 1986]

$$I_i^{\rm m} = C(\overline{\widetilde{V}_i \widetilde{T}} - \widetilde{V}_i \ \overline{\widetilde{T}})$$
(Eq. 7)

where the constant *C* is used to adjust the amplitude of  $I^{\text{m}}$ . Automated procedures for evaluating the model constants have been devised by Germano *et al.* (1991). Implementation of this general scheme for a variant of the scale-similarity method (known as the nonlinear gradient method) yields model constants C that are typically closed to unity in both magnetoconvection and plane-layer dynamo calculations (Matsui and Buffett, 2005). These results are consistent with conclusions drawn previously by comparing  $I_i^{\Delta}$  and  $I_i^m$  using fully resolved calculations (Buffett, 2003; Matsushima, 2004). A number of technical challenges remain to be solved to deal with the effects of boundaries and nonuniform grid spacing. However, the scale-similarity method provides a framework for making progress in modeling the effects of core turbulence.

### Other approaches and considerations

Another method for dealing with resolved motions in numerical simulations is based on Lagrangian averages of fluid parcel trajectories (Holm, 2002). The derivation of the governing equations (known as the alpha model) is based on a variational description of ideal fluid motion (Chen *et al.*, 1999). The current version of the alpha models uses a closure based on Taylor's hypothesis for frozen-in turbulence, although more elaborate descriptions of the small-scale fluctuations could be used, in principle. Extensions of the model to include dissipative effects have been developed using a filtered form of Kelvin's circulation theorem (Foias *et al.*, 2001) and the results have been cast in the form of an LES model (Montgomery and Pouquet, 2002), even though the underlying derivation is fundamentally different. These recent developments offer promising new lines of investigation for the study of core turbulence. It is too early to know whether any of these methods will find widespread use in geodynamo models.

Computational considerations will also govern the choice of suitable turbulence models. The most viable models must be adaptable to computational schemes that can exploit massively parallel computers. Almost all of the existing geodynamo models rely on a spectral expansion of the fields in spherical harmonics. This approach is ideally suited for determining the potential field outside of the core. However, it is poorly suited for parallel computing. The use of spherical harmonics requires excessive communication between processors, and this problem becomes more acute as the number of processors increases. Increasing availability of massively parallel computers has motivated a shift in attention to other methods of solution that are more efficient for parallel computations. New dynamo models based on finite elements (Chan *et al.*, 2001; Matsui and Okuda, 2004), finite differences (Kageyama and Sato, 2004), and spectral elements (Fournier *et al.*, 2004) are now

in various stages of development. One or more of these methods may become the future standard. The choice of turbulence models should be guided by these recent trends because the success of turbulence models is often dependent on the method of solution (Meneveau and Katz, 2000).

# CORE VISCOSITY

### **Definition of viscosity**

The transport properties of fluid materials (either solid or liquid) are determined by their viscosity, which defines the resistance of the material to fluid flow (i.e., how "runny" it is). Viscosity,  $\eta$ , describes the time dependence of material motion through the ratio of applied shear stress,  $\sigma$ , to strain rate,  $\dot{\epsilon}$  via

$$\eta = \frac{\sigma}{\dot{\varepsilon}} \tag{Eq. 1}$$

The Earth's liquid outer core will have a relatively low viscosity compared to that of the solid inner core, which deforms on a much longer timescale. In geophysics, the quantity  $\eta$  is referred to as the dynamic viscosity, which, when normalized by the density,  $\rho$ , is termed the kinematic viscosity, v:

$$v = \frac{\eta}{\rho}$$
(Eq. 2)

Viscosity is a quantity dependent on the properties of the fluid at a molecular level. Therefore, both the viscosities defined above may also be referred to as "molecular viscosity." In the outer core, fluid motion occurs over a range of length scales from that at a molecular level to large-scale motion with characteristic distances comparable with the outer core radius. Such large-scale motion does not exist in isolation, but has embedded within it turbulence over a range of length scales, which serve to drain the largest scale flow of its energy. Consequently, this energy dissipation causes an increase in the viscosity of the largescale fluid, resulting in an "effective viscosity" or "turbulent viscosity" of a much larger magnitude than the molecular viscosity defined earlier. This effective viscosity has been observed experimentally in turbulent fluids yet it is very difficult to quantify and impossible to derive rigorously; however estimates for effective viscosities are often used when modeling the outer core. Viscosity is a very important parameter in geophysics since the viscosity of materials in the Earth's core are a contributory factor in determining overall properties of the core itself, such as core convection (see Core properties and Core convection); indeed, the fundamental equations governing the dynamics of the outer core and the generation and sustention of the magnetic field are dependent, in part, on the viscosity of the outer core fluid.

### Quantifying outer core viscosity

There have been many estimates made for outer core viscosity derived from geodetic, seismological, geomagnetic, experimental, and theoretical studies. However, the values so obtained span 14 orders of magnitude (see Secco, 1995).

Geodetic observations (e.g., free oscillations, the Chandler wobble, length of day variations, nutation of the Earth, tidal measurements, gravimetry) lead to viscosity estimates ranging from 10 mPa s (observations of the Chandler wobble, Verhoogen, 1974) to 10<sup>13</sup> mPa s (analysis

of free oscillation data, Sato and Espinosa, 1967). Theoretical geodetic studies (e.g., viscous coupling of the core and mantle, theory of rotating fluids, *inner core oscillation* (q.v.), core nutation) lead to viscosity estimates ranging from 10 mPa s (evaluation of decay time of *inner core oscillation* (q.v.), Won and Kuo, 1973) to  $10^{14}$  mPa s (secular deceleration of the core by viscous coupling, Bondi and Lyttleton, 1948). Generally much higher values for viscosity ( $10^{10}-10^{14}$  mPa s) are obtained from seismological observations of the attenuation of P- and S-waves through the core (e.g., Sato and Espinosa, 1967; Jeffreys, 1959), and from geomagnetic data (e.g.,  $10^{10}$  mPa s; Officer, 1986).

The viscosities of core-forming materials may also be determined experimentally in the laboratory and theoretically through computer simulation. Empirically, viscosity follows an Ahrrenius relation of the form (see Poirier, 2002):

$$\eta \propto \exp\left(\frac{Q_{\rm v}}{k_{\rm B}T}\right)$$
 (Eq. 3)

where  $Q_v$  is the activation energy. Poirier (1988) analyzed data for a number of liquid metals and found that there is also an empirical relation between  $Q_v$  and the melting temperature:

$$Q_{\rm v} \simeq 2.6 R T_{\rm m}$$
 (Eq. 4)

This very important result implies that the viscosity of liquid metals remains constant (i.e., independent of pressure) along the melting curve and therefore equal to that at the melting point at ambient pressure, which is generally of the order of a few mPa s. Furthermore, Poirier went on to state that the viscosity of liquid iron in the outer core would, therefore, be equal to that at ambient pressure ( $\sim$ 6 mPa s).

On a microscopic level, an approximation for the viscosity of liquid metals is given by the Stokes-Einstein equation, which provides a relationship between diffusion and viscosity of the form:

$$D\eta = \frac{k_{\rm B}T}{2\pi a} \tag{Eq. 5}$$

where *a* is an atomic diameter, *T* is the temperature,  $k_{\rm B}$  is the Boltzmann constant, and *D* is the diffusion coefficient.

Theoretical values for diffusion coefficients have been obtained from *ab initio* molecular dynamics simulations on liquid iron at core conditions (de Wijs et al., 1998), leading to a predicted viscosity of ~12-15 mPa s using the Stokes-Einstein relation above. However, although the Stokes-Einstein equation has proved successful in establishing a link between viscosity and diffusion for a number of monatomic liquids, it is not necessarily the case that it should be effective for alloys or at high pressures and temperatures. To address the validity of the Stokes-Einstein relation and to assess the effect of impurities on viscosity coefficients, a number of experimental and theoretical studies have been performed on the Fe-FeS system. High-pressure tracer diffusion experiments (Dobson et al., 2001) have been carried out on liquid Fe-FeS alloys at 5 GPa, resulting in high diffusivities  $(10^{-5} \text{ cm}^2 \text{ s}^{-1})$  in excellent agreement with *ab initio* molecular dynamics calculations performed at the same conditions (Vočadlo et al., 2000). When incorporated into Eq. 5, these diffusivities lead to values for viscosity of a few mPa s.

Direct viscosity measurements (Dobson *et al.*, 2000) of Fe-FeS alloys by means of the falling-sphere technique have been made at similar pressures and temperatures to those used in the diffusion experiments above; these resulted in values for viscosities in excellent agreement with those derived experimentally using the Stokes-Einstein relation. Furthermore these results are in excellent agreement with *ab initio* molecular dynamics calculations of viscosity based on rigorous Green-Kubo functions of the stresses obtained directly from the simulations (Vočadlo *et al.*, 2000). All of these results thus provide

both experimental and theoretical verification of the Stokes-Einstein relation (Eq. 5).

The results from these studies further show not only that the viscosity of liquid iron at core pressures is approximately equal to that at low pressures, verifying Poirier's groundbreaking and insightful result (Poirier, 1988), but also that the introduction of light elements into Fe liquid does not appear significantly to effect the values. Both *ab initio* calculations and experiments consistently give viscosities of the order of a few mPa s. This suggests that viscosity changes little with homologous temperature, and it is now generally accepted that the viscosity of the outer core is likely to be a few mPa s (comparable to that of water on the Earth's surface).

In general, viscosities derived from Earth observations are high  $(10^7-10^{14} \text{ mPa s})$  and those based on laboratory experiments and theoretical considerations are much lower (~1-10 mPa s). The disparate values for viscosity arise for two main reasons: the type of viscosity being measured (molecular or effective) and the large uncertainties associated with the interpretation of Earth observation data. It is also possible that viscosity measurements made from the direct observations of the Earth are not actually measuring viscosity at all, but some other effects that are being attributed to viscosity; this would certainly be the case if the "true" viscosity were of the order of mPa s, since such a small viscosity is unlikely to be detectable.

A low viscosity leads to viscous forces that are essentially negligible when compared to the Coriolis force, supporting the view of an outer core in a state of small-circulation turbulent convection rather than a more coherent pattern of convection on a much larger scale comparable with the core radius. If this is the case, it is necessary to obtain accurate values for viscosity in order to quantify this turbulence in the outer core.

### Viscosity and the inner core

The inner core is not perfectly elastic and has a finite viscosity with deformation occurring over long timescales. Placing numerical constraints on the viscosity of the inner core is fundamental to understanding important core processes such as differential *inner core rotation* (q.v.), *inner core oscillation* (q.v.), and *inner core anisotropy* (q.v.) (see Bloxham, 1988).

High-temperature experiments on solid iron at ambient pressure lead to estimates for viscosities of  $\sim 10^{13}$  Pa s (Frost and Ashby, 1982); however, this is likely to be a lower limit as the value may increase at higher pressures. Seismological and geodetic observations have led to a number of estimates for inner core viscosity ranging from  $10^{11}$  to  $10^{20}$  Pa s (see Dumberry and Bloxham, 2002). In particular, Buffett (1997) modeled the viscous relaxation of the inner core by calculating the relaxation time for the inner core to adjust, as it rotates, back to its equilibrium shape after small distortions due to perturbations in gravitational potential imposed by the overlying mantle. He suggested that the viscosity has to be constrained to be either less than  $10^{16}$  Pa s (if the whole inner core is involved in the relaxation) or greater than  $10^{20}$  Pa s (if there is no relaxation of the inner core), although this latter case may lead to gravitational locking and hence no differential rotation.

Quantifying the viscosity of the phases present in the inner core at a microscopic level is a very difficult problem. At temperatures close to the melting point (as expected in the inner core) viscous flow is likely to be determined either by dislocation creep (Harper-Dorn creep) or diffusion creep (Nabarro-Herring creep).

The overall viscosity of inner core material has diffusion-driven and dislocation-driven contributions:

$$\eta = \left( \left( \frac{1}{\eta_{\text{diff}}} \right) + \left( \frac{1}{\eta_{\text{disl}}} \right) \right)^{-1}$$
(Eq. 6)

Diffusion-controlled viscosity, whereby the material strain is caused by the motion of lattice defects (e.g., vacancies) under applied stress, is given by

$$\eta_{\rm diff} = \frac{d^2 RT}{\alpha D_{\rm sd} V} \tag{Eq. 7}$$

where *d* is the grain size, *R* is the gas constant, *T* is the temperature,  $\alpha$  is a geometric constant, and *V* is the volume. The self-diffusion coefficient,  $D_{sd}$ , is given by

$$D_{\rm sd} = D_0 \exp\left(-\frac{\Delta H}{RT}\right) \tag{Eq. 8}$$

where  $D_0$  is a preexponential factor and  $\Delta H$  is the activation enthalpy for self-diffusion.

For simple materials, dislocation-controlled viscosity, whereby material strain is caused by the movement of linear defects along crystallographic planes, is given by

$$\eta_{\rm disl} = \frac{RT}{\rho D_{\rm sd} V} \tag{Eq. 9}$$

where  $\rho$  is the dislocation density.

Both dislocation- and diffusion-controlled creep mechanisms are thermally activated and the thermally controlled parameter in both cases is the self-diffusion coefficient,  $D_{\rm sd}$ . A commonly used empirical relation for metals assumes that  $\Delta H$  is linearly proportional to the melting temperature,  $T_{\rm m}$ , and hence that

$$D_{\rm sd} = D_0 \exp\left(-\frac{gT_{\rm m}}{T}\right) \tag{Eq. 10}$$

where g is a constant taking a value of  $\sim 18$  for metals (Poirier, 2002).

Considering iron close to its melting point at core pressures (~5500 K), and using reasonable estimates for other quantities in Eqs. 7, 9, and 10 ( $\alpha \sim 42$ ,  $D_0 \sim 10^{-5}$  m<sup>2</sup> s<sup>-1</sup>,  $V \sim 5 \times 10^{-6}$  m<sup>3</sup> mol<sup>-1</sup>), we obtain values for  $\eta_{\rm diff}$  and  $\eta_{\rm disl}$  of  $\sim 10^{21} d^2$  Pa s and  $\sim 6 \times 10^{22} / \rho$  Pa s, respectively. Unfortunately, the strong dependence of the viscosity expressions on the completely unknown quantities of grain size and dislocation density means that it is extremely difficult to produce reliable final numerical values. Grain sizes in the inner core could be anything from  $10^{-3} - 10^3$  m, resulting in diffusion viscosities in the range  $10^{15} - 10^{27}$  Pa s; dislocation densities could be as low as  $10^6$  m<sup>-2</sup> or nearer to the dislocation melting limit of  $10^{13}$  m<sup>-2</sup>, resulting in dislocation driven viscosities of  $10^9 - 10^{16}$  Pa s. Thus, even the relative contributions from dislocation controlled and diffusion controlled viscosity are as yet unknown.

Clearly, inner core viscosity is not a well-constrained property, with estimates varying over many orders of magnitude. Future microscopic simulations, combined with high-resolution seismic and geodetic data, should constrain this quantity further and thereby improve our understanding of inner core dynamics.

# CORE, ADIABATIC GRADIENT

# Introduction

The importance of temperature T to physical problems of Earth's core is well understood. The adiabatic gradient dT/dz is also important because it induces the transfer of conductive power (the larger the adiabatic gradient, the more conductive power is transferred). When conduction is the dominant form of heat transfer, as it is in the transfer of heat from the core to the mantle, the relation between power Q(Watts) transferred and the adiabatic gradient is

$$Q = Ak \left(\frac{\mathrm{d}T}{\mathrm{d}z}\right) \tag{Eq. 1}$$

where A (m<sup>2</sup>) is the area; k (W m<sup>-1</sup>K<sup>-1</sup>) is the thermal conductivity, a physical property of core material; and z (m) is depth. The ratio of Q to A is called energy flux, Q (W m<sup>-2</sup> or J t<sup>-1</sup> m<sup>-2</sup>).

In an adiabatic state, such as that found in Earth's outer core, the adiabatic gradient of the temperature profile is at constant entropy S, and dT/dz in Eq. 1 is replaced by  $(\partial T/\partial z)_S$ . Equation 1 becomes

$$Q = Ak \left(\frac{\partial T}{\partial z}\right)_{S}$$
(Eq. 2)

To evaluate Eq. 2 for the power transferred from the core to the mantle (at radius 1221 km, the core side of the core-mantle boundary (CMB), or at pressure P = 135 GPa), the core's surface area on the core side of the CMB ( $15.26 \times 10^{13}$  m<sup>2</sup>) is needed.

Adiabaticity is defined as a condition of no heat input or heat output in a region where heat flow occurs. The core has energy input from various sources, yet remains in an adiabatic state. Because the outer core is in a low-viscosity liquid state and well-mixed and because the flows are fast, any departure from the equilibrium of adiabaticity is immediately compensated for. Masters (see *Density distribution in the core*) found that a density gradient could be estimated from normal mode eigenfrequencies (an advanced seismic technique). His density gradient showed adiabaticity.

*Ab-initio* calculations by de Wijs *et al.* (1998) and Vočadlo *et al.* (2003) verify that the value of the core's viscosity is close to that at ambient conditions. The low viscosity of the core confirms the applicability of Eq. 2 to the outer core.

In the following section, we derive an equation for the adiabatic gradient of the core in terms of two parameters of Earth from seismology and two parameters (T and  $\gamma_{\ell}$ , the liquid Grüneisen parameter) from mineral physics. In the section entitled, "Data for the outer core's adiabatic gradient," we make the calculation for the adiabatic gradient versus pressure for the outer core using two sets of mineral physics data. In the section entitled "Data for the inner core's adiabatic gradient," we make the calculation for the adiabatic gradient," we make the calculation for the adiabatic gradient versus radius of Earth for the inner core using two sets of mineral physics data. In the last section, we discuss the implications arising from information listed in the previous sections, especially the maximum power transferred from Earth's outer core to its mantle by conduction.

# The adiabatic gradient's dependence on the Grüneisen parameter

The adiabatic gradient of Earth's interior depends on the value of the Grüneisen parameter  $\gamma$ . Although the formula for this parameter has many manifestations (see *Grüneisen's parameter for iron and Earth's core*), its general definition is that it measures the change in pressure resulting from a change in energy density. The formula for  $\gamma$  fundamental to derivations in this article is

$$\gamma = -\left(\frac{\partial \ln T}{\partial \ln V}\right)_{S} = \left(\frac{\partial \ln T}{\partial \ln \rho}\right)_{S}$$
(Eq. 3)

where T is temperature, V is volume,  $\rho$  is density, and S indicates constant entropy or a path along an adiabat. This equation is applicable to the outer core because we have shown that adiabaticity exists there. We rewrite Eq. 3 to show how temperature varies with density on an adiabat

$$\left(\frac{\partial T}{\partial \rho}\right)_{S} = \frac{\gamma T}{\rho} \tag{Eq. 4}$$

Using the definition of the adiabatic bulk modulus given by  $K_S = \rho(dP/d\rho)$ , we have

$$\left(\frac{\partial T}{\partial P}\right)_{S} = \frac{\gamma T}{K_{S}} \tag{Eq. 5}$$

which shows how temperature varies with pressure along an adiabat. Using the equation for hydrostatic equilibrium in a fluid,  $(\partial P/\partial z)_S = \rho g$ , where g is gravity and z is depth, Eq. 5 is transformed to show how temperature varies with depth along an adiabat

$$\left(\frac{\partial T}{\partial z}\right)_{S} = \frac{\gamma g T}{\phi}$$
(Eq. 6)

where  $\phi$ , the seismic parameter,  $K_S/\rho = v_p^2 - 4/3v_s^2$ , is determinable from the seismic velocities. To write Eq. 6 where the depth z is replaced by the radial distance of Earth r, take z = a - r (where a is Earth's radius), so that

$$\left(\frac{\partial T}{\partial r}\right)_{S} = -\frac{\gamma g T}{\phi} \tag{Eq. 7}$$

To evaluate Eq. 6 or 7, take data for  $\phi$  and g from seismic tables, in particular, PREM (Dziewonski and Anderson, 1981), and data on  $\gamma$ and T from mineral physics sources such as enumerated below. When considering Earth's interior, it is important to distinguish gamma associated with a liquid phase from gamma associated with a solid phase ( $\gamma_1$ , liquid;  $\gamma_s$ , solid). Although the formula for gamma is often the same for both phases, the values are usually different because the physical properties of the two phases are different. For the outer core,  $\gamma_1$  is the proper choice and  $\gamma_s$  is to be used for the inner core. For low values of pressure,  $\gamma_1 \gg \gamma_s$ , but  $\gamma_1 \rightarrow \gamma_s$  as the pressure increases (see Figure 4, *Grüneisen's parameter for iron and Earth's core*). At the ICB (inner core boundary) pressure,  $\gamma_1 \cong \gamma_s$  (see discussion in last section).

# Data for the outer core's adiabatic gradient

A major goal in mineral physics for the last two decades has been to find accurate values of the temperature of the outer core along its adiabat and the associated gamma,  $\gamma_1$ . Since the year 2000, advances in theory and experiment have made possible establishment of good values for these two important parameters at core conditions. Three important advances are listed below:

- a. Values for physical properties of solids at extreme conditions (calculated using *ab-initio* techniques) have been published for the last two decades, but only in the last six years have good *ab-initio* results on liquid iron at core conditions become available. Calculations on properties of liquid hcp iron and of simulated core material at high pressure and temperature have been made by Dario Alfè and his colleagues at University College, London (Alfè *et al.*, 2001, 2002a,b,c); resulting data, especially on  $\gamma_1$  and  $T_m$  are found in Table C7.
- b. Stacey and Davis (2004) presented calculations on the physical properties of the core, including  $\gamma_1$  and *T*, based only on Stacey's K-primed equation of state (Stacey, 2000) and seismic data. Their unique approach does not require the intermediate step of using properties of pure iron followed by adding impurities. These new data are used in this article and compared with those arising from the *ab-initio* method. Data from Stacey and Davis are found in Tables C7 and C8.
- c. Properties of solid iron at extreme conditions are needed at the solid-liquid boundary of the core (330 GPa) and throughout the inner core. Experiments on the variation of the Debye constant  $\Theta_D$  with volume for hcp iron through the pressure range of the core

1. 12

(Anderson *et al.*, 2001) provided the foundation for determination of  $\gamma_s$  versus *V*, the melting temperature (solidus,  $T_m$ ) and the adiabatic temperature (Anderson, 2002a,b; Anderson *et al.*, 2003; Isaak and Anderson, 2003). This method, called the thermal physics approach, relies heavily on thermodynamics and experimental data. Data from this method are found in Table C8.

$$\left(\frac{T_1}{T_0}\right) = \left(\frac{\rho_1}{\rho_0}\right) \tag{Eq. 8}$$

The variation of  $(\partial T/\partial z)_S$  with respect to pressure and temperature using Eq. 6 is shown in Table C7. It is noted that the adiabatic gradient at the CMB (135 GPa) is high (0.996 K km<sup>-1</sup> – 0.886 K km<sup>-1</sup>), comparable to the value used by Nimmo *et al.* (2004), 0.80 K km<sup>-1</sup>. The Stacey and Davis adiabatic gradient values are somewhat (~15%) lower than those of Alfè *et al.* 

#### Data for the inner core's adiabatic gradient

Table C8 displays the calculated adiabatic gradient values for the solid inner core obtained using adiabatic temperature data and  $\gamma_s$  values taken from thermal physics (Anderson, 2002a, Figure 9) and from the K-primed EoS method (Stacey and Davis, 2004). The thermal physics method adopted 1.53 as the value of  $\gamma_s$  throughout the inner core, since  $\gamma_s$  is virtually independent of volume near the ICB (Anderson, 2002a). When  $\gamma_s$  is independent of volume or density, Eq. 4 can be rewritten as  $(dT/T) = \gamma(d\rho/\rho)$ , yielding

which holds for any region in which  $\gamma$  is independent of depth. In the thermal physics approach, the density ratio ( $\rho(r)/12763.60$ ) is used to find the temperature ratio of T(r)/5250 for  $\gamma = \gamma_s = 1.53$ .

Stacey and Davis retain five significant figures in their data, probably in part because PREM tabular data have five significant figures. If their values of  $\gamma_s$  in Table C8 were rounded to three significant figures, a constant value of  $\gamma_s = 1.39$  would hold throughout the entire inner core. Therefore, the calculated value of  $(\partial T/\partial r)_S$  is only listed to three significant figures. The calculated adiabatic gradient from the K-primed EoS approach is about 15% lower than that arising from the thermal physics approach at the ICB pressure.

# Implications of a high adiabatic gradient at the CMB

Equation 2 shows that a high value of  $(\partial T/\partial z)_S$  at the CMB, coupled with a high value of k results in a high value of Q, which is the conductive power transferred from the core to the D" region. The work here implies a large value for the power Q conducted from the core to the mantle. The value of thermal conductivity k to be used in Eq. 1 is needed.

There are three recent estimates of the value of *k* at the core side of the CMB where P = 135 GPa. Labrosse *et al.* (1997) proposed 60 W m<sup>-1</sup> K<sup>-1</sup>. Anderson (1998) proposed 44 W m<sup>-1</sup> K<sup>-1</sup>. Stacey and Anderson (2001) proposed 46 W m<sup>-1</sup> K<sup>-1</sup>. (Older estimates of *k* are: 40 W m<sup>-1</sup> K<sup>-1</sup> (Stevenson, 1981) and 28.6 W m<sup>-1</sup> K<sup>-1</sup> (Stacey, 1992).) Many of the estimates referenced above are based on shockwave work on electrical conductivity measurements of iron-silica alloy done at the Lawrence Livermore National Laboratory (Matassov, 1977). (Matassov's work is recorded in his Ph.D. dissertation filed in the Library of the University of California at Davis, California, and also as an Lawrence Livermore National Laboratory Technical Report (UCRL-52322)).

To find k for a solid, it is necessary to add the lattice conductivity  $k_1$  to the electronic conductivity  $k_e$ . But  $k_1$  is smaller, 3.1 W m<sup>-1</sup> K<sup>-1</sup> (Stacey and Anderson, 2001), and less sensitive to P and T than  $k_e$ . We take

$$k = (3.1 + k_e) \quad W m^{-1} K^{-1}$$
 (Eq. 9)

and obtain  $k_{\rm e}$  from electrical conductivity measurements,  $\sigma$ . We assume that the solid-state conductivity at core pressure can be used for a liquid at core pressure, even though the liquid does not have a periodic lattice. There is a correction to be made in using *k* with a solid rather than a liquid. Braginsky and Roberts (1995) invoked a 10% reduction in thermal conductivity at the transition.

Electrical conductivity  $\sigma$  can be measured more easily at high pressure than thermal conductivity because the latter is a transport property requiring accurate measurements of gradients, whereas the former requires the simpler measurements of current and field. The Wiedemann-Franz ratio, by which the conduction electrons' contribution  $k_e$  to the total thermal conductivity k is calculated from  $\sigma$ , was derived using the classical free electron model of atoms (Joos, 1958)

$$\frac{k_{\rm e}}{\sigma} = \frac{1}{3} \left(\frac{\pi k}{e}\right)^2 T \tag{Eq. 10}$$

It is seen that  $k_e$  is proportional to both T and  $\sigma$ , where k is the Boltzmann constant and e is the electron's charge. On an isotherm,  $k_e$  is proportional to  $\sigma$ .

The value of k reported by Bi *et al.* (2002) for pure iron at core conditions is 30 W m<sup>-1</sup> K<sup>-1</sup>, and a similar value, also for pure iron at core conditions, was found in the work of Matassov (1977); both values were obtained from shock-wave experiments. Our interest here, however, is ultimately in core materials, not pure iron.

Bridgman (1957) found that electrical resistivity is increased as the silicon content is increased in an Fe-Si alloy. Electrical conductivity, being the inverse of electrical resistivity, must therefore decrease as silicon content increases, and from Eq. 10, thermal conductivity must also decrease as silicon content increases. However, pressure increases k.

We follow Stacey's (see *Core, thermal conduction*) derivation of  $k_e$  from Matassov's 1977 measured electrical conductivity and use Stacey's derived parameters for CMB conditions,  $k_{\ell} = 3.1 \text{ W m}^{-1} \text{ K}^{-1}$ ,  $k_e = 43.21 \text{ W m}^{-1} \text{ K}^{-1}$ , and  $k = 46.31 \text{ W m}^{-1} \text{ K}^{-1}$ . These values

are for a liquid core, of an Fe-Ni-Si composition, in which T = 3739 K and  $\gamma_{\ell} = 1.433$  (Stacey and Davis, 2004), from which we find a value of Q(CMB) = 6.23 TW (see Table C9).

The value of  $k_e$  scales as T at constant P (see equation 10) and is therefore larger at the CMB if the  $T_{\rm m}$  is larger than Stacey's 3739 K. Alfè et al. (2002a,b) found  $T_{\rm m}$  to be 4112 K, so in this case the appropriate value of  $k_e$  is 47.52 W m<sup>-1</sup> K<sup>-1</sup>, larger than Stacey's value (see Table C9). But the value for  $\gamma_1$  (CMB) found by Alfè *et al.* (2002a,b), 1.527, is larger than that found by Stacey, and this induces a larger value of  $(\partial T/\partial z)_S$  (0.996). The net result is that for Alfè *et al.*'s data, Q(CMB) = 7.69 TW, larger than Stacey's value, 6.23 TW (see Table C9). The bottom row of Table C9 contains experimental (thermal physics) data. In the thermal physics approach, the measured  $\gamma$ (not shown) is for a solid, not a liquid. Since we are interested in a liquid core, this value of  $\gamma_s$  is generally not appropriate for a calculation of Q. However,  $\gamma_1$ , while much larger than  $\gamma_s$  at low pressure, decreases rapidly with pressure. (A plot of  $\gamma_1$  and  $\gamma_s$  versus pressure is shown in Figure 1 of Anderson, 1998). Convergence of  $\gamma_s$  and  $\gamma_1$  appears to occur above the CMB pressure, 135 GPa. At the ICB pressure (330 GPa), the difference between  $\gamma_1$  (from theory) and  $\gamma_s$  (from experiment) is vanishingly small. Thus, we take  $\gamma_s = \gamma_1$  at the ICB and use the data on  $\gamma_1$  versus pressure to find  $T_{\rm m}$  (CMB) and Q(CMB), as shown below.

We now give details on the determination of  $T_{\rm m}$  and  $k_{\rm e}$  from the *ab initio* and thermal physics approaches. The value of  $T_{\rm m}$  (CMB) in Table C9 for the *K'* equation of state is for the core composition itself, since the *K'* equation of state deals with the real Earth. For the *ab initio* and thermal physics approaches, values of  $T_{\rm m}$  are initially determined at the liquid-solid boundary for pure iron and then changed as corrections for light impurities are invoked. In these two approaches, two corrections must be made. First, there is a correction, resulting from the light impurities, called the temperature depression.

The temperature depression is calculated by assuming chemical equilibrium between the solid and liquid phases. The value  $\Delta T_{\rm m} = T_{\rm m} - T_{\rm m}^*$  represents the temperature depression from  $T_{\rm m}$  of pure iron, where the superscript \* represents the melting temperature of the solute. The symbols  $c_x^l$  and  $c_x^s$  represent the mole fraction of the solute in the liquid and solid phases, respectively. The formula for  $\Delta T_{\rm m}$  is (Landau and Lifshitz, 1958)

$$\Delta T_{\rm m} = \frac{k T_{\rm m}(c_x^s - c_x^l)}{\Delta S} \tag{Eq. 11}$$

where  $\Delta S$  is the entropy of melting. By assuming no impurities in the solid core and ideal solutions, Stevenson (1981) simplified equation 10 to an approximation holding only for the liquid outer core,  $\Delta T_{\rm m}/T_{\rm m} = -\Sigma \ln(1 - \chi_i)$ , where  $\chi_i$  is the mole fraction of the *i*th impurity. The approximation is now known to overestimate the value of  $\Delta T_{\rm m}$ . Anderson (1998) used this approximation to find  $\Delta T_{\rm m}$  for various combinations of light impurities in iron and obtained values near -1000 K.

Alfè *et al.* (2002b) solved the general problem given by equation 11, taking into account that there are light impurities in the inner core as well as the outer core and that partitioning of impurities can occur at

<sup>c</sup>Anderson (1998); Anderson et al. (2003).

the boundary of the liquid and the solid. Alfè *et al.* (2002b) used the impurities O, S, and Si and assumed concentrations for the core. They found:

- a. A large concentration of oxygen impurities ( $\sim 8$  mole percent) is in the outer liquid core and a much smaller concentration ( $\sim 0.3$  mole percent) is in the inner solid core (Alfè *et al.*, 2002b). These oxygen concentrations in the inner and outer cores explain the density jump at the ICB (a solid-liquid core interface) found from seismology. Silicon and sulfur impurity concentrations, which are almost evenly distributed between the inner and outer cores, cannot help explain the density jump.
- b.  $\Delta T_{\rm m}$  due to impurities = -700 K (Alfè *et al.*, 2002a), which satisfies the seismically determined density jump at the ICB. Since  $T_{\rm m}$  of iron at the ICB pressure is 6200 K, the value of  $T_{\rm m}(\rm{ICB}) = 5500 \,\rm{K}$  in the *ab initio* approach. Thus,  $\Delta T_{\rm m}/T_{\rm m} = -0.1129$ .

To find the temperature depression due to impurities from the thermal physics approach, we adopt the results of the calculation for  $\Delta T_m/T_m$  from the *ab initio* approach, e.g.,  $\Delta T_m/T_m = -0.1129$ . Since  $T_m$  for iron at the ICB pressure is 6050 K (Anderson *et al.*, 2003), we have  $\Delta T_m = -683$  K and  $T_m$ (ICB) = 5367 K.

We now make the calculation for the value of  $T_{\rm m}$  of the core at the CMB pressure (135 GPa). The value of  $\gamma_1$  along the liquidus found using *ab initio* methods goes from 1.488 at the CMB to 1.527 at the ICB, a change of only 3% (Alfè, pers. comm. 2003). These values are sufficiently close such that the value of  $T_{\rm m}$  (CMB) may be calculated using  $\gamma = 1.51$  in equation 8, resulting in

$$T_{\rm m}({\rm CMB}) = T_{\rm m}({\rm ICB})(9903/12\,166)^{\gamma}$$
 (Eq. 12)

For  $\gamma = 1.51$  and  $T_{\rm m}(\rm{ICB}) = 5500$  K, we find  $T_{\rm m}(\rm{CMB}) = 4112$  K from the *ab initio* method. For the thermal physics method, we use equation 12 with  $\gamma = 1.51$ , obtaining  $T_{\rm m}(\rm{CMB}) = 3940 \pm 100$  K, using  $\Delta T_{\rm m}/T_{\rm m} = -0.1129$  and  $T_{\rm m}(\rm{ICB}) = 5367$  K. In the calculations, we have implicitly assumed that the values are for the liquidus, even though the measured properties are for the solidus in the thermal physics approach. We justify this because at the ICB the measured  $\gamma_{\rm s} = 1.50$ , whereas from the *ab initio* approach the value is  $\gamma_{\rm l} = 1.53$ . Thus,  $\gamma_{\rm l}$  and  $\gamma_{\rm s}$  have nearly converged. We assume convergence and therefore can use the liquidus properties for the adiabatic decompression calculation. We assign an error of  $\pm 100$  K to  $T_{\rm m}(\rm{CMB})$  because of the lack of exact convergence.

The value of thermal conductivity must be found. Since  $T_{\rm m}$ (CMB) is higher for the *ab initio* method and the thermal physics method than for the *K'* EoS method, the value of  $k_{\rm e}$  is correspondingly higher. Equation 10 shows that  $k_{\rm e}$  is proportional to *T*, and appropriate values of  $k_{\rm e}$  and *k* are entered in Table C9. The resulting values of Q(CMB) in Table C9 are found from equation 1. It is seen that the highest value of Q(CMB), 7.7 TW, is from the *ab initio* method and the lowest value, 6.2 TW, is from the *K'* EoS method. Midway between the extremes is the value of Q(CMB) from the thermal physics method, 7.0  $\pm$  0.2 TW.

How is one to choose between the three values of Q(CMB) shown in Table C9? First, we note that the three values are fairly close, especially when one considers the differences in the three methodologies. Second, all three methods have a history of success, so preferring a value from one method is somewhat arbitrary. Third, perhaps the best way to regard these results is that Q(CMB) should lie between a minimum value, 6.2 TW, and a maximum value, 7.7 TW. It is to be noted that the maximum value, 7.7 TW, is the closest to three recent results arising from theories of core thermal history. The total power passing from the core to D" was reported as 8.3 TW by Gubbins *et al.* (2003), 9 TW by Gubbins *et al.* (2004), and 7.31 TW by Nimmo *et al.* (2004).

# CORE, BOUNDARY LAYERS

### **Basic ideas**

It might be said that the term *boundary layer* means different things to different people. To someone observing fluid flowing past a flat plate, it might seem that there are two distinct regimes of motion. Far from the plate, the flow might seem too fast for the eye to follow, markers carried by the fluid appearing blurred as they speed past the plate; near the plate however the flow is so sluggish that it is easily followed by eye. The observer may call this the boundary layer, and the region beyond the free-stream or the mainstream, and he may feel that the interface between the two is reasonably sharp, so that he can call it the edge of the boundary layer. The theoretician will see no such sharp interface but will employ a mathematical technique, sometimes called matched asymptotics that similarly distinguishes an inner region near the plate from the outer region beyond. For him, the edge of the boundary layer is a region where the two solutions are required to agree with one another, i.e., to match.

To be successful, the asymptotic approach requires that the kinematic viscosity, v, is small, as measured by an appropriate nondimensional parameter, such as the inverse Reynolds number in the case of the flow past the plate, or the Ekman number, E, for the situations we encounter below. The thickness,  $\delta$ , of the boundary layer is then small compared with the characteristic scale, *L*, of the system, so that  $\varepsilon = \delta/L$  is small and vanishes with *v*; this does not imply that it is proportional to *v*.

The inner and outer solutions are developed as expansions in powers of  $\varepsilon$ . The relative size of successive terms in the expansions is determined by the matching process. Provided  $\varepsilon$  is sufficiently small, only a few terms in each expansion are needed to obtain useful solutions of acceptable accuracy. In what follows, we shall retain only the first, or "leading" term in the expansion of the inner solution, u, but will require the first and second terms in the expansion of the outer solution, U. The primary (leading order) part,  $U_0$ , of the outer solution is independent of v and can therefore only satisfy one condition at a stationary impermeable boundary  $\Gamma$ , namely  $U_{0\perp} \equiv \mathbf{n} \cdot \mathbf{U} = 0$ , where **n** is the unit normal to  $\Gamma$ , directed into the fluid. The components  $\mathbf{U}_{0\parallel}$  of  $\mathbf{U}_0$  that are tangential to  $\Gamma$  will then in general be nonzero on z = 0, where z measures distance from  $\Gamma$  in the direction of **n**. The task of the boundary layer is to reconcile  $\mathbf{U}_{0\parallel}$  at z = 0 with the no-slip condition:  $\mathbf{u} = \mathbf{0}$  on  $\Gamma$ . This means that  $\mathbf{u}_{\parallel}$  must, through the action of viscosity, be reduced from  $\mathbf{U}_{0\parallel}$  to zero in the distance  $\delta$ . To achieve this deceleration, the viscous term in the momentum equation,  $-v\nabla^2 \mathbf{u}_{\parallel}$ , must be finite and nonzero. Since this force is of order  $v\mathbf{u}_{\parallel}/\delta^2$ , it follows that  $\delta$  is proportional to  $v^{1/2}$ .

To derive the inner expansion, the stretched coordinate,  $\zeta = z/\delta$ , is introduced to replace the distance z from  $\Gamma$ . The boundary layer is then characterized by  $\zeta = \mathcal{O}(1)$  and  $\partial_{\zeta} \equiv \partial/\partial \zeta = \mathcal{O}(1)$ , so that  $\partial_z \equiv \partial/\partial z = \mathcal{O}(1/\delta) \gg 1/L$ . In contrast,  $\nabla_{\parallel}$  is much smaller; as in the mainstream, it is  $\mathcal{O}(1/L)$ . The matching principle asserts that the inner and outer expansions should agree with each other at the edge of the boundary layer, which is defined as a region where  $z \ll L$  but  $\zeta \gg 1$ . [For example, if  $z = \mathcal{O}(L\delta)^{1/2}$ , then  $z/L = \mathcal{O}((\delta/L)^{1/2}) \downarrow 0$ and  $\zeta = \mathcal{O}((L/\delta)^{1/2}) \uparrow \infty$  as  $\varepsilon \downarrow 0$ .]

A significant consequence follows from mass conservation and the matching principle. Since variations in density across the thin boundary layer can be ignored at leading order, mass conservation requires that  $\nabla \cdot \mathbf{u} = 0$ . At leading order, this gives

$$\partial_{\zeta} \mathbf{u}_{\perp} + \nabla_{\mathbf{S}} \cdot \mathbf{u}_{\parallel} = 0.$$
 (Eq. 1a)

Here  $\nabla_s$  is the surface divergence, which may be defined, in analogy with the better known definition of the three-dimensional divergence, as a limit. For any vector  $\mathbf{Q}$  depending on position  $\mathbf{x}_{\parallel}$  on  $\Gamma$  and directed tangentially to  $\Gamma$ ,

$$\nabla_{\mathbf{S}} \cdot \mathbf{Q} = \lim_{A \to 0} \frac{1}{A} \oint_{\gamma} \mathbf{Q} \cdot \mathbf{N} ds.$$
 (Eq. 1b)

Here  $\gamma$  is the perimeter of a small "penny-shaped disk" on  $\Gamma$  of area *A*; ds is arc length and **N** is the outward normal to  $\gamma$  lying in  $\Gamma$ . This is shown in Figure C35, which also gives the disk a small thickness

**Figure C35** Efflux from the top of a "penny shape" volume encompassing the boundary layer. This compensates the volume flux deficit in the boundary layer through the sides of the volume.

 $z = \ell$ . Since Nds = ds × n, where the vector element ds of arc length is in the right-handed sense with respect to n, an application of Stokes's theorem to Eq. (1b) gives

$$\boldsymbol{\nabla}_{\mathbf{S}} \cdot \mathbf{Q} = \lim_{A \to 0} \frac{1}{A} \oint_{\gamma} \, \mathrm{d} \mathbf{s} \cdot (\mathbf{n} \times \mathbf{Q}) = \lim_{A \to 0} \frac{1}{A} \int_{A} \, \mathrm{d} \mathbf{S} \cdot (\boldsymbol{\nabla} \times (\mathbf{n} \times \mathbf{Q})),$$

where  $d\mathbf{S} = \mathbf{n}dS$  is the vector element of surface area on A. From which it follows that

$$\boldsymbol{\nabla}_{\mathrm{S}} \cdot \mathbf{Q} = \mathbf{n} \cdot \boldsymbol{\nabla} \times (\mathbf{n} \times \mathbf{Q}). \tag{Eq. 1c}$$

This is generally a more convenient form of the surface divergence than (1b).

Since  $\Gamma$  is impermeable,  $\mathbf{u}_{\perp} = 0$  on  $\zeta = 0$  and Eq. (1a) gives (on taking  $\mathbf{Q} = \int_{0}^{\zeta} \mathbf{u}_{\parallel} d\zeta$ )

$$\mathbf{u}_{\perp}(\zeta) = \mathbf{n} \cdot \boldsymbol{\nabla} \times \left( \int_{0}^{\zeta} \mathbf{u}_{\parallel} d\zeta \times \mathbf{n} \right).$$
 (Eq. 1d)

We now choose the "top" face of the penny in Figure C35 to be at the edge of the boundary layer, i.e.,  $\delta \ll \ell \ll L$ . Then, by the asymptotic matching principle, the left-hand side of Eq. (1d) is both  $u_{\perp}(\zeta \uparrow \infty)$  and  $U_{\perp}(z \downarrow 0)$ . Since the right-hand side of Eq. (1d) is  $\mathcal{O}(\delta)$ , this contribution to U is small compared with  $U_0$ , i.e., it refers to the second, or "secondary," term  $U_1$  in the expansion of U. This also establishes that the ratio of the secondary and primary terms in the expansion of U is  $\mathcal{O}(\delta)$  and not, as might have been supposed a *priori*,  $\mathcal{O}(v) = \mathcal{O}(\delta^2)$ .

It follows from (1d) that, for z = 0,

$$\mathbf{U}_{1\perp} = \mathbf{n} \cdot \boldsymbol{\nabla} \times (\mathbf{Q}_{\parallel} \times \mathbf{n}), \qquad (\text{Eq. 2a})$$

where  $\mathbf{Q}_{\parallel}$  is now the volume flux deficit in the boundary layer:

$$\begin{split} \mathbf{Q}_{\parallel} &= \delta \int_{0}^{\infty} (\mathbf{u}_{\parallel} - \mathbf{U}_{\parallel}) \mathrm{d}\zeta, \quad \text{or} \quad \mathbf{Q}_{\parallel} = \int_{0}^{z/\delta \uparrow \infty} (\mathbf{u}_{\parallel} - \mathbf{U}_{\parallel}) \mathrm{d}z. \end{split} \tag{Eq. 2b, c}$$

The second of these equivalent forms, which will be used later, provides a convenient way of reminding us that the *z*-integration is only across the boundary layer and not across the entire fluid. In each expression,  $\mathbf{U}_{\parallel}$  is evaluated at z = 0 and therefore depends on  $\mathbf{x}_{\parallel}$  only.

Equation 2a provides a crucial boundary condition on  $U_1$ . Further boundary conditions are not needed and in fact could not be imposed without overdetermining the solution. Not even the term  $v\nabla^2 U_0$ appears in the equation governing  $U_1$ , since this term is  $\mathcal{O}(v) = \mathcal{O}(\delta^2)$ , i.e., is asymptotically small compared with  $U_1$ . For flow past a flat plate, the source (2a) at the boundary has the effect of displacing the effective boundary by an amount of order  $\delta$ , which is then often called "the displacement thickness"; e.g., see Rosenhead (1963, Chapter V.5). For the Ekman and Ekman-Hartmann layers considered in "The Ekman layer" and "The Ekman-Hartmann layer" below, the effect of the secondary flow is more dramatic.

Ekman layers arise at the boundaries of highly rotating fluids; Ekman-Hartmann layers are their generalization in magnetohydrodynamics (MHD). The Ekman-Hartmann layer must reconcile both the mainstream flow **U** and the magnetic field **B** to conditions at a boundary  $\Gamma$ , where we assume that  $\mathbf{u} = \mathbf{0}$  and  $\mathbf{b} = \mathbf{B}_{\Gamma}$ . It follows from  $\nabla \cdot \mathbf{b} = 0$  that  $b_{\perp}$  is the same everywhere in the boundary layer. It therefore coincides with  $B_{\Gamma\perp}$  at the wall and with  $B_{0\perp}$  at the edge of the boundary layer. The remaining components of **b** change rapidly through the boundary layer:  $\mathbf{b} = \mathbf{B}_0$  at its "upper" edge and  $\mathbf{b} = \mathbf{B}_{\Gamma}$ , at its "lower" edge. This occurs because the current density,  $\mathbf{j}_{\parallel}$ , in the boundary layer is large. In analogy with Eq. (2a), there is a secondary current flow  $J_{1\perp}$  between the boundary layer and the mainstream given by

$$J_{1\perp} - J_{\Gamma\perp} = \mathbf{n} \cdot \boldsymbol{\nabla} \times (\mathbf{I}_{\parallel} \times \mathbf{n}), \qquad (\text{Eq. 3a})$$

where  $I_{\parallel}$  is the electric current deficit:

$$\begin{split} \mathbf{I}_{\parallel} &= \delta \int_{0}^{\infty} (\mathbf{j}_{\parallel} - \mathbf{J}_{\parallel}) d\zeta, \quad \text{or} \quad \mathbf{I}_{\parallel} = \int_{0}^{z/\delta \to \infty} (\mathbf{j}_{\parallel} - \mathbf{J}_{\parallel}) dz. \end{split} \tag{Eq. 3a, b}$$

If the exterior region, z < 0, is electrically insulating,  $J_{\Gamma} = 0$ , so bringing Eq. (3a) even closer to Eq. (2a). When attention is focused on the mainstream magnetic field alone, I is the symptom of the boundary layer that has most significance, and it is thought of as a "current sheet." In a similar way, the volumetric deficit Q may be regarded as a "vortex sheet."

The theory necessary to evaluate **Q** and **I** will be described in "The Ekman layer." It will be found that, as far as the effects of viscosity are concerned, the relevant boundary layer scale is the Ekman layer thickness,  $\delta_{\rm E} = (\nu/\Omega)^{1/2} = E^{1/2}L$ , where  $E = \nu/\Omega L^2$  is the Ekman number and  $\Omega$  is the angular speed of the system.

# **Geophysical overtones**

The mathematical concepts introduced above need to be handled with care when applied to a complex object like the Earth's core. Various intricate physical effects can occur in the core and a mathematical model by essence requires some simplifying assumptions. Let us first note that the dynamics of the Earth's core is often modeled by a set of coupled physical quantities: the magnetic field, the fluid velocity, and a driving mechanism (usually thermal and/or chemical). This introduces (see Anelastic and Boussinesq approximations) at least three diffusivities. The magnetic diffusivity largely dominates the two others. It follows that boundary layers (associated with low diffusivities) can develop both based on the smallness of viscosity (as discussed above) and on the smallness of say the thermal diffusivity (compositional diffusivity being even smaller). The thickness of such thermal (compositional) boundary layers,  $\delta_{\kappa}$ , depends on the thermal (compositional) diffusivity (or the relevant turbulent diffusivity),  $\kappa$ , of core material. These layers are conceptually significant in understanding how heat enters and leaves the FOC. We shall not consider them in this article and refer the reader to Anelastic and Boussinesq approximations.

Assume that  $L = 2 \times 10^6$  m is a typical large length scale of core motions and magnetic fields (see *Core motions*). If the molecular viscosity v is  $10^{-6}$  m<sup>2</sup>/s, then E is about  $10^{-15}$ . This suggests that an asymptotic solution to core MHD is fully justified as far as the effects of viscosity are concerned. A mainstream solution would be expected away from the boundaries and a boundary layer would develop near the mantle and near the solid inner core.

This line of thought is also the basis for the determination of core surface motions from observations of the main geomagnetic field and its secular variation. On the assumption that electric currents generated in the mantle by the geodynamo are negligible, the observed fields can be extrapolated downwards to the CMB and used to provide information about the fluid motions "at the top of the core," using Alfvén's theorem. A difficulty however remains: the fluid in contact with the mantle co-rotates with it by the no-slip condition. There *is* no relative motion! Realistically, one can hope only to determine the mainstream flow at the edge of the boundary layer. The connection between the fields at the CMB to the fields at the edge of the boundary layer was considered by Backus (1968), who presented an analysis of Ekman-Hartmann type. Hide and Stewartson (1972) made further developments of the theory.

The boundary layer thickness,  $\delta_E$ , obtained from the above estimate of the Ekman number is however only about 10 cm and it is natural to wonder whether such a thin layer can have any effect whatever on the dynamics of a fluid body that is about ten million times thicker! Turbulence provides amelioration. It is widely accepted that the molecular viscosity is inadequate to transport large-scale momentum in the core, its role being subsumed by small-scale turbulent eddies. These, and the associated momentum flux, are highly anisotropic through the action of Coriolis and Lorentz forces (Braginsky and Meytlis, 1990). Nevertheless, a crude ansatz is commonly employed: the molecular v is replaced by an isotropic turbulent viscosity having the same order of magnitude as the molecular magnetic diffusivity, that is to say about 1 m<sup>2</sup>/s. Then  $E \approx 10^{-9}$  and the asymptotic approach still seems secure. Even ignoring the possible intrinsic instability of the boundary layer (see "Stability of the Ekman-Hartmann layer"), it is reasonable to suppose that the small-scale eddies would penetrate the boundary layer so that a better estimate of  $\delta_{\rm E}$  would be 100 m. That such a layer would have a dynamical effect on the dynamics of the core then seems less implausible.

There are, however, skeptics who believe that, even if the boundary layers are 100 m thick, they are still too thin to be of geophysical interest. Kuang and Bloxham (1997) removed them by replacing the noslip conditions on the core-mantle boundary (CMB) and inner core boundary (ICB) by the conditions of zero tangential viscous stress. This step obviously eliminates viscous coupling between the fluid outer core (FOC) and mantle and between the FOC and the solid inner core (SIC). Then, in the absence of other coupling mechanisms, the rotation of the mantle and the SIC does not affect the dynamics of the FOC and spin-up does not occur (see "The Ekman layer"). Geophysical justification for the step rests on estimates indicating that, owing to the large electrical conductivity of the SIC and despite the relatively small electrical conductivity in the mantle, the magnetic couples between the FOC and both the mantle and the SIC still greatly exceed the viscous couples, which can therefore be disregarded by adopting the zero viscous stress conditions. In this article we shall ignore such complications and adopt the "traditional approach" where no-slip conditions apply at both boundaries. See also Core-mantle coupling.

Although the smallness of *E* makes the asymptotic approach to MHD very attractive, purely analytic methods are not powerful enough to provide the solutions needed; numerical methods must be employed. One might nevertheless visualize a semianalytic, seminumerical approach in which the computer finds an inviscid mainstream flow **U** and magnetic field **B** that satisfy the boundary conditions (2a) and (3a). This too is not straightforward, since solutions for v = 0 raise important numerical difficulties and to restore *v* to the mainstream would be tantamount to repudiating the boundary layer concept.

At this stage it is natural to wonder what use asymptotic methods have in core MHD. In the present state of algorithmic development and computer capability, the answer may seem to be, "Not much!" The boundary layer concept is, however, valuable in locating regions requiring special attention in numerical work, such as free shear layers and boundary layer singularities ("Free shear layers"). Moreover, the only way of verifying that the numerical simulations have reduced the effect of viscosity on core dynamics to a realistic level is by confronting them with the expectations of asymptotic theory.

### The Ekman layer

Consider an incompressible fluid of uniform density,  $\rho$ , moving steadily with velocity  $\mathbf{u}$ , relative to a reference frame rotating with constant angular velocity  $\mathbf{\Omega}$ . In this reference frame, the Coriolis force per unit volume,  $2\rho\mathbf{\Omega} \times \mathbf{u}$ , is balanced by the pressure gradient  $-\nabla p$  and the viscous stresses  $\rho v \nabla^2 \mathbf{u}$ , where v is the kinematic viscosity. The normal component of this balance gives, to leading order in the boundary layer expansion,  $\nabla_{\perp} p = \mathbf{0}$ , which implies that the pressure, p, throughout the boundary layer coincides with the pressure, P, in the mainstream at the edge of the boundary layer. The tangential components give dominantly

$$2\Omega_{\perp}\mathbf{n} \times \mathbf{u}_{\parallel} = -\nabla_{\parallel}(P/\rho) + v\partial_{zz}\mathbf{u}_{\parallel}, \qquad (\text{Eq. 4})$$

which shows that only the component,  $\Omega_{\perp} \equiv \Omega \cdot \mathbf{n}$ , of angular velocity normal to the boundary is significant at leading order. We assume here that  $\Omega_{\perp} \neq 0$ .

Inside the *Ekman layer* governed by Eq. (4), the interplay between the additional viscous forces needed to meet the no-slip boundary condition causes the flow to be deflected from the direction of U, leading to the well known Ekman spiral of the velocity  $\mathbf{u}(z)$  as  $z/\delta$  increases from zero to infinity; see Figure C36.

As a consequence of the Ekman spiral there is a transverse mass transport, which is quantified by the volume flux deficit

$$\mathbf{Q}_{\parallel} = \frac{1}{2} \delta_{\mathrm{E}} [-\mathbf{U}_{0} + (\mathrm{sgn} \Omega_{\perp}) \mathbf{n} \times \mathbf{U}_{0}], \quad \text{where} \quad \delta_{\mathrm{E}} = \sqrt{(\nu/|\Omega_{\perp}|)}$$
(Eq. 5a, b)

is the appropriately redefined Ekman layer thickness which, over curved boundaries such as the CMB and ICB, depends on  $x_{\parallel}$  through  $\Omega_{\perp}$ . The velocity  $U_{1\perp}$  follows directly from Eq. (2a); see also Greenspan (1968, p. 46):

$$\mathbf{U}_{1\perp} = \mathbf{n} \cdot \mathbf{u} = \frac{1}{2} \mathbf{n} \cdot \nabla \times \{ \delta_{\mathrm{E}} [\mathbf{n} \times \mathbf{U}_0 + (\mathrm{sgn}\Omega_{\perp})\mathbf{U}_0] \}, \qquad (\mathrm{Eq.}\ 6a)$$

which, when the mainstream velocity  $\mathbf{U}_0$  is geostrophic and boundary is planar normal to the rotation vector  $(\mathbf{n} \times \mathbf{\Omega} = \mathbf{0})$ , takes the simpler form

$$\mathbf{U}_{1\perp} = \mathbf{n} \cdot \mathbf{u} = \frac{1}{2} \delta_{\mathrm{E}}(\mathrm{sgn}\Omega_{\perp}) \mathbf{n} \cdot \boldsymbol{\nabla} \times \mathbf{U}_{0}. \tag{Eq. 6b}$$

This relates the normal flow to the vorticity  $\nabla \times U_0$  of the primary mainstream flow (see also Pedlosky, 1979).

The phenomenon described by Eq. (6) is often called Ekman pumping or *Ekman suction* depending on whether  $u_{\perp} >$  or < 0. It should again be stressed that the secondary flow induced by the mainstream boundary condition (6) is scaled by the boundary layer thickness  $\delta_{\rm E}$ and is therefore small. It is worth emphasizing however that this modification of the effective boundary conditions introduces dissipation into the mainstream force balance, and this generally provides the dominant dissipation mechanism for a sufficiently large-scale flow. More precisely, for all flows in the mainstream characterized by a length scale larger than  $LE^{1/4}$ , dissipation within the boundary layers will dominate over the bulk effects of viscosity. Indeed, Ekman pumping/suction is a particularly significant process in determining the evolution of the angular momentum of a rotating fluid, which occurs on the spin-up timescale,  $\tau_{s-u} = E^{-1/2}/\Omega = E^{1/2}L^2/\nu$ , i.e., on a timescale intermediate between the rotation period  $2\pi/\Omega$  (the day) and the viscous diffusion time  $L^2/v$  (which, for the molecular v, would exceed the age of the Earth).

**Figure C36** Side (*left*) and top (*right*) views of the Ekman layer profile. The velocity executes a spiral from zero velocity on the boundary to the mainstream velocity **U** at the edge of the boundary layer. The theory of the Ekman layer adumbrated above assumes that conditions are steady. It can be adapted to time-dependent situations provided they do not change too rapidly, i.e., provided that they occur on timescales longer than the rotation period  $2\pi/\Omega$ . When considering the effects on core flow of the lunisolar precession, in which  $\Omega$  changes on the diurnal timescale, the present theory is inapplicable.

# The Ekman-Hartmann layer

The situation described in "The Ekman layer" is now generalized to MHD; the fluid is electrically conducting and a magnetic field is present. In the mainstream, the electric current density, **J**, is given by Ohm's law:

$$\mathbf{J} = \sigma(\mathbf{E} + \mathbf{U} \times \mathbf{B}), \tag{Eq. 7a}$$

where **E** is the electric field and  $\sigma$  is the electrical conductivity. The Lorentz force per unit volume,  $\mathbf{J} \times \mathbf{B}$ , is therefore of order  $\sigma B^2 U$ . In the Earth's core, this is comparable with the Coriolis force  $2\rho \mathbf{\Omega} \times \mathbf{U}$ . The Elsasser number,  $\Lambda = \sigma B^2 / \rho \Omega$ , is therefore of order unity. The asymptotic limit of interest is therefore  $E \downarrow 0$  with  $\Lambda = \mathcal{O}(1)$ . Since  $\Lambda = M^2 E$ , where  $M = BL(\sigma / \rho v)^{1/2}$  is the Hartmann number, it follows that  $M \sim E^{-1/2} \uparrow \infty$  as  $E \downarrow 0$ .

Both **B** and the magnetic field, **b**, in the boundary layer obey Gauss's law, and to dominant order  $\nabla \cdot \mathbf{b} = 0$  gives, as before ("Basic ideas"),  $\partial_{\zeta} \mathbf{b}_{\perp} = 0$ , from which  $\mathbf{b}_{\perp} = B_{\Gamma \perp} = \mathbf{B}_{0\perp}$ , at the edge of the mainstream. We shall suppose that  $\mathbf{B}_{0\perp} \neq 0$ . Ohm's law in the boundary layer is essentially the same as (7a) but, in our notation, it is written as

$$\mathbf{j} = \sigma(\mathbf{e} + \mathbf{u} \times \mathbf{b}). \tag{Eq. 7b}$$

We again suppose steady conditions so that  $\mathbf{E} = -\nabla \Phi$  and  $\mathbf{e} = -\nabla \phi$ , where  $\Phi$  and  $\phi$  are the electric potentials in the mainstream and boundary layer. The above expressions in terms of electric potentials correspond to a low magnetic Reynolds number description. It is important to remember we are here concerned with the magnetic Reynolds based on the boundary layer scale. This is a very small quantity in the case of the Earth's core. To leading order, the normal component of Eq. (7b) is  $e_{\perp} = -\partial_{\zeta}\phi = 0$  and this shows that, throughout the boundary layer,  $\phi$  coincides with  $\Phi$  both at the edge of the mainstream and on the boundary itself. This generally depends on  $\mathbf{x}_{\parallel}$ , so that a current  $\mathbf{J}_{\Gamma} = \sigma_{\Gamma} \mathbf{E}_{\Gamma}$  flows in the stationary wall, if its conductivity  $\sigma_{\Gamma}$  is nonzero. To leading order, the components of Eq. (7b) parallel to  $\Gamma$  together with Ampère's law,  $\mu \mathbf{j} = \nabla \times \mathbf{b}$ , where  $\mu$  is the magnetic permeability, imply

$$\mu^{-1}\mathbf{n} \times \partial_z \mathbf{b}_{\parallel} = \sigma(-\nabla_{\parallel}\phi + \mathbf{u}_{0\parallel} \times \mathbf{B}_{0\perp}). \tag{Eq. 8}$$

[The last term in Eq. (7b) also contributes  $U_{1\perp} \times b_{0\parallel}$  but, as this is asymptotically smaller than the term  $u_{0\parallel} \times B_{0\perp}$  retained, it has therefore been discarded.]

The determination of the boundary layer structure requires the equation of motion to be satisfied too. This differs from Eq. (4) by the addition of the Lorentz force. This may be decomposed into a magnetic pressure gradient and the divergence of the Maxwell stress **bb**/ $\mu$ . The magnetic pressure can be absorbed into *p* to form a total pressure which, by the same argument as before, is constant across the boundary layer to leading order. The components of the equation of motion parallel to  $\Gamma$  are governed by

$$2\Omega_{\perp}\mathbf{n} \times (\mathbf{u}_{\parallel} - \mathbf{U}_{0\parallel}) = -(\mathbf{B}_{\perp}^2/\rho\mu\eta)(\mathbf{u}_{\parallel} - \mathbf{U}_{0\parallel}) + \nu\partial_{zz}\mathbf{u}_{\parallel} \quad (\text{Eq. 9})$$

see Gilman and Benton, (1968) and Loper, (1970).

Equations 8 and 9 determine the structure of the Ekman-Hartmann layer which, in the limit  $\Lambda \downarrow 0$ , becomes the Ekman layer considered in "The Ekman layer" (see Figure C37). For  $\Lambda \uparrow \infty$ , the Coriolis force

**Figure C37** Streamwise component of the velocity in the boundary layer for different values of the Elsasser number, illustrating the smooth transition from an Ekman-type boundary layer to the Hartmann-type boundary layer.

is unimportant and the theory reduces to that governing the Hartmann layer, which is a well known boundary layer that arises in the study of MHD duct flow at large Hartmann number; see, e.g., Roberts (1967), Müller and Bühler (2001). It is then found that

$$\mathbf{u}_{\parallel} = \mathbf{U}_{0\parallel} [1 - \exp(z/\delta_{\mathrm{H}})]$$
(Eq. 10a, b)

where  $\delta_{\rm H} = \sqrt{(\rho v/\sigma)/|B_{\perp}|}$  is the Hartmann layer thickness. For a flat boundary, there is no flux deficit and  $U_{1\perp}$  therefore vanishes. Equations (8) and (9) also show that

$$\Lambda = B_{\perp}^2 / \rho \mu \eta \Omega_{\perp} = \left(\delta_{\rm E} / \delta_{\rm H}\right)^2 \tag{Eq. 11}$$

is a convenient redefinition of the Elsasser number measuring the relative importance of Lorentz and Coriolis forces in determining the boundary layer structure. For small A, the Ekman spiral persists together with the associated boundary layer pumping. As *E* increases through O(1)values, these effects decrease until at large A the flow becomes unidirectional without any associated boundary layer pumping.

#### Free shear layers

Supposing that the Earth's fluid core occupies the spherical  $r_i \le r \le r_0$ , we redefine the Ekman and Hartmann numbers by

$$E = v/r_0^2 \Omega = \delta_{\rm E}^2/r_0^2$$
 and  $M^2 = r_0^2 |\mathbf{B}|^2 / \rho v \mu \eta = r_0^2 / \delta_{\rm H}^2$   
(Eq. 12a, b)

respectively, and redefine the Elsasser number (11) as  $\Lambda = M^2 E$ . In what follows,  $(r, \theta, \varphi)$  will be spherical coordinates in which the colatitude  $\theta$  is zero at the north pole. We shall also employ cylindrical polar coordinates  $(s, \varphi, z)$ .

As explained earlier, Ekman-Hartmann layers are generally present on both the CMB,  $r = r_0$  and the ICB  $(r = r_i)$ . Since horizontal variations are negligible in comparison with the very rapid variation across the layers, the curvature of the spherical boundaries does not affect our earlier results as these depend only on the components of  $\Omega$  and **B** normal to the boundaries. Where these vanish, the theory adumbrated in "The Ekman layer" and "The Ekman-Hartmann layer" breaks down, and boundary layer singularities arise. To focus on these, we at first consider only the nonmagnetic case, M = 0. At the equator of the inner sphere, where the Ekman layer is singular, Eq. (2a) ceases to apply and a new force balance is struck, and a new type boundary layer arises called the equatorial Ekman layer. This is intimately linked to a free shear layer, which surrounds the tangent cylinder, i.e., the imaginary cylinder touching the inner sphere at the equator and having generators parallel to the rotation axis (see *Inner core: tangent cylinder*). This shear layer exhibits a complicated asymptotic structure that is best illustrated by the Proudman-Stewartson problem (Proudman, 1956; Stewartson, 1957, 1966), which concerns the slow steady axisymmetric flow induced by rotating the solid inner core at a slightly faster rate than the outer solid mantle. The flow pattern that occurs in this fundamental configuration illustrates the interplay between the various boundary and shear layers. It is important to stress that these layers do not take into account magnetic effects. Such effects are important in the Earth core and lead to a variety of shear layers whose details are not discussed here (see Kleeorin *et al.* 1997).

The mainstream flow is dominantly geostrophic and azimuthal:  $U_G = U_G(s)\hat{\varphi}$ , where  $\hat{\varphi}$  denotes the unit vector in the  $\varphi$ -direction. Outside the tangent cylinder,  $s = r_i$ , the fluid co-rotates with the outer sphere, and there is no Ekman layer on the CMB. Within the tangent cylinder,  $U_G(s)$  adjusts its value so that the Ekman suction,  $-U_r(r_i) = \mathcal{O}(E^{1/2}U_G)$ , into the Ekman layer on the ICB equals the Ekman pumping,  $U_r(r_o)$ , out of the Ekman layer on the CMB. This generates a secondary flow  $U_z(s)\hat{z}$  in the mainstream that has only a z-component. It depends on s alone; such flows are termed geostrophic. In the northern (southern) hemisphere it is negative (positive).

As the tangent cylinder is approached from within,  $U_G$  tends to the inner sphere velocity. The jump in the geostrophic velocity across the tangent cylinder is smoothed out in an exterior quasigeostrophic layer  $(s > r_i)$  in which the effects of Ekman pumping on the outer core boundary  $\sim \Omega E^{1/2} \partial_s U_G$  is now balanced in the axial vorticity equation by lateral friction  $v \partial_{sss} U_G$  in a layer of width  $\mathcal{O}(r_0 E^{1/4})$ , the Stewartson  $E^{1/4}$ -layer. There is a comparable but thinner  $E^{2/7}$ -layer inside  $(s < r_i)$ , whose main function is to smooth out  $\partial_s U_G$  and so achieve continuity of stress.

These quasigeostrophic layers do not resolve all the flow discontinuities. The secondary mainstream flow,  $U_z(s)\hat{z}$ , feeds the Ekman layers on the ICB with fluid. In each hemisphere, the associated mass flux deficit,  $\mathbf{Q}_{\parallel}$ , is directed towards the equator and builds up as the equator is approached. Mass conservation demands that this fluid be accounted for, and this is one of the main functions of the shear layer at the tangent cylinder. The fluid is ejected towards the CMB as a jet in an inner ageostrophic layer of width  $\mathcal{O}(r_0 E^{1/3})$ , the Stewartson  $E^{1/3}$ -layer.

As the equator is approached, the Ekman layer becomes singular: from (5b),  $\delta_{\rm E} \sim \mathcal{O}(|\theta - \pi/2|^{-1/2}E_i^{1/2}r_i) \to \infty$ , as  $\theta \to \pi/2$ , where  $E_i = v/r_i^2 \Omega = E(r_0/r_i)^2$  is the Ekman number based on the inner core radius. When  $|\theta - \pi/2| = \mathcal{O}(E_i^{1/5})$  however, this expression for  $\delta_{\rm E}$ becomes of the same order as the distance,  $\mathcal{O}((\theta - \pi/2)^2 r_i)$ , of the point concerned in the Ekman layer from the tangent cylinder. This defines the lateral extent,  $\mathcal{O}(E_i^{1/5}r_i)$ , of the equatorial Ekman layer, i.e., the distance over which the solution (5a) fails. The radial extent of the equatorial Ekman layer is  $\mathcal{O}(E_i^{2/5}r_i)$ .

The MHD variant of Proudman-Stewartson problem reveals various other shear layers (Hollerbach, 1994a; Kleeorin *et al.*, 1997; Dormy *et al.*, 2002), while a nonaxisymmetric version exhibits even more structure (Hollerbach, 1994b; Soward and Hollerbach, 2000). Other investigations have been undertaken in plane layer (Hollerbach, 1996) and cylindrical (Vempaty and Loper, 1975, 1978) geometries.

### Stability of the Ekman-Hartmann layer

The laminar Ekman-Hartmann layer profiles are determined by the linearized equations 8 and 9. This corresponds to a small Re approximation, where Re = UL/v is the Reynolds number and L is some characteristic length, possibly the core radius  $r_0$ , but perhaps smaller. In view of the low viscosity in the Earth's liquid core, and of its large size, Re is naturally huge. In the boundary layers, however, the relevant length scale is the boundary layer width  $\delta$ . Thus the corresponding Reynolds number Re<sub>BL</sub> =  $U\delta/v$  (often referred to as the "boundary layer Reynolds number") is much less than Re<sub>0</sub> =  $Ur_0/v$  for the full core. Since the width of the Ekman-Hartmann layer is based on the normal components  $\Omega_{\perp}$  and  $B_{\perp}$  of both the rotation and the magnetic field, Re<sub>BL</sub> depends on position,  $\mathbf{x}_{\parallel}$ . Both these components decrease with latitude (at any rate for a magnetic field having dipole symmetry) and so the boundary layer width  $\delta$  increases as the equator is approached, just as we explained in connection with the equatorial Ekman layer. Consequently the boundary layer Reynolds number Re<sub>BL</sub> increases in concert.

Evidently the boundary layer Reynolds number  $Re_{BL}$  is much smaller than  $Re_0$  and for geophysical parameter values it may be sufficiently small to justify the linear approach described in the previous sections. In that circumstance a linear stability analysis may be undertaken to determine a critical value of  $Re_{BL}$  (say  $Re_c$ , which the boundary layer becomes unstable (usually as a traveling wave). It is well known that boundary layer profiles with inflection points are generally prone to instability (e.g., Schlichting and Gersten, 2000). So, on the one hand, the Hartmann layer (10), which lacks an inflection point, is extremely stable to disturbances up to high values of  $Re_{BL}$  while, on the other hand, the Ekman and Ekman Hartmann profiles, which spiral, can develop instabilities at moderate  $Re_c$ .

Much effort has been devoted identifying the critical Reynolds number  $\text{Re}_c$  and the associated traveling wave mode of instability, whose orientation is determined by its horizontal wave vector  $\mathbf{k}_{\parallel}$ . Comprehensive Ekman layer stability studies have been undertaken in both the case of vertical rotation  $\Omega_{\parallel} = \mathbf{0}$  (Lilly, 1966) and oblique rotation  $\Omega_{\parallel} \neq \mathbf{0}$  (Leibovich and Lele, 1985).

The Ekman-Hartmann layer stability characteristics have been investigated in the context of the Earth's liquid core. For a model with normally directed magnetic field and rotation ( $\Omega_{\parallel} = B_{\parallel} = 0$ ), it has been shown for Earth core values of  $\Omega$  and *B* (Gilman, 1971) that Re<sub>BL</sub> is less than the critical value Re<sub>0</sub> necessary for an instability to grow. Since Re<sub>BL</sub> is so small, the linearization leading to Eqs. (8) and (9) is justified. The more general orientation with  $\Omega_{\parallel} \neq 0$  and  $B_{\parallel} \neq 0$  appropriate to the local analysis of a shell with an axisymmetric dipole magnetic field has also been studied. Desjardins *et al.* (2001) show that, while the Ekman-Hartmann layer is stable in the polar caps, an equatorial band extending some 45° both north and south of the equator could develop instabilities.

# CORE, ELECTRICAL CONDUCTIVITY

Core processes responsible for the geomagnetic field dissipate energy by two competing mechanisms that both depend on the electrical conductivity,  $\sigma_e$ , or equivalently the reciprocal quantity, resistivity,  $\rho_e = 1/\sigma_e$ . The obvious dissipation is ohmic heating. A current of density *i* (amperes/m<sup>2</sup>) flowing in a medium of resistivity  $\rho_e$  (ohm m) converts electrical energy to heat at a rate  $i^2 \rho_e$  (watts/m<sup>3</sup>). Thus one requirement for a planetary dynamo is a sufficiently low value of  $\rho_e$  (high  $\sigma_e$ ) to allow currents to flow freely enough for this dissipation to be maintained. In a body the size of the Earth, this means that the core must be a metallic conductor. However, a metal also has a high thermal conductivity, introducing a competing dissipative process (see *Core, thermal conduction*). The stirring of the core that is essential to dynamo action maintains a temperature gradient that is at or very close to the adiabatic value (see also *Core, adiabatic gradient*) and conduction of heat down this gradient is a drain on the energy that would otherwise be available for dynamo action.

Heat transport by electrons dominates thermal conduction in a metal and the thermal and electrical conductivities are related by a simple expression (the Wiedemann-Franz law; see *Core, thermal conduction*). Thus, while the viability of a dynamo depends on a conductivity that is high enough for dynamo action, it must not be too high. In reviewing planetary dynamos, Stevenson (2003) concluded that high conductivity is a more serious limitation. It is evident that if the Earth's core were copper, instead of iron alloy, there would be no geomagnetic field.

# The conductivity of iron

By the standards of metals, iron is a rather poor electrical conductor. At ordinary temperatures and pressures its behavior is complicated by the magnetic properties, but these have no relevance to conduction under conditions in the Earth's deep interior. We are interested in the properties of nonmagnetic iron, which means iron above its Curie point, the temperature of transition from a ferromagnetic to a paramagnetic (very weakly magnetic) state (1043 K), or in one of its nonmagnetic crystalline forms, especially the high pressure form, epsilon-iron  $(\in$ -Fe). Extrapolations from high temperatures and high pressures both indicate that the room temperature, zero pressure resistivity of nonmagnetic iron would be about 0.21  $\mu\Omega$  m. This is slightly more than twice the value for the familiar, magnetic form of iron and more than ten times that of a good conductor, such as copper. This is one starting point for a calculation of the conductivity of the core. A more secure starting point is the resistivity of liquid iron, just above its zero pressure melting point (1805 K), 1.35  $\mu\Omega$  m, although this is only marginally different from a linear extrapolation from 0.21  $\mu\Omega$  m at 290 K, because melting does not have a major effect on the resistivity of iron.

# Effects of temperature and pressure

For a pure metal, resistivity increases almost in proportion to absolute temperature, but increasing pressure has an opposite effect. Phonons, quantized thermal vibrations of a crystal structure, scatter electrons, randomizing the drift velocities that they acquire in an electric field. The number of phonons increases with temperature, shortening the average interval between scattering events and increasing resistivity. Pressure stiffens a crystal lattice, restricting the amplitude of thermal vibration, or, in quantum terms, reducing the number of phonons at any particular temperature. It is convenient to think of the vibrations as transient departures from a regular crystal structure and that electrons are scattered by the irregularities. Although this is a highly simplified view it conveys the sense of what happens. Temperature increases crystal irregularity and pressure decreases it.

The temperature and pressure effects are given a quantitative basis by referring to a theory of melting, due in its original form to F.A. Lindemann. As modified by later discussions, Lindemann's idea was that melting occurs when the amplitude of atomic vibrations reaches a critical fraction of the atomic spacing. Stacey (1992) suggested that this was equivalent to saying that melting occurs at a particular level of the same crystal irregularity as is responsible for electrical resistivity and therefore that the resistivity (of a pure metal) is constant on the melting curve. The suggestion was given a mathematical basis by Stacey and Anderson (2001), simplifying the problem of extrapolating the resistivity of pure iron to core conditions. We need to know only how far the core is from the melting curve of iron and to make a relatively minor adjustment from the resistivity of liquid iron at zero pressure.

To verify the validity of this approach we can examine the available measurements on resistivity of iron and its alloys at relevant pressures and temperatures. The only experiments used the shock-compression method to measure resistivities at pressures up to 140 GPa, just inside the core range. The primary data source is an unpublished thesis by G. Matassov, who made a series of measurements on Fe-Si alloys and assembled earlier measurements on Fe and Fe-Ni. Some care is required in the interpretation because temperature is uncontrolled and must be estimated from insecure thermodynamic data on the Hugoniot or shock-compression curve, but Stacey and Anderson (2001) found that within the 10% uncertainty of the calculation the resistivity of pure solid iron at the melting point and a pressure of 140 GPa agreed with the zero pressure melting point value.

# Effect of impurities

Theory is weaker when we consider the effect of alloying ingredients, that is impurity resistivity (see *Core composition*). Measurements on dilute alloys of iron with several other elements at nominal pressures up to 10 GPa (7% of the pressure at the top of the core) were reported by P.W. Bridgman. In this range the impurity effect is reasonably simple. It is more or less independent of both temperature and pressure and the added resistivity increases in a regular way with the total impurity content but is similar for different elements. These observations are helpful to our understanding of impurity resistivity in alloys with higher impurity contents, for which the simple picture breaks down, and to the behavior at much higher pressures, but for direct observations we rely almost entirely on data in the Matassov thesis.

Assuming that the conclusion from measurements on dilute alloys, that the total impurity content is more important than the identities of the impurity atoms, can be extended to higher concentrations, we can use the Fe-Si and Fe-Ni data reported by Matassov as indicative of core resistivity, without knowing what the core impurities are. We simply require sufficient of these core impurities to lower the outer core density by 10% relative to pure iron. On this basis Stacey and Anderson (2001) estimated the core impurity resistivity to be 0.90  $\mu\Omega$  m.

# Conductivity variation within the core

The density contrast between the inner, solid and outer, liquid cores substantially exceeds the difference between densities of solid and liquid of the same composition. The inferred partial rejection of light solutes by the solid as the inner core grows (see Convection, chemical) means that there is a melting point depression and that the inner core boundary temperature is below the melting point of pure iron (see Melting temperature of iron in the core). The difference is less higher up in the core because the melting point gradient is steeper than the adiabat, so that there is a slight increase in resistivity upwards in the core. The temperature corrections are applied to the pure liquid iron melting point resistivity, assumed to coincide with the zero pressure value, 1.35  $\mu\Omega$  m, by taking resistivity to be proportional to absolute temperature and then the constant impurity resistivity, 0.90  $\mu\Omega$  m, is added. In this way Stacey and Anderson (2001) obtained outer core resistivities of 2.12  $\mu\Omega$  m at the core-mantle boundary and 2.02  $\mu\Omega$  m at the inner core boundary. The difference is less than the uncertainties in these values, but the variation is real. With a lower impurity content, plus solidification, the inner core resistivity is about 1.6  $\mu\Omega$  m.

Converting these values to conductivities, we have  $\sigma_e = 4.7 \times 10^5$  S m<sup>-1</sup> at the core-mantle boundary,  $5.0 \times 10^5$  S m<sup>-1</sup> at the inner core boundary, and  $6.3 \times 10^5$  S m<sup>-1</sup> in the inner core.

# Magnetic diffusivity

It is sometimes convenient to refer not to conductivity or resistivity but to magnetic diffusivity. For nonferromagnetic materials, this is

$$\eta_{\rm m} = \rho_{\rm e}/\mu_0$$

where  $\mu_0 = 4\pi \times 10^{-7}$  H m<sup>-1</sup> is the permeability of free space. As for any other diffusivity the SI unit is m<sup>2</sup>s<sup>-1</sup> and with the resistivity estimates above the outer core value is 1.6 to 1.7 m<sup>2</sup>s<sup>-1</sup>.

# Introduction

The technique of considering the stability of some basic state to a perturbation is an essential one in fluid dynamics since it can give significant insight into fundamental mechanisms (see for example Chandrasekhar, 1961; Drazin and Reid, 1981). The classic example is that of Rayleigh-Bénard convection, in which fluid is contained between two horizontal flat plates. The lower plate is heated and the upper cooled. Since colder fluid is heavier than warmer fluid, the basic state consists of fluid at rest, with density  $\rho$  increasing with height z. This configuration is potentially unstable (heavy fluid lying over light fluid). However, convection (overturning of the fluid) will only take place if the density gradient  $d\rho/dz$  is sufficiently large; the buoyancy force arising from the variation in density must be large enough to overcome the viscous drag of the fluid. An alternative way of thinking about this is to consider a small parcel of fluid. Consider a perturbation of the basic state that causes the parcel to move upwards. This results in the displacement of heavier fluid downward, the whole process releasing gravitational potential energy stored in the basic state. If this energy is greater than the work done against viscous drag then the perturbation will grow. Otherwise it will decay. The density gradient that marks the borderline between these two situations is known as the critical density gradient. The nondimensional number commonly used to measure the density gradient is known as the Rayleigh number

$$Ra \equiv g\alpha\beta\ell^4/\nu\kappa. \tag{Eq. 1}$$

where g is the gravitational acceleration,  $\alpha$  the coefficient of volume expansion  $(-\rho^{-1}\partial\rho/\partial T)$ ,  $\beta$  the temperature gradient (-dT/dz),  $\ell$  the distance between the plates, v the kinematic viscosity, and  $\kappa$  the thermal diffusivity of the fluid.

Much can be learned from linear theory which determines the critical value  $Ra_c$  of the Rayleigh number. Of fundamental interest to the geodynamo problem is the dependence of  $Ra_c$  on the rotation rate  $\Omega$  and the magnetic field **B** (see *Core convection*).

Here, since the topic of thermal instability (or convection) is dealt with elsewhere, we shall focus on other sources of instability, in particular magnetic instability. The principle is the same; the basic state stores energy and a perturbation may extract that energy. The perturbation grows (i.e., the basic state is unstable) if energy is extracted and is more than enough to overcome any diffusive losses.

#### Magnetic instability

Associated with any magnetic field **B** is its magnetic energy  $\int_{V} (B^2/2\mu) dV$ where  $\mu$  is the magnetic permeability and V is the region containing the field. If a rearrangement of field lines would result in a lower magnetic energy (just as the interchange of heavy and light fluid, as discussed above, results in a lower gravitational potential energy), then there is the possibility of instability driven by the magnetic field. Of course, the field cannot be considered in isolation. In the Earth's core, the field permeates a conducting fluid and the evolution of the field and the motion of the core fluid are strongly coupled. This inevitably constrains what rearrangements of field lines are possible. If a permitted rearrangement results in a lower total energy, then instability will result if the energy released exceeds the diffusive losses resulting from the rearrangement.

Mean-field dynamo theory (see Dynamos, mean field) focuses on the generation of an axisymmetric (or mean) magnetic field by the action of a mean electromotive force (e.m.f.) and differential rotation. A topic that has received somewhat less attention is that of the stability of the field to nonaxisymmetric perturbations. In mean-field dynamo theory, the field is maintained when the generation effect of the mean e.m.f. and differential rotation balance the decay due to ohmic diffusion. However, if the field is sufficiently strong and it satisfies certain other conditions then the field may be in an unstable configuration. Instability can extract energy from the mean field, so the generation mechanism may have a second sink of energy to counteract. Magnetic instabilities may therefore play an important role in determining what fields are observed and how strong they are. Linear theory has established that the minimum field strength required for instability (though depending on many factors) is comparable with estimates of the Earth's toroidal field strength. Also, a careful analysis (McFadden and Merrill, 1993) of the reversal data has concluded that "reversals are triggered by internal instabilities of the fluid motion of the core." Here, we review the various classes of magnetic instability and the conditions required for instability.

#### **Classes of instability**

Energy can be extracted from a basic magnetic field by a rearrangement of field lines in one of two ways; with or without reconnecting field lines. In a perfectly conducting fluid, field lines are frozen into the fluid (see *Alfvén's theorem*) and field lines can neither be broken nor reconnected. This constrains what perturbations are possible. An instability is known as ideal if it can extract energy without reconnecting field lines and can therefore exist in a perfectly conducting fluid. Alternatively, if the existence of an instability depends on reconnecting field lines and is therefore absent in a perfectly conducting fluid, the instability is described as resistive.

A given magnetic field configuration  $\mathbf{B}$  in an ideal fluid may be stable. Adding resistive effects can destabilize it. While initially somewhat counter-intuitive, the reason is quite clear; adding the effect of resistivity increases the number of degrees of freedom of the system by allowing field-line reconnection. A very similar situation is familiar in parallel shear flows where an inviscid flow may be stable, but can be destabilized by adding viscosity (see for example Drazin and Reid, 1981).

### The key parameter; the Elsasser number

For both ideal and resistive modes of instability, resistive effects (otherwise known as ohmic diffusion) also play a more traditional role; diffusion acts to damp out instability if diffusion is sufficiently strong, just as is the case for viscosity in thermal convection, see Eq. (1). The key parameter in the case of magnetic instability in a rapidly rotating system (such as the Earth's core) is the Elsasser number

$$\Lambda \equiv \frac{B^2}{2\Omega\mu_0\rho_0\eta} \left( = \frac{\sigma B^2}{2\Omega\rho_0} = \frac{\tau_\eta}{\tau_s} \right),$$
 (Eq. 2)

where the ohmic diffusion time

$$\tau_{\eta} = \frac{\mathcal{L}^2}{\eta} \tag{Eq. 3}$$

and the slow MHD time scale

$$\tau_s = \frac{2\Omega}{\Omega_A^2}, \text{ where } \Omega_A^2 = \frac{\mathcal{B}^2}{\mu_0 \rho_0 \mathcal{L}^2}.$$
 (Eq. 4)

In the above,  $\mathcal{B}$  is the magnetic field strength,  $\Omega$  is the rotation frequency of the Earth,  $\mu_0$  is the magnetic permeability of free space,  $\rho_0$  is the core density,  $\mathcal{L}$  is a characteristic length scale, for example the radius of the core,  $\sigma$  is the electrical conductivity, and  $\eta = 1/(\mu_0 \sigma)$  is the magnetic diffusivity.

The Elsasser number is a nondimensional measure of the field strength. It can also be thought of as an inverse measure of the strength of magnetic diffusion;  $\Lambda \to \infty$  is the perfectly conducting limit. The expression of  $\Lambda$  in terms of the ratio of  $\tau_{\eta}$  and  $\tau_{s}$  is instructive;  $\tau_{s}$  is the timescale on which diffusionless magnetic waves evolve in a rapidly rotating system for which  $\Omega \gg \Omega_{\Lambda}$  ( $\Omega_{\Lambda}$  is the Alfvén frequency, see *Alfvén waves*). When  $\Lambda$  is large ( $\tau_{\eta} \gg \tau_{s}$ ) the timescale on which magnetic diffusion acts and we therefore expect diffusive damping to be negligible. By contrast, when  $\Lambda$  is of order unity we can expect diffusive damping to be important. When  $\Lambda$  is small, the magnetic field is weak; it will have insufficient energy to drive an instability and will not play a dominant role in the dynamics of the fluid.

# Conditions for instability

As expected from the above argument, detailed model calculations (based on the simultaneous solution of the Navier-Stokes equations and the magnetic induction equation for a prescribed axisymmetric field in a given geometry, see for example Fearn, 1994) indeed show that a necessary condition for magnetic instability is

$$\Lambda > \Lambda_c$$
 (Eq. 5)

where the exact value of  $\Lambda_c$  of course depends on the choice of field used in the model. Values of order 10 are typical. This is significant, because, for the Earth's core,  $\Lambda = 10$  corresponds to a field strength of some 5 mT. Field strengths in the core are believed to be of this order so it is probable that magnetic instabilities are relevant to the dynamics of the Earth's core, and indeed may play an important role in constraining the field strength.

In addition to the condition (5) on the field strength, instability is also dependent on the field geometry (or shape). Condition (5) is about there being sufficient energy stored in the field. The geometric conditions described below are about whether that energy can be extracted. The specific discussion here is tailored to the case of a rapidly rotating fluid, as is appropriate for application to the Earth's core. Most of the qualitative ideas, though, apply equally well to systems that are not rotating or where rotational effects are much less important, for example in laboratory plasmas (e.g., see Davidson, 2001) and the solar atmosphere (e.g., see Priest, 1982).

### Ideal instability

Motivated by the belief that the toroidal part of the core field dominates the poloidal part, early work focussed on purely azimuthal fields of the form

$$\mathbf{B} = B\mathbf{e}_{\phi} \tag{Eq. 6}$$

where  $(s, \phi, z)$  are cylindrical polar coordinates and  $\mathbf{e}_{\phi}$  is the unit vector in the  $\phi$ -direction and z is the axial direction. A local stability analysis for B = B(s) (Acheson, 1983) has shown this to be unstable if B increases sufficiently rapidly with s somewhere in the core. The nature of this condition has led to the alternative name field gradient instability. If  $B \propto s^{\alpha}$  then the condition for the field-gradient instability is  $\alpha > 3/2$ . More generally Acheson (1983) found instability if

$$\Delta \equiv \frac{2s^2}{B} \frac{\mathrm{d}}{\mathrm{d}s} \left(\frac{B}{s}\right) > m^2, \tag{Eq. 7}$$

where m is the azimuthal wavenumber of the instability.

Numerical studies of field (6) have confirmed Acheson's prediction and then gone on to consider more complex fields (see Fearn, 1994 for a review). Where Eq. (7) is not satisfied everywhere, there is a tendency for the instability to be concentrated in the region where Eq. (7) is satisfied.

It is worth commenting at this stage on the field  $B \propto s(\alpha = 1)$  that results from a uniform current in the z-direction. This choice leads to a particularly simple form of the Lorentz force. For this reason, it has often been used in studies of the effect of a magnetic field on thermally driven convection. It is not ideally unstable in a rapidly rotating system, but *is* ideally unstable in a nonrotating system. Rotation is therefore seen to have an inhibiting effect. There are several studies that identify rather esoteric instabilities of magnetic origin for  $B \propto s$ . Fearn (1988) was able to link these to the presence of some additional effect, for example stable density stratification, counteracting the inhibiting effect of rotation. The message from this is that while  $B \propto s$  is a perfectly adequate choice for the purpose of studying the effect of a magnetic field on convection, it is not a typical field for the study of magnetic instability.

### Resistive instability

Resistive instability is usually associated with so-called critical levels  $\mathbf{k} \cdot \mathbf{B} = 0$  where  $\mathbf{k}$  is the wave vector of the instability. For fields of the form (6), this condition reduces to B = 0, i.e., resistive instability is associated with there being a zero of the azimuthal field somewhere in the core. The condition  $\mathbf{k} \cdot \mathbf{B} = 0$  is well known in the nonrotating plasma physics literature and the main effect of rotation is to modify the timescale on which the instability operates. Field-line curvature is unimportant; the instability has been found both for curved fields of the form (6) and for straight field lines.

# Discussion

Further studies have looked at adding a *z*-dependence to *B* and also investigated poloidal fields. These have shown that the basic qualitative understanding derived from studying the field (6) is robust; see discussion and references in Fearn (1998). In applying these ideas to the core, we know that the mean toroidal field vanishes on the axis, so must increase with *s* somewhere, before decreasing again to zero at the core-mantle boundary. It is also likely that the resistive

instability condition  $\mathbf{k} \cdot \mathbf{B} = 0$  will be satisfied somewhere. To further investigate fields relevant to the core, Zhang and Fearn (1994, 1995) have investigated the stability of the toroidal and poloidal decay modes of the core (see Figures C38 and C39) and found them to be unstable, with  $\Lambda_c$  typically in the range 10–20. Given all this, it seems highly likely that any dynamo generated field will have a configuration that is unstable somewhere in the core. Whether or not it is actually unstable will then depend on the field strength.

Several studies have investigated the combined effects of thermal convection and magnetic instability. A recent study (Zhang and Gubbins, 2000) builds on the Zhang and Fearn work referred to above, incorporating a basic magnetic field that is a combination of toroidal and poloidal decay modes and also includes density stratification. In general, instability is a result of both thermal and magnetic forcing.

**Figure C38** Contours of  $\mathbf{B}_{\phi}$  for two toroidal decay modes (*one on the left and one on the right*) studied by Zhang and Fearn (1994). Reproduced with the permission of Taylor & Francis.

**Figure C39** Field lines for two poloidal decay modes (*one on the left and one on the right*) studied by Zhang and Fearn (1995). Reproduced with the permission of Taylor & Francis.
One way of visualizing this is through a graph of Ra<sub>c</sub> versus  $\Lambda$ . This has a negative gradient (Ra<sub>c</sub> decreases as  $\Lambda$  increases) with the graph cutting the horizontal axis (Ra = 0) at  $\Lambda = \Lambda_c$ . As  $\Lambda$  is decreased from this point the contribution from magnetic energy to the instability decreases and the thermal contribution must increase (Ra<sub>c</sub> increases) to compensate. The slope of the graph depends on the Roberts number  $q = \kappa/\eta$ , approaching the vertical for small q.

#### Recent developments

The stability analyses leading to an understanding of the necessary conditions for instability (see above) have all been linear. Such analyses can say nothing about how the growth of the instability feeds back on the dynamo process generating **B**.

The effect of the instability can be thought of as twofold. Firstly, and most simply, the instability extracts energy from the field so represents a drain on the field's energy in addition to ohmic diffusion. We therefore expect that for a given energy source driving the geodynamo, the field generated would be weakened by the presence of an instability. The big question is "by how much?" Secondly, there will be a mean e.m.f. associated with the instability. This will feed back on the mechanism generating the field. Recent work (Fearn and Rahman, 2004) has begun to investigate this and found that this feedback effect can be important and that magnetic instability can significantly constrain the strength of the mean field.

## CORE, THERMAL CONDUCTION

The three-dimensional stirring of the outer core that is required for dynamo action is very rapid compared with thermal diffusion, ensuring that the temperature gradient is maintained very close to the adiabatic value (see *Core, adiabatic gradient*). Thus there is a steady flux of conducted heat at all levels, regardless of the convected heat transport. Thermal convection requires additional heat, but there is also a possibility of refrigerator action by compositional convection, carrying some of the conducted heat back down (see *Core convection* and *Core composition*). Either way the conducted heat cannot contribute to dynamo action, but is a "base load" on core energy sources that must be provided before anything else can happen. The magnitude of this "base load" depends on the thermal conductivity.

## Relationship between thermal and electrical conductivities

Heat transport in the core alloy is dominated by the conduction electrons. We can write the total conductivity,  $\kappa$ , as a sum of two terms,  $\kappa_e$  representing the electron contribution and  $\kappa_\ell$  the lattice contribution, with  $\kappa_e \gg \kappa_\ell$ 

 $\kappa = \kappa_{\rm e} + \kappa_{\ell}$ 

An originally empirical but now well documented and theoretically understood relationship connects  $\kappa_e$  to the electrical conductivity,  $\sigma_e$ (see *Core, electrical conductivity*). This is the Wiedemann-Franz law:

$$\kappa_{\rm e} = LT\sigma_{\rm e}$$

where *T* is absolute temperature and  $L = 2.45 \times 10^{-8} W\Omega K^{-2}$ , known as the Lorentz number, is the same for all metals. Derivations of the Wiedemann-Franz law (see, for example, Kittel, 1971) assume that the temperature is not too low and that the mechanisms of electron scattering are the same for electrically and thermally energized electrons. These conditions are satisfied in the core. Thus, we estimate thermal conductivity from electrical conductivity, for which there are satisfactory independent estimates.

Lattice conductivity,  $\kappa_{\ell}$ , occurs in all materials and is discussed under *Mantle, thermal conductivity* (*q.v.*). It is not well constrained theoretically, but is so much smaller than  $\kappa_{\rm e}$  that the uncertainty has little influence on the estimated total  $\kappa$  for the core. Following Stacey and Anderson (2001), we assume a uniform value,  $\kappa_{\ell} = 3.1 \text{ Wm}^{-1} \text{K}^{-1}$ throughout the core and add this to  $\kappa_{\rm e}$ , as obtained from the Wiedemann-Franz law.

The variation in  $\rho_e(=1/\sigma_e)$  over the depth range of the outer core is slight. Values given under *Core, electrical conductivity* (q.v.), 2.12  $\mu\Omega$  m at the core-mantle boundary decreasing to 2.02  $\mu\Omega$  m at the inner core boundary, are used here to represent the radial variation, retaining digits beyond the level of absolute significance. These give the values of  $\kappa$  listed in Table C10. Most of the radial variation is

Table C10 Thermal conduction in the core

due to the temperature factor in the Wiedemann-Franz law, with the adiabatic temperature profile also given in the table. The inner core is more nearly isothermal, but both electrical and thermal conductivities are higher on account of the lower content of "impurities." The impurity resistivity is taken to be half of the outer core value of 0.90  $\mu\Omega$  m.

## Conducted heat in the outer core

The flux of conducted heat through any radius is

 $\dot{Q} = \kappa A \mathrm{d}T/\mathrm{d}z$ 

where  $A = 4\pi r^2$  is the area of the surface at radius *r* and dT/dz = -dT/dr is taken as the adiabatic gradient and also listed in Table C10. The decrease in  $\dot{Q}/A$  with depth is caused by the decreasing temperature gradient, which more than compensates for the increase in  $\kappa$ .

#### Diffusivity and thermal relaxation of the inner core

To discuss progressive cooling we need to know the thermal diffusivity, defined by

 $\eta = \kappa / \rho C_p$ 

with  $\rho$  being density and  $C_P$  the specific heat (see *Core properties, physical*). This is the ratio of conductivity to heat capacity per unit volume and is a measure of the speed with which the internal temperature of a body may change by conduction of heat into or out of it. The unit is m<sup>2</sup> s<sup>-1</sup>, reflecting the fact that the time required for any change depends on the square of the linear dimension of a body. In the case of a sphere there is a simple expression for thermal relaxation in terms of  $\eta$ . Consider a uniform sphere (with no internal heat sources) of total radius *R* and a surface temperature *T*(*R*) that is held constant as the interior loses heat by conduction to the surface. The internal temperature profile, *T*(*r*), relaxes towards a radial dependence given by

$$T(r) - T(R) = [T(r=0) - T(R)] \sin(\pi r/R) / (\pi r/R)$$

and decays exponentially with time, t

$$T(r) - T(R) = [T(r) - T(R)]_{t=0} \exp(-t/\tau)$$

where

$$\tau = (1/\eta)(R/\pi)^2$$

is the thermal relaxation time constant.

In applying this to the inner core, we see from Table C10 that it suffices to assume a constant thermal diffusivity,  $\eta = 8.5 \times 10^{-6} \text{ m}^2 \text{s}^{-1}$ . Taking  $R = 1.22 \times 10^6$  m, we have  $\tau = 1.77 \times 10^{16} \text{s} = 0.56 \times 10^9$  years. The significance of this number is that it is small enough to ensure that, unless the inner core has more than  $5 \times 10^{11}$  W of radiogenic heat, its temperature gradient is less than adiabatic, disallowing inner core convection and a convective explanation of its anisotropy (see *Inner core anisotropy*). This concentration of radiogenic heat in the core as a whole would give about  $10^{13}$  W, preventing core cooling and causing difficulty with thermal history. Radiogenic heat in the inner core is not allowed for in Table C10.

## Competition between heat sources and conduction

Consider the heat loss by the core due to bodily cooling only, with neglect of the gravitational energy of compositional convection and latent heat of inner core formation. The temperature profile remains adiabatic, so that the rate of temperature fall at any depth is proportional to temperature and increases inwards. There is also an inward increase in the heat capacity per unit volume, due to the increasing density. In this situation the total heat flux through any radius would be almost exactly proportional to the conducted heat flux, Q, as listed in Table C10. Convective instability would arise throughout the outer core at the same value of the total heat flux from the core. Still without considering the gravitational energy release, when we introduce the latent heat release at the inner core boundary, the added flux is the same at all radii, r, so that the additional heat flux per unit area varies as  $1/r^2$ . Then the total heat flux exceeds the conducted heat by a margin that increases inwards. It follows that the driving force for

122

convection and dynamo action is strongest deep in the outer core and it is possible that the outer part would not convect thermally, but is driven by the compositional convection. But, whatever the process, the stirring action maintains an adiabatic gradient in the outer core, with the consequent conducted heat, Q, listed in Table C10.

# CORE-BASED INVERSIONS FOR THE MAIN GEOMAGNETIC FIELD

Maps of the Earth's magnetic field have been made for navigational purposes since at least the time of *Edmond Halley* (q.v.); for details see *Main field modeling*. This activity has culminated in production of the *International Geomagnetic Reference Field* (q.v.) using a representation of the main field in spherical harmonic (or geomagnetic or Gauss) coefficients by least-squares fitting to global data set. The basic mathematical representation and statistical procedure were developed by *C.F. Gauss* (q.v.); the current approach using computers is described in Barraclough and Malin (1968).

The geomagnetic field B is represented as the gradient of a potential V satisfying Laplace's equation:

$$B = -\nabla V$$
$$\nabla^2 V = 0,$$

the solution of which is written in terms of spherical harmonics as the sum

$$V(r,\theta,\phi) = a \sum_{l=1}^{\infty} \sum_{m=0}^{l} \left(\frac{a}{r}\right)^{l+1} \left[g_l^m \cos m\phi + h_l^m \sin m\phi\right] P_l^m(\cos\theta)$$
(Eq. 1)

where  $r, \theta, \phi$  are the usual spherical coordinates, *a* is Earth's radius, and  $P_l^m$  is an associated Legendre function (see *Harmonics, spherical*). The measured component of the magnetic field is determined by differentiating *V* and setting  $r, \theta, \phi$  to the coordinates of the measurement point. The unknown geomagnetic coefficients  $\{g_l^m, h_l^m\}$  are then determined by truncating the series at some suitable degree *L* and fitting to the observations by minimizing the sum of squares of the residuals. The truncation point depends not only on the quality and coverage of the measurements but also on the level of magnetization of crustal rocks, which is regarded as noise because the main field is defined as the part of the geomagnetic field that originates in the core. The truncation point has risen from L = 8 to L = 10 as data quality has improved, and may increase further in the near future. The core field is now thought to dominate below L = 12 while the crustal field is thought to dominate above that level, although the cross-over point is difficult to establish.

There are problems with abruptly truncating a spherical harmonic series. These are closely related to the more familiar problem of truncating a Fourier series abruptly—indeed, the expansion (1) is exactly a Fourier series in  $\phi$ . Truncating an infinite series can be thought of as multiplying the coefficients by a "truncation sequence" that is equal to 1 if  $l \leq L$  and to 0 if l > L. In the space domain this is equivalent to convolution with the spatial function corresponding to the truncation sequence. In ordinary Fourier spectral analysis the truncation function, or  $\sin N\phi/\sin \phi$ , where N depends on the width of the boxcar or truncation level. The spherical harmonic problem is two-dimensional but the principle is the same: the spatial representation of the truncated series is the convolution of the spatial representation of the infinite series:

$$V_L(r,\theta,\phi) = \int V(r,\theta',\phi')A(\theta,\phi;\theta',\phi')d\Omega'$$
 (Eq. 2)

where A is the spatial representation of the trunction function, or averaging function, and the integral is taken over all solid angles  $\Omega'$ . Symmetry arguments show that A must be only a function of the angular distance  $\Delta$  between  $(\theta, \phi)$  and  $(\theta', \phi')$  (Whaler and Gubbins, 1981):

$$A(\theta, \phi; \theta', \phi') = \frac{1}{4\pi} \sum_{l=2}^{L} (2l+1) P_l(\cos \Delta).$$
 (Eq. 3)

A is also plotted in Figure C40. Note the similarities between A and the sinc function: both have peaks at the estimation point  $(\theta, \phi)$  and both have zeroes and oscillations or side lobes well away from the estimation point. These are obviously undesirable because the estimate is influenced by the magnetic field over a very wide area. Side lobes in the spherical case are particularly insidious because of the very large lobe at 180°—the estimate is strongly influenced by behavior at the antipodal point! In Fourier spectral analysis this problem is treated by tapering the Fourier series rather than truncating it abruptly and a whole range of tapers and their properties have been studied. The same can be applied to the spherical problem, and in our case we can design the taper by assuming the field originates in the Earth's core.

The part of the geomagnetic field at the Earth's surface that originates in the core is large scale because short wavelengths are attenuated with distance upward to the Earth's surface (see Upward and downward continuation). The magnetic potential at the core surface is obtained from equation 1 by setting r = c, the core radius. This increases the degree l spherical harmonic coefficients by a factor  $(a/c)^{l+1}$ , where  $a/c \approx 1.8$ . The shorter wavelengths are severely attenuated by upward continuation from the core and are increased by downward continuation to the core. Any field model we produce by fitting data at the Earth's surface may therefore produce a very rough field at the core surface, with a large amount of energy in shorter wavelengths. Indeed, the Earth's surface has no physical significance in this problem at all, it is simply the place where measurements are made. Shure et al. (1982) therefore proposed finding the model that was in some sense optimally smooth at the core surface. This needs a mathematical definition of "smooth," the simplest being to minimize the "surface energy,"  $\int B^2 d\Omega$ , where **B** is evaluated at r = c, the surface of the core. Shure et al. (1982) prove a number of useful properties of this solution; the most important is uniqueness, which means the core-surface constraint can replace truncation of the spherical harmonic series.

**Figure C40** Truncating a spherical harmonic series at degree *L* is equivalent to convolving the original function of (,) with an averaging function  $A_L()$ , where is the angular distance from the point (,). Averaging functions are shown for 3 levels of truncation, L = 4, 8, 12. Note the side lobes, which have the undesirable effect of allowing the field at considerable distance from the point (,) to influence the result, and the very large side lobe at 180°. Tapering instead of abrupt truncation can reduce or remove the side lobes, improving resolution at the expense of increasing the error.

These core-based inversions have been implemented in two distinct ways, one by developing functions called harmonic splines (Shure *et al.*, 1982) and one by slight modification of the existing IGRF procedure (Gubbins, 1983); uniqueness guarantees the solutions are the same, and here I focus on the latter method. The constraint

$$\int \boldsymbol{B}^2 \mathrm{d}\Omega = 4\pi \sum_{l=1}^{\infty} \sum_{m=0}^{l} (l+1) \left(\frac{a}{c}\right)^{2l+4} (g_l^{m2} + h_l^{m2}) = M \quad \text{(Eq. 4)}$$

may be incorporated in the least squares fit to the data by the method of Lagrange multipliers. This modifies the normal equations of the least squares method by adding a factor proportional to  $(l+1)^2 (a/c)^{2l}$ to each diagonal element. This procedure is called "damping," but very specific damping as dictated by the physics of the problem, the requirement that the main field originate in the core. The damping is very powerful because the diagonal elements are increased by an additional factor of  $\left[(l+2)a/(l+1)c\right]^2$  for each rise in degree and the result is a very smooth magnetic field at the Earth's surface. The factor  $[(l+2)/(l+1)]^2$  is relatively unimportant because damping only has a significant effect on the solution at high l when there is little control from the data, and at high l this factor approximates to 1. The downward continuation factor, however, remains at  $(a/c)^2 \approx 3.2$ . The degree of smoothness is determined by the choice of M, which also determines the fit to the data, larger M allowing a rougher field that will fit the data better. In practice M is adjusted until both the fit and the roughness of the field are satisfactory, usually when the fit to the data matches the error estimates and/or the norm of the model matches an a priori estimate. Solution is accomplished numerically again by truncating the spherical harmonic series, but at a much higher level than is needed in the absence of damping. A truncation point of 20 is usually enough to ensure numerical convergence to 5 significant figures. Harmonic splines give the exact solution in principle, but they require numerical evaluation of integrals and are therefore not analytically exact.

A Bayesian formulation allows one to place formal errors on the geomagnetic coefficients obtained from core-based inversions. Replacing the constraint (4) with  $\int B^2 d\Omega < M_1$  defines a volume in parameter space that can be used to derive formal bounds on the geomagnetic coefficients. Little use has been made of these formal

errors at the Earth's surface, but some attempts have been made to use them to estimate the accuracy of our estimates of the core field. This requires a stronger constraint than Eq. (4), which imposes no limits on the core field. Constraints based on bounding the Ohmic heating using estimates of the heat flow across the *core-mantle boundary* (q.v.) do produce finite limits, but they are too large to be of any interest. Enhancing the constraint has led to some debate; the interested reader is referred to the original articles (Bloxham and Gubbins, 1986; Backus, 1988; Bloxham *et al.*, 1989).

Core-based inversions arose because theoreticians needed selfconsistent models of the Earth's main magnetic field for comparing with output from dynamo models, determining *core motions* (q.v.)and other studies such as decadal variations in the *length of the day* (q.v.), which the IGRF failed to provide. The work on core-based models has culminated in time-dependent models and movies of the core field (see *Time-dependent models of the geomagnetic field*) that have stimulated many new ideas in geomagnetism. The IGRF continues to be derived using traditional methods, as is perhaps appropriate given its use in mapping and the need for continuity of standards, but in the near future we may see some move towards using core-based regularization in the IGRF also.

## CORE-MANTLE BOUNDARY TOPOGRAPHY, IMPLICATIONS FOR DYNAMICS

Ever since it was suggested (Hide and Malin, 1970) that the observed correlation between the variable parts of the Earth's surface gravitational and geomagnetic fields may be explained by the influence of topography (or surface bumps) on the core-mantle interface, there has been considerable interest in the resulting electromagnetic induction and core magnetohydrodynamics (see *Core motions; Core-mantle coupling, topographic*). Though the size of the bumps is uncertain, seismic data suggests that the biggest bumps, on the longest length scales, have heights up to the order 10 km (see *Core-mantle boundary, seismology*) Though this is small compared to the core radius, they may have a considerable influence on core motion provided that the horizontal scale is large because of the large Coriolis force and the resulting influences of the *Proudman-Taylor theorem* (*q.v.*). Other Core-mantle couplings, including electromagnetic and thermal, have also been investigated.

## Wave motions

The excitation of *magnetohydrodynamic waves* (q.v.) at the coremantle boundary has been investigated within the framework of a 2-D model. Relative to rectangular Cartesian coordinates (x,y,z), the boundary is close to the plane z = 0 with small undulations described by z = h(x). The system rotates rapidly about the *z*-axis,  $\mathbf{\Omega} = (0, 0, \Omega)$ , and the electrically conducting fluid, constant density  $\rho$ , permeability  $\mu$ , conductivity  $\sigma$ , occupying the region z > h is permeated by the unidirectional magnetic field  $\mathbf{B}_0 = (B_0(z), 0, 0)$ . Both the linear sheared field  $B_0 = B'_0 z$  (Anufriev and Braginsky, 1975) and the uniform field  $B_0 = \text{constant}$  (Moffatt and Dillon, 1976) have been investigated. The aligned uniform flow  $\mathbf{U}_0 = (U_0, 0, 0)$  is maintained and the steady linear waves excited due to its motion over the sinusoidal boundary  $h = h_0 \sin(x/L)$  are considered.

In both these problems, inertia and viscosity are neglected while ohmic dissipation is retained. The key dimensionless parameters are the Elsasser number  $\Lambda = \sigma B_0^2 / \rho \Omega$  and the magnetic Reynolds number  $R_{\rm m} = \sigma \mu L U_0$ . For the simpler uniform magnetic field problem (Moffatt and Dillon, 1976) solutions are sought proportional to  $\exp(-\lambda z/L)$ , where  $\lambda$  is a complex constant, which satisfies the dispersion relation

$$4\lambda^2 [R_{\rm m} - {\rm i}(1-\lambda^2)]^2 + \Lambda^2 (1-\lambda^2) = 0.$$

Three of the roots  $\lambda = \lambda_n (n = 1, 2, 3)$  have positive real part. These distinct solutions must be combined to meet the boundary conditions

at the CMB. Generally the motion has a boundary layer character. In the limit  $R_m \rightarrow \infty$ , however, wave-like solutions (Re  $\lambda = 0$ ; MC-waves) are possible, when  $2L\Omega U_0 > B_0^2/\mu\rho$ ; otherwise they are evanescent.

#### Convection

#### Sphere

The role of core-mantle boundary-bumps on Boussinesq convection (see Anelastic and Boussinesq approximations; Core convection) in a rapidly rotating self-gravitating sphere, radius  $r_0$ , containing a uniform distribution of heat sources (see Convection, nonmagnetic rotating) has been investigated (Bassom and Soward, 1996). Relative to cylindrical polar coordinates  $(s, \phi, z)$  (the z-axis and rotation axis are aligned), we denote the core boundary location by  $z = z_{\pm}(s, \phi)(z_{+} \text{ and } z_{-} \text{ in}$ the northern and southern hemispheres respectively) small bumps are considered of z-height  $\sqrt{r_0^2 - s^2} \mp z_{\pm}$  proportional to  $\sin m\phi$ . The main new idea linked to the topography is that the geostrophic contours  $s = s_G$ , on which the separation  $\mathcal{H}(s_G, \phi) = z_{+} - z_{-}$  is constant, are no longer circular  $s_G = \bar{s}_G = \text{constant}$  but distorted so that they become  $s_G - \bar{s}_G \propto \varepsilon(r_0/m) \sin m\phi$  with  $\varepsilon \ll 1$ .

In rapidly rotating systems fluid motion is constrained by the *Proudman-Taylor theorem* (q.v.), which demands that geostrophic flow  $U_G$  follows the geostrophic contours. Since gravity is radial, so is the buoyancy force  $\mathbf{F}_B = f_B \mathbf{r}$ . In the case of a sphere without bumps  $\mathbf{F}_B$  has no component parallel to the geostrophic contour. The buoyancy force can do no work and so no such convective motion is possible. Instead the onset of convection is quasigeostrophic and has the character of thermal Rossby waves (see *Rotating convection, nonmagnetic rotating; Core, magnetic instabilities*) with short azimuthal length scale  $\mathcal{O}(E^{1/3}r_0)$ , where  $E = v/r_0^2\Omega$  is the Ekman number. On the other hand, with bumps there is a small component  $\mathcal{O}(\varepsilon)$  of  $\mathbf{F}_B$  aligned to the geostrophic contour, which allows for the possibility that the buoyancy force can do work that drives  $\mathbf{U}_G$ .

The results for the onset of the geostrophic mode of convection identify the importance of bump height as measured by the parameter

$$\Theta = \varepsilon / m^{1/2} E^{1/4}$$

On increasing the bump height from zero, the thermal Rossby wave is preferred until  $\Theta = O((mE^{1/3})^{1/4})$ . Thereafter a steady geostrophic mode is preferred, for which the adverse density gradient necessary to drive it decreases with increasing bump height (i.e.,  $\Theta$ ). The main interest is for large scale bumps with  $mE^{1/3} \ll 1$  for which the transition occurs at small  $\Theta$ , while even order one values of  $\Theta$  are readily obtained for geophysically realistic parameter values. For an Ekman number  $E = O(10^{-8})$ , based on a turbulent viscosity, the estimate of  $\Theta = O(1)$  is achieved by undulations of about 10 km in depth on a horizontal length scale comparable to the core radius length scale, while both the depth and lateral extent length scale estimates are reduced considerably when based on  $E = O(10^{-15})$  appropriate to the kinematic rather than the turbulent viscosity.

To drive the geostrophic flow, diffusive processes must occur which lead to density variations along the geostrophic contours. This leads to an  $\mathcal{O}(\varepsilon)$  secondary "convective" motion vital to drive the geostrophic flow determined by a variant of *Taylor's condition* (*q.v.*), which takes account of Ekman boundary layer suction and pumping (see *Core, boundary layers*), first obtained in the dynamo context. When  $\Theta \ll 1$  this "convective" motion is confined close to the outer boundary (shallow convection), but when  $\Theta \gg 1$  penetrates the full height *H* of the geostrophic columns (deep convection).

The nature of the geostrophic mode is sensitive to the boundary conditions. In the case of rigid boundaries, motion is localized close to some critical radius  $s = s_c$  on a short radial length  $\mathcal{O}(E^{1/8}r_0)$  as effected by Ekman pumping at the boundary. In contrast for stress-free

boundaries, there is negligible Ekman pumping and geostrophic motion driven by the buoyancy force is diffused by lateral friction (internal viscous stresses) so as to fill the sphere.

## Annulus

Since many of the important physical features of rotating spherical convection are reproduced by Busse's annulus model, which provides a model for convection localized in radial extent in the vicinity of  $s = s_c$  (see *Convection, nonmagnetic rotating*), it has also been employed for the case of a bumpy boundary. There are some essential differences even in the linear theory between the spherical and annular cases. Since the *z*-dependence is suppressed in the annulus model, it has no equivalent of the shallow convection mode. Instead, there is a minimum O(1) value of  $\Theta$  at which the steady geostrophic mode can occur. Below that value the geostrophic mode is oscillatory.

The theory has been developed and extended into the nonlinear regime from an asymptotic point of view with  $E \ll 1$  (Bell and Soward, 1996). That theory focuses exclusively on the geostrophic mode of convection. In contrast, results have been obtained numerically at large but finite *E* (Hermann and Busse, 1998), which illustrate both the thermal Rossby and geostrophic modes of convection. Both developments address possible long wavelength modulation. Experimental results have been reported (Westerburg and Busse, 2003) and compared with the theoretical predictions.

# CORE-MANTLE BOUNDARY TOPOGRAPHY, SEISMOLOGY

The main compositional change in the Earth, the core-mantle boundary (CMB), translates into a strong discontinuity in seismic propertiesdensity, bulk modulus, rigidity-that affects the propagation of seismic waves very significantly. If chemical and dynamic processes induce topographic variations of the CMB, as it appears plausible, then seismology should in principle be able to detect and map them. In fact, systematic geographical variations of seismic body wave travel times pointed to the existence of large-scale undulations of the CMB. Also, stochastic analyses of travel times, and detection of scattered seismic energy, have been used to characterize the statistical properties of boundary topography down to spatial scales of a few kilometers. Modeling the relevant seismic waves remains however a challenging task, because the rays also cross the heterogeneous mantle, including the very complicated D" layer-both must be accounted for-and because the signal to noise ratio in available data is very small. As a result, in spite of a general recognition of the existence of large and small scale "seismic" topography of the CMB, the debate on the actual shape and amplitude range—of the order or hundreds of meters to kilometers—is still under way, as agreement among different models is often unsatisfactory

Reflection and refraction at the CMB generate a variety of seismic phases, which are coded by seismologists following a simple convention by which each leg of the ray and each topside reflection is represented by a letter (see *Seismic phases*). PcP designates seismic energy that traveled as a P wave from the hypocenter, was reflected at the core and went back up as P again (Figure C41). PKKP is a wave that traveled through mantle, outer core, was reflected at the bottom of the CMB, and went back up to the surface. PKIKP are rays traveled almost straight across the whole Earth. The seismic phase most often used is PcP, because it has good sensitivity to CMB radius, it is easily identified on seismograms (Figure C42), and has traveled through the heterogeneous part of the Earth for the shortest path possible. Additionally, CMB-refracted phases (PKP and PKIKP, Figure C42) and

**Figure C41** Some seismic ray paths interacting with the core-mantle boundary. Body waves reflected at the mantle (PCP) and the core-side (PKKP) of the CMB, as well as refracted waves—PKP, crossing the outer core, and PKIKP, penetrating to the inner core—have been used to study the shape of the CMB. PCP rays are affected the least by deep earth structure. These ray paths are traced in a spherically symmetric reference earth model.

**Figure C42** High-pass (1 Hz) filtered seismograms for a magnitude 6.0 earthquake located beneath Aleutian Islands. Top panels show two time windows—with the same, arbitrary, vertical amplification—of the record from seismographic station YKW3 at Yellowknife (N.W.T., Canada) with epicentral distance of 3873 km, or 35°. Horizontal scale is time, in seconds, since event origin. The bottom panel shows the seismogram from station SNAA (Sanae, Antarctica) with epicentral distance of 17773 km, about 160°, for the same earthquake. Both PKIKP and PKP arrivals are visible.

underside reflections (PKKP) have also been used in large-scale tomographic studies. A discrepancy of the travel time of a core phase with respect to the reference value can be interpreted as due to a different radius of the reflector/refractor.

Of course, the theoretical travel times of core phases must necessarily account for the three-dimensional variations of wave speed in the whole mantle. Core phases do not have good sensitivity to the vertical location of heterogeneities in the Earth structure, and are therefore not capable, alone, of discriminating well between small variations of wave speed or boundary radius. Our analysis must then rely on a mantle model previously determined by means of direct P waves. After these critical corrections are made, statistical analyses of travel time "residuals" (Morelli and Dziewonski, 1987; Rodgers and Wahr, 1993; Garcia and Souriau, 2000) have shown the existence of small but geographically coherent signal, that would correspond to boundary undulations with an amplitude of the order of a few kilometers on length scales of several hundred to a few thousand kilometers. For each single seismic phase, boundary undulation would in fact tradeoff rather well with velocity perturbations in a thin, highly heterogeneous layer. The presence of this signal on top-side reflections (PcP) would require this layer to be located on the mantle side of the CMB. The original observation in favor of the topographic origin of the travel time anomalies (Morelli and Dziewonski, 1987) consisted of the agreement of the maps derived from separate PcP and PKP analyses, in spite of the opposite signs of their sensitivity to CMB radius perturbation-reflected and refracted waves could be consistently fit by allowing CMB radius to vary, but would otherwise require anticorrelated boundary layer wave speed heterogeneities. Later studies, using different data selection rules and mantle models, were unable to find such a good correlation, but maps derived exclusively from PcP data shared some common traits (Figure C43). Likeness among models derived from the other seismic phases is worse or nonexistent. The unsatisfactory correspondence raises some skepticism on the current ability of seismology to accurately map the shape of the CMB, discriminating it from other structural complexities. Some intriguing correspondence among maps derived from PcP indeed exist (Figure C43): elevated regions appear under the north Pacific, the Indian, and the north Atlantic oceans; depressed regions figure beneath central Africa, southeast Asia, and the Pacific coast of South America. The presence of at least some of these anomalies is also supported by mantle dynamic models (see Core-mantle boundary topography, implications for dynamics). The worse performance of PKP and PKKP data may derive from additional complexities in their modeling. Although no compelling evidence of lateral variations of seismic speed in the outer core has ever been found, waves transmitted through the boundary could possibly also be affected by structure of the core-mantle transition zone located beneath the seismic reflector-in the case of PKIKP, also by the seismically heterogeneous and anisotropic inner core. The added complication of each ray sampling the CMB in two (PKP) or three (PKKP) spots, combined with a rarefied sampling, may constitute yet another source of error. A plausible scenario then involves a core-mantle transition zone with a complicated structure, not only involving undulations of a sharp boundary, but also seismic velocity gradients-which we are still unable to model globally, and which can consequently contaminate in various ways the retrieved topography. PcP data may be the least affected, yielding better agreement among different analyses.

Spatial resolution of travel times is limited by the wavelength and is often represented by the Fresnel zone. For P body waves used in travel time studies, the Fresnel zone is about 300km wide at the CMB. Information on smaller length scales can be obtained by studying high

**Figure C43** Seismic models of long-wavelength CMB topography (from top to bottom: Morelli and Dziewonski, 1987; Obayashi and Fukao, 1997; Rodgers and Wahr, 1993). All models are derived from analysis of PcP travel times, and are represented by low-degree spherical harmonics (qv) expansions (up to degree 5 for the last model, 4 for the others). The grayscale represents changes of core radius with respect to the reference figure of hydrostatic equilibrium, up to +10 km (white) and -10 km (black).

frequency scattered energy or the pulse distortion of short-period body waves, preferably in situations where the scattered energy precedes, rather than follows, the main seismic arrival, so that it is not obliterated by the coda. (This is possible for seismic phases, such as PKKP, which follow a maximum-time path.) By studying precursors to PKKP it has been possible to infer the existence of CMB topography with root mean square amplitude a few hundred meters with a correlation length of 7–10 km (Earle and Shearer, 1997).

Seismic imaging of the core-mantle boundary topography is in principle quite straightforward, but it is in reality complicated by a number of practical issues. The scanty and irregular global sampling of the CMB, the imperfect account of mantle and core structure, the simplified theoretical modelling of wave propagation, all concur with the small signal to noise ratio to limit the imaging potential of seismic core data. As a result, the different studies on the topic have not quite gone beyond a qualitative agreement, and often disagree. However, the qualitative correspondence found among different models, the stochastic analyses of travel times, and the accordance with inferences from mantle dynamic modeling, point towards the existence of kilometric topography at the CMB. Better knowledge of the seismic structure of the Earth's mantle, including the still elusive D" layer, and perhaps a better modeling of the full effects of such three-dimensional structures on seismic waves, are still needed to wipe our glasses and clarify our vision.

## CORE-MANTLE BOUNDARY, HEAT FLOW ACROSS

The boundary between the core and the mantle is of huge importance for the dynamics of the Earth's interior and the seat of many interesting phenomena: (see *Core-mantle boundary and Core-mantle coupling, thermal*). From the core point of view, this is the surface across which all heat produced must escape. The value of the integrated heat flow across the core-mantle boundary (CMB) is then of primary importance for the thermal evolution of the core and it controls the amplitude of the energy sources available to drive the geodynamo (see *Geodynamo, energy sources*).

All the energy that flows out of the core must be transported upward across the mantle. The mantle is primarily solid (except in the very localized regions of partial melting) but it can creep and is subject to convective movements on time scales of some tens of millions of years (Myr), the surface expression of these motions being plate tectonics. On the other hand, the outer core is liquid, with a viscosity close to that of water (see *Core viscosity*) and its dynamics is then much faster. The secular variation of the magnetic field suggests that the velocity in the fluid core is on the order of  $10^{-4}$  m s<sup>-1</sup> (e.g., Hulot *et al.*, 2002) which, together with the radius of the core  $3.48 \times 10^6$  m, gives a typical time scale of about a thousand years.

The mantle, being much more sluggish than the core, constitutes the limiting factor for the thermal evolution of the Earth, and the heat flow across the CMB is the heat flow that mantle convection can accept. Of course, the state of the core affects this value by imposing a temperature difference between the bottom and the top surfaces of the mantle, that is, in nondimensional units, a Rayleigh number for the mantle. Both systems are then coupled in their evolution.

## Total heat loss of the core

#### Energy balance of the mantle

The heat flow across the CMB is controlled by mantle convection and gross estimates of its integrated value can be obtained by use of the global energy balance of the mantle. This balance states very simply that the heat flow at the surface of the Earth is, to first approximation, equal to the sum of three terms: The heat production by decay of radioactive elements in the mantle, the cooling heat associated with the heat capacity of the mantle (this term is called secular cooling of the mantle), and the heat flow across the CMB. The latter of these terms should then be obtained by simple difference, providing all others can be determined accurately. We will see here that this approach can give reasonable estimates but hardly any precise value.

Other energies are involved in the thermodynamics of mantle convection but they are either negligible or internally balanced. Among the first group, one can cite tidal friction (Verhoogen, 1980), latent heat due to the secular movement of phase boundaries upon mantle cooling and adiabatic heating from slow contraction. Another energy term, which is often discussed, viscous dissipation, can be locally important but does not enter the global energy balance because it is internally balanced by the work of buoyancy forces (as is the case for the core: see *Geodynamo, energy sources* and Hewitt *et al.* (1975)). Gravitational energy due to chemical stratification was a very important source of energy during the formation of the core (Stevenson, 1981), early in Earth history, but is likely gone by now. Similar processes like the formation of the continental crust or opposite ones like the slow mixing of a primordial chemical stratification (Davaille, 1999) could still be at work but are likely negligible due to the small masses involved.

The total heat loss of the Earth is reasonably well known to be about 42 TW from heat flux measurements made both on oceans and continents, as well as interpolation based on models for the cooling of oceanic plates (Sclater et al., 1980). The value of total heat production by radioactive decay relies on cosmochemical models for the formation of the Earth, or more precisely on the choice of meteorites that is supposed to have formed the Earth. Most models assume a CI carbonaceous chondrite origin for the Earth, leading to a total heat production in the silicate Earth (mantle plus crust) of about 20 TW (see Javoy, 1999, for a critical discussion). The distribution of the heat-producing isotopes (<sup>40</sup>K, <sup>235</sup>U, <sup>238</sup>U, <sup>232</sup>Th) in the Earth is clearly nonuniform, the continental crust being largely enriched compared to the mantle, but this matter does not affect the estimates presented here as long as the heat flow at the surface is considered. The secular cooling term is the least well constrained of all terms but we can already see that, unless the mantle is actually heating up, the heat flow across the CMB cannot be greater than 22 TW, a value obtained in the case of a steady mantle temperature.

To get a more useful upper bound one needs a model of thermal evolution of the mantle. Unfortunately, our understanding of mantle convection is still far from complete and no entirely satisfying model of mantle cooling is available at present. In particular, these models usually predict a very fast cooling of the Earth in the early stages of the evolution so that they cannot maintain the present surface heat flow with the concentration in radioactive elements estimated from geochemistry (e.g., Grigné and Labrosse, 2001). Nevertheless, these models all predict present day rate of mantle cooling between 50 and 100 K Ga<sup>-1</sup> (e.g., Schubert et al., 2001), which is similar to estimates based on the chemistry of basalts (e.g., Abbott et al., 1994). Using a heat capacity of about  $10^3 \text{ J kg}^{-1} \text{ K}^{-1}$  and a mass of the mantle of 4  $10^{24}$  kg, this gives a contribution of secular cooling of about 6-12 TW to the heat flow at the surface. Subtracting this value to the 22 TW estimated above, a heat flow across the CMB of 10-16 TW is obtained. Considering the very approximate nature of this estimate, it should only be taken as a crude but plausible range.

#### A mechanical point of view

Alternatively to looking at the global balance of the mantle and modeling its temporal evolution, the heat flow at the CMB has been estimated by computing the buoyancy flux of the different mantle hot plumes that are supposed to be responsible for the formation of hotspot tracks, such as Hawaii. Using different hotspot catalogs, values around 3 TW for the total heat coming out of hotspots have been typically obtained (Davies, 1988) and this value has been often quoted as the total heat loss of the core. The idea behind that estimate is that all the heat that comes out of the core is collected in the boundary layer at the bottom of the mantle and transported upward to the surface by mantle plumes, the surface expressions being hotspots.

The value obtained is low compared to the range given previously but could be acceptable (considering the approximate nature of this range), although the reasoning used to get it is questionable. Without even entering the long standing debate regarding the origin of hotspots, two issues regarding the link between the heat transported to the surface by hot mantle plumes and the total heat loss of the core can be raised, both coming from the difficulty of considering any particular dynamical object as a separate entity in a convective flow. First, it is difficult to imagine that hot plumes move straight up from the boundary layer where they originate to the surface without any effect of the large-scale mantle circulation associated with plates. Several models actually show that many (if not most of) hot plumes that form at the bottom of a convective system containing some important ingredients of mantle convection such as temperature-dependent viscosity, volumetric (radiogenic) heating, and large (plate size) scale flow do not rise to the surface (Labrosse, 2002).

Second, there are two modes of cooling of the core, both operating simultaneously. You can take some hot matter and move it upward in the form of plumes or take some cold matter from the surface and spread it on top of the core. This separation is a little arbitrary since in both cases you replace some hot matter by some cold matter, but, in the former, this matter comes from the ambient mantle whereas in the latter it comes from the surface, in the form of plates. The relative importance of these two modes depends on both the mass flux of cold matter brought to the boundary and the temperature difference involved. Both these parameters are more important for the cold down welling currents than for the hot up welling plumes in convection models that include volumetric heating (Labrosse, 2002) and it is easy to think that this difference will be even larger in the case of the mantle, where cold plates represent the dominant feature of lateral heterogeneities. This means that a better estimate of the heat flow across the CMB could be obtained if the mass flux associated with plates were known in the lower mantle. This is unfortunately not the case and no estimate better than the one proposed using the gross energy balance above seems possible for the time being.

## Estimates from the core side

Even though mantle convection controls the heat flow across the core mantle boundary, the fact that a dynamo has been operating in the core for most of its history places constraints on this value: It must be large enough to maintain the dynamo action. The thermodynamics of a convective geodynamo has been studied by several authors (see *Geodynamo, energy sources*) and the results will be shortly recalled here.

The decay time of the dipole of the Earth is of the order of 15 ka (see *Geodynamo, dimensional analysis and timescales*), that is much smaller than the age of the Earth magnetic field, which means that a dynamo action must be regenerating it against ohmic dissipation. A particularity of the thermodynamics of convective flows, compared to the classical Carnot engine, is that the work is performed inside the system so that the energy balance only states the equilibrium between the sum of heat sources and the total heat loss, the heat flow across the CMB in the case of interest here. On the other hand, an entropy balance can be used to relate the total ohmic dissipation in the core to the energy sources that drive the dynamo, with the introduction of some efficiency factors. Several combinations of different energy sources are possible, particularly depending on whether one thinks that radioactive elements are present in the core or not, and added to the uncertainties attached to most physical parameters, a total heat flow across the CMB in the range of 5-15 TW can be predicted for a total ohmic dissipation in the core of about 1-2 TW. It must be noted that the uncertainty in this total ohmic dissipation is probably the largest in the whole set of parameters of this type of derivation, owing to our current lack of knowledge concerning an important part of the magnetic field in the core, the toroidal, and the small scale poloidal part.

The estimates discussed above fall in about the same range as those obtained previously from the mantle side, which can be taken as a good sign, but it means that it does not really help in narrowing down this range. Another point of comparison is provided by the average adiabatic temperature gradient in the core, along which about 7 TW is conducted. If the actual heat flow is lower than this value, a stable thermal stratification would tend to be established at the top of the core.

## Lateral variations

In addition to the value of the total heat flow across the CMB, the amount and scale of lateral variations of the heat flux may be of equal importance for the dynamics of the core. These lateral variations are imposed by mantle convection and evolve on timescales much longer than those associated with the dynamo. These variations can then be seen as a permanent inhomogeneous boundary condition imposed on the core by the mantle, the effects of which being still not completely understood (see *Inhomogeneous boundary conditions and the dynamo*).

Convection being responsible for the heterogeneities in seismic velocities at the bottom of the mantle, it is tempting to use the images of these heterogeneities as produced by seismic tomography to convert them to maps of lateral variations of the heat flux at the CMB. This assumes that all the lateral variations in seismic velocities are of thermal origin and that a single, so-called, conversion factor can be used for the operation. On the other hand, there is some evidence for a non-purely thermal origin of these heterogeneities, in which case the chemical part of the signal must first be separated, a still formidable task. Several studies about the effect of heterogeneous boundary conditions on core dynamics (e.g., Glatzmaier *et al.*, 1999; Olson and Christensen, 2002) have nevertheless assumed a purely thermal origin of the lateral variation of the seismic velocities and the heat flux pattern obtained is often called the "tomographic heat flux," the amplitude of the lateral variations remaining a largely unknown adjustable parameter. This pattern is essentially controlled by the large-scale structure of tomographic images and, in particular, features a large heat flux ring falling bellow the subduction zones around the Pacific Ocean (Figure C44). This can be optimistically taken as a sign of consistency since the subducting plates, if they reach the bottom of the mantle, will produce a high heat flux.

There is no direct measurement of the amplitude of the lateral variations of heat flux at the CMB, but some argument can be made about their being quite large. First, the contrast between the core and the mantle is as important as the one between the mantle and the ocean, so that variations of the same relative importance can be expected at the CMB than at the surface. The existence of crypto-continents at the CMB has even been proposed (e.g., Stacey, 1991), and such could be the name given to the piles of chemically dense material that are envisioned in some models of mantle convection with chemical heterogeneities (e.g., Tackley, 1998; Davaille, 1999). At the Earth surface, the mean heat flux through oceanic plates is about 100 mW m<sup>-2</sup>, with a pic-to-pic variation equal to this value (Sclater et al., 1980), and it is reasonable to assume that variations of the same relative amplitude exist at the CMB. One can even defend the case of larger variations, owing to the fact that these variations are controlled by the effect of down welling plates, which are associated with the lateral variations of the heat flux at the surface. One can for example construct a mantle convection model driven by internal heating and a top surface maintained at a low temperature with a zero net heat flow at the bottom surface, although displaying lateral variations of a quite large amplitude. Pic-to-pic variations of the heat flux at the core mantle boundary of the same order as the mean value present then a conceivable picture.

The possibility of thermal stratification that was mentioned above has to be discussed again in the context of the lateral variations of the heat flux at the CMB. Considering the likely importance of these variations and the closeness of the estimates of the actual heat flux at the CMB and of that conducted down the adiabatic temperature gradient, it is likely that some regions of the CMB present a stable

**Figure C44** Pattern of heat flux lateral variations at the core mantle boundary in the so-called "tomographic" model of Christensen and Olson (2003). Heat flux higher than averaged is in plain contours and correlate well with the position of subduction zones at the surface. Reproduced by permission of U. Christensen and P. Olson and Elsevier.

CORE-MANTLE COUPLING, ELECTROMAGNETIC

thermal stratification. The effects of such patches on the dynamics of the core and the generation of the magnetic field are still largely unknown but have to be investigated.

## Variations with time

The heat flux across the CMB is not only varying laterally but also with time, on the timescale of mantle convection. Moreover, the pattern of lateral variations is also evolving on the same timescales and both temporal evolutions are likely to be of great importance to understand the long-term variations of the magnetic field. Unfortunately, the knowledge that one can get for the time evolution of the heat flow across the CMB is even scarcer than about the present day value. In particular, most of what we know about the present heat loss of the Earth comes from the study of the seafloor (Sclater et al., 1980), which is not older than about 200 Ma. However, one can put forward the argument that some ergodicity holds so that the variations of this heat loss with time can be as large as the lateral variations observed at the present day. Most of the heat loss of the Earth comes from the formation of mid-oceanic ridges and the heat budget of the Earth can be considerably changed by modifying the number of active ridges, or equivalently the average size of mantle convection cells. For example, the Atlantic ocean is responsible for about 6 TW of the 30 TW of total oceanic heat flow and it opened between 180 and 120 Ma ago. Before that time, if no other ridge of equivalent importance was active, the heat loss of the Earth must have been 6 TW lower than at present.

From the previous discussion, one can easily imagine (although not prove) variations of the total heat loss of the Earth of the order of 10 TW on timescales of about 200 Ma (Grigné *et al.*, 2005). As for the heat flow across the CMB, it is likely to have undergone variations on a similar timescale, with amplitudes that could be as large as the amplitude of the present day lateral variation, which, unfortunately, is poorly known as discussed above. This means that important variations of the ohmic dissipation in the core must have occurred (see *Geo-dynamo, energy sources*) and understanding the link between these variations and the variations of the magnetic field characteristics would provide a means of investigating this evolution.

## CORE-MANTLE COUPLING, ELECTROMAGNETIC

Variations in length of day (equivalently, the rate of rotation of the Earth's surface) are observed on timescales from subdaily to millions of years. They result either from external torques (for example, the tidal torques exerted on the Earth by the moon and sun), or from the exchange of angular momentum between different reservoirs within the Earth system. Of these, the fluid core is by far the most massive, and there is convincing evidence that at least *decadal variations in length of day* ( $\Delta$ LOD) (*q.v.*) result from the exchange of angular momentum between the core and the mantle. Such exchange requires a coupling mechanism between the core and mantle. The mechanisms that have been suggested fall into four classes: viscous coupling, *topographic coupling* (*q.v.*), gravitational coupling, and electromagnetic coupling.

Although the mantle is a poor electrical conductor in comparison with the molten iron core, it is nonetheless not a perfect insulator. Currents flowing in the core can "leak" into the mantle and changing magnetic fields from the core, which penetrate the mantle, can induce electric currents. These currents incur resistive losses, which, as a result of Lenz' law, do work against the processes generating them. Globally, a torque between the core and mantle is generated.

Many attempts have been made to quantify the effect of electromagnetic coupling between the core and the mantle. The underlying theory is presented by Gubbins and Roberts (1987) amongst others. The torque  $\Gamma$  is given by the moment of the Lorentz force integrated over the mantle

$$\Gamma = \int_M \mathbf{r} \times (\mathbf{J} \times \mathbf{B}) \, \mathrm{d} V$$

where  $\mathbf{r}$  is the position vector,  $\mathbf{J}$  the current density, and  $\mathbf{B}$  the magnetic field, integrated over the volume *V* of the conducting mantle *M*. This integral can be reformulated as a surface integral calculated over the core mantle boundary (CMB)

$$\Gamma = -\frac{1}{\mu_0} \int_{\rm CMB} \left( \mathbf{r} \times \mathbf{B} \right) B_{\rm r} \, \mathrm{d}S$$

where  $\mu_0$  is the permeability of free space, and  $B_r$  is the radial magnetic field at the CMB. The axial component  $\Gamma_z$  of this torque (which affects the length of day) can be written

$$\Gamma_z = -\frac{c^3}{\mu_0} \int_{\text{CMB}} B_{\varphi} B_{\text{r}} \sin^2 \theta \, d\theta \, d\varphi \tag{Eq. 1}$$

where c is the radius of the core,  $\theta$  is colatitude,  $\varphi$  is longitude, and  $B_{\varphi}$  is the field in the longitudinal direction.

Because the radial field  $B_r$  must be continuous over the core-mantle boundary, it can in principle be inferred from *downward continuation* (q.v.) of the field observed at the Earth's surface, but  $B_{\varphi}$  is less straightforward. A magnetic field can be divided into two parts, written

$$\mathbf{B} = \nabla \times T\mathbf{r} + \nabla \times \nabla \times S\mathbf{r}$$

where *T* and *S* are the toroidal and poloidal scalars respectively (see, for example, Gubbins and Roberts, 1987).  $B_{\varphi}$  has a component from both the toroidal and poloidal fields.

It is convenient to divide the EM torque into three parts. The first, the poloidal torque, depends on the poloidal component of  $B_{\omega}$ , which can be inferred by using *time-dependent models of the geomagnetic* field (q.v.) for a known mantle conductivity structure, and solving the diffusion equation in the mantle by an iterative, multiple timescale scheme. The toroidal component of  $B_{\varphi}$  cannot be inferred directly from observations at the Earth's surface. (Attempts have been made to infer the toroidal field from measurements of electric field in submarine telephone cables, but without conclusive results.) The torque which it generates is commonly subdivided into two parts, the advective torque (associated with magnetic induction in the conducting mantle due to changing field at the CMB) and the leakage torque (arising from direct flow of current ("leakage") from the core into the mantle) (e.g., Holme, 1997a and references therein). The advective torque can in principle be inferred from a model of the flow at the top of the core. The radial field at the CMB is advected by the flow and its passage through the conducting mantle leads to magnetic induction. The leakage torque cannot be constrained at all from surface observations, but it has been assumed that the characteristic time scale for changes in diffusive processes at the CMB is likely to be too long for them to be responsible for decadal variations in LOD. (However, results from numerical simulations of the dynamo process suggest that this argument may be weak.)

All components of the torque depend crucially on the structure of the *electrical conductivity of the mantle* (q.v.). Downward continuation of the surface field to the CMB assumes an insulating mantle, while EM coupling requires a conducting mantle. However, EM coupling is most strongly enhanced by high conductivity near the base of the mantle, particularly in D", while secular variation is less sensitive to deep mantle conductivity and more to upper mantle conductivity. Therefore, conductivity located deep in the mantle can give strong EM coupling without greatly affecting downward continuation. A variety of processes have been suggested which might lead to a high conductivity layer at the base of the mantle, including but not limited to core-mantle reaction, partial melt in the lowermost mantle (perhaps associated with *ULVZs* (q.v.), sedimentation of a light component of core fluid at the top of the core, phase transformation of lower mantle silicates, and chemical heterogeneity from a slab graveyard. Any or all of these mechanisms could contribute; for the advective torque, to first order only the conductance (integrated conductivity) of such a layer is important. For EM coupling to be a significant contributor to decadal variations in LOD, a value of this conductance of  $10^8$  S seems to be necessary. This could arise from, for example, a 200 m thick layer of material of core conductivity, or a conductivity of 500 S m<sup>-1</sup> over a

D" thickness of 200 km. There have been many attempts to calculate or estimate the three components of the torque, particularly focusing on the last 150 years or so, to determine whether EM coupling can account for decadal var*iations in length of day* (q.v.). All studies obtain similar behavior for the poloidal torque: it is found to be westward on the mantle, with only small variations. For deep-mantle conductance of 10<sup>8</sup> S, its value is typically an order of magnitude too small, and unable to explain the oscillatory decadal signal in LOD. There has been much less agreement as to the advective torque, arising because of nonuniqueness in modeling of *core motions* (q.v.). The time variation of the radial field is used as a tracer of fluid motion (assuming that diffusion is negligible on decadal time scales-the frozen-flux approximation (q.v.)), but this provides only one equation to constrain two components of the CMB flow (for example, northwards and westwards). To obtain the other component, other physical assumptions (for example, steadiness, or tangential geostrophy) are adopted, but nevertheless, there are still an infinite number of flows that can explain the secular variation to within a given tolerance. Unfortunately, the advective torque depends on precisely the part of the flow that is not constrained by the observations, but instead by the additional physical constraints. (Magnetic induction from the constrained part of the flow contributes to the poloidal torque.) As a result, it is perhaps not surprising that the torque calculated varies significantly depending on the assumptions adopted. In particular, assuming a steady flow gives an EM torque that does not vary sufficiently to explain the observed  $\Delta$ LOD. Torques calculated from tangentially geostrophic flows have shown correlation with  $\Delta$ LOD, particularly if a phase shift between the two signals (due to a delay in transmission of electromagnetic signals through the mantle) is allowed. The confusion is reduced somewhat by considering the inverse problem: is it possible to find a core flow which both explains the observed secular variation and the changes in LOD through EM coupling? The answer is yes, provided a deep mantle conductance of at least 10<sup>8</sup> S is present (Holme, 1997b). Equally, however, flows exist which produce no net torque, or the exact opposite of the observed torque, and still fit the secular variation. While observations do not allow EM coupling to be ruled out as the primary mechanism of core-mantle angular momentum exchange, neither is it possible to confirm its importance (Holme, 1997a).

Most calculations of the torque have assumed a spherically symmetric distribution of mantle conductivity. However, the *core-mantle boundary* (q.v.) (CMB) region is known to be very heterogeneous in other physical properties, so it might also be expected to show strong variations in electrical properties. Work is limited on what effect such variations might have on the EM torque, but it seems unlikely that isolated conductivity anomalies could be large enough to either influence secular variation or contribute greatly to coupling. It has been argued that small-scale coupling can enhance magnetic friction, increasing the effectiveness of EM coupling (Buffett, 1996), but on the large scale, only conductance structure of *spherical harmonic* (q.v.) degree 1 causes significant changes from the calculations assuming laterally uniform conductance (Holme, 1999), and all evidence is that the deep mantle is dominated by structure that is instead of spherical harmonic degree 2.

This review has concentrated on the effects of electromagnetic coupling on decadal variations in LOD. However, the EM torque also has components perpendicular to the Earth's rotation axis, which contribute to precessional and nutational processes. EM core-mantle coupling plays a particularly important role in the damping of free-core nutations (Buffett, 2002). The limiting value of mantle conductance for which this process is important is again  $10^8$  S, in agreement with the value at which coupling becomes significant for variations in LOD.

It has been shown that EM coupling can explain variations in LOD, but this is a purely kinematic calculation. The dynamics of the process are less promising. As an idealization of *torsional oscillations* in the core, consider the equation of motion for a simple damped harmonic oscillator

$$\ddot{\theta} + \alpha \dot{\theta} + \omega^2 \theta = 0$$

where  $\theta$  is a measure of angular displacement, and the dots indicate time derivatives. Conservative coupling mechanisms (see Core-mantle *coupling, topographic*) and gravitational contribute primarily to the  $\omega^2$ term, allowing the system to support oscillations, while dissipative coupling mechanisms (viscous and electromagnetic) contribute primarily to the  $\alpha$  term, leading to damping of these oscillations. The dominant spherical harmonic (q.v.) component of  $B_r$  at the CMB, as at the Earth's surface, is the axial dipole, despite the effects of downward continuation (q.v.). If changes in core angular momentum are carried by torsional oscillations, then the EM torque for an axial dipole field is directly proportional to the angular momentum relative to the mantle (giving  $\alpha$  as a positive constant in the equation above). With only EM coupling, the angular momentum then decays exponentially: a conductance of 10<sup>8</sup> S leads to a damping time of order 90 years, with higher conductance giving a correspondingly shorter timescale. That decadal variations in LOD are observed therefore provides an approximate upper limit on the mean deep mantle conductance: a value of 10<sup>9</sup> S would give a damping time of only 9 years, which is probably too short for free torsional oscillations, which we believe we see. With this insight, we can rule out EM coupling as a primary mechanism to influence paleomagnetic reversal preferred paths, or leading to the observed low level of secular variation in the Pacific over timescales of centuries.

Thus, dynamically, it seems unlikely that EM coupling should be the sole mechanism for explaining decadal variations in length of day—topographic or gravitational coupling are dynamically more favorable to support torsional oscillations. However, a dissipative mechanism is also required for angular momentum transfer, and because the *viscosity* of the core (q.v.) is small, EM coupling is the most likely such mechanism. Probably the most promising combination of mechanisms comes from the theory of inner core gravitational coupling to the mantle, in which motions of the inner core excite torsional oscillations in the fluid core, which are then damped by electromagnetic coupling with the mantle. Therefore, although EM coupling is unlikely to be the sole mechanism for explaining decadal variations in LOD (q.v.), it is nonetheless likely to play an important role.

## **CORE-MANTLE COUPLING, THERMAL**

Convection in the Earth's core is driven by the removal of heat from the core by the mantle. In order to remove that heat along with heat from internal heat sources in the mantle, the mantle convects. Thus, at the most fundamental level, convection in the core and in the mantle are coupled. Without mantle convection, the rate of core cooling would be insufficient to maintain core convection. However, the coupling between mantle convection and core convection is not limited to the gross thermodynamics of the core-mantle system: mantle convection results in lateral variations in temperature and composition in the mantle, which in turn affect the pattern of heat flux from the core in to the mantle.

The lateral variations in heat flux from the core that are imposed by the mantle mean that the mantle may exert a long-term influence on the pattern of convection in the core, since the pattern of mantle convection changes on a timescale (say  $10^8$  years) that is much longer than the timescale of core convection (say  $10^3$  years).

To understand this further, we begin with a simple physical picture of thermal core-mantle coupling; we then consider the observational evidence and finally we consider results from numerical modeling.

## Simple physical model

The heat flux across the core-mantle boundary depends upon the thermal conductivity of and the temperature gradient in the immediately overlying mantle. In this context, by immediately overlying mantle we mean the part of the mantle within the thermal boundary layer at the core-mantle boundary in which the dominant mechanism of heat transport is conduction.

Beneath this thermal boundary layer lies the core-mantle boundary: lateral temperature variations on the core-mantle boundary (assuming that it is an equipotential surface) are of order  $10^{-3}$  K. Above the thermal boundary, the lateral temperature variations in the mantle are of order  $10^2$  or  $10^3$  K. As a result, lateral variations in the temperature gradient at the core-mantle boundary are due to the lateral variations in temperature along the core-mantle boundary itself. Thus, where the lowermost mantle is hotter than average, for example in a hot upwelling region, the magnitude of the temperature gradient at the core to the mantle and, conversely, where the lowermost mantle is colder, for example in a cold downwelling region, the heat flux will be increased.

An alternative way of viewing this is from the perspective of the core. The core responds to lateral temperature variations in the mantle

by re-distributing the heat from the core so as to tend to reduce the lateral temperature variations in the mantle. Where the mantle is colder, more heat flows from the core into the mantle.

Mantle convection may also result in lateral variations in composition, which in turn may result in lateral variations in thermal conductivity. These too will result in lateral variations in heat flux: where thermal conductivity in the lowermost mantle is lower than average the heat flux will also be lower than average and vice versa.

A crucial difference between convection in the core and in the mantle, as mentioned above, concerns timescales. In the core, the convective turnover timescale is about 1000 years, while in the mantle it is perhaps as large as 100 Ma. This difference is important because it means that any lateral variations in heat flux imposed on the core by the mantle are stationary on a timescale much greater than the timescale of core convection; in other words, convection in the core may be expected to carry the imprint of lateral variations in heat flux at the core-mantle boundary over a timescale much greater than that on which one might otherwise expect on the basis of considerations of core dynamics in isolation from the mantle.

This provides the key to looking for evidence of core-mantle thermal coupling. Features in the magnetic field that are persistent over timescales comparable or longer than the timescale of core convection may provide evidence of control of the pattern of core convection and hence of the magnetic field by the mantle.

## **Observational evidence**

There are four chief lines of observational evidence for thermal core-mantle interactions: the Pacific dipole window (Fisk, 1931; Cox, 1962), static flux bundles at the core-mantle boundary (Bloxham and Gubbins, 1987), variations in the frequency of geomagnetic reversals (Cox, 1975; Jones, 1977), and the concentration of geomagnetic reversal paths in certain longitude bands (Laj *et al.*, 1991, 1992).

## The Pacific dipole window

The central paradigm of geomagnetism is the geocentric axial dipole hypothesis, which maintains that over sufficiently long time intervals the magnetic field averages to that of a geocentric dipole aligned with the rotation axis. Departures from this configuration are referred to as nondipole fields though these must, if the geocentric axial dipole hypothesis holds, be transient. Thus nondipolar fields and secular variation are, on an appropriate timescale, in large part synonymous.

The Pacific dipole window is a region in which the magnetic field around the Pacific region is more nearly dipolar than elsewhere, or equivalently in which the paleomagnetic secular variation is of lower than typical amplitude.

Fisk (1931), from an examination of magnetic observatory data, discovered that secular variation in the Pacific region is anomalously low. Interest in this observation increased following the suggestions of Allan Cox and Richard Doell, based on paleomagnetic studies of Hawaiian lava flows, that nondipole field has been small over the last million years (Doell and Cox, 1961, 1965; Cox and Doell, 1964) and that the low secular variation seen by Fisk dates back at least as far as 1750 (Doell and Cox, 1963). This anomalous behavior in the magnetic field became known as the Pacific dipole window. For the reasons described above, we may consider the Pacific dipole region as one in which the field is more nearly dipolar than elsewhere, or equivalently one in which, on appropriate timescales, the paleomagnetic secular variation is of lower than typical amplitude.

Although some doubt has been since cast on these assertions on paleomagnetic grounds (McElhinny and Merrill, 1975, for example), there is little doubt that the secular variation is different in vigor in the Pacific form elsewhere at least on timescales of several hundred (Bloxham *et al.*, 1989; Jackson *et al.*, 2000) to several thousand years (Johnson and Constable, 1998).

Cox and Doell (1964) suggested two possible causes of the Pacific dipole window: first, that a region of high electrical conductivity in the

mantle screens the secular variation; and second that thermal interactions between the mantle and core affected the pattern of convection in the core. Their work was the first to propose that the mantle many influence the morphology of the geomagnetic field.

#### Static flux bundles at the core-mantle boundary

Using a sequence of maps of the magnetic field at the core-mantle boundary between 1715 and 1980, Gubbins and Bloxham (1987) identified certain features in the field that had drifted little during more than 250 years. Prominent among these static features are a pair of concentrations of magnetic flux at high latitude in each hemisphere, arranged nearly symmetrically about the equator. If westward drift were uniform at the core-mantle boundary, then these patches should have drifted through about 50° during the interval of their study. Even though the magnetic field at the core-mantle boundary is relatively poorly determined in the earliest part of their study, a drift of 50° would have been readily apparent. More recently, using a vastly improved data set, Jackson et al. (2000) found substantially the same field morphology over this interval. Furthermore, earlier work, limited to studying the magnetic field at the Earth's surface rather than at the core-mantle boundary, had suggested that while some parts of the magnetic field drift, others are stationary (Yukutake and Tachinaka, 1969; James, 1970).

Three aspects of the high-latitude flux bundles identified by Gubbins and Bloxham (1987) need to be explained: first, their latitude; second, their symmetry about the equator; and, third, their longitude and the fact that they do not drift. The explanation of the first two aspects does not involve core-mantle interactions per se and is instead a result of the tangent cylinder in the core (Gubbins and Bloxham, 1987). More pertinently to this discussion, Bloxham and Gubbins (1987) proposed that the longitude and stationarity of the high-latitude flux bundles results from thermal core-mantle interactions on account of the fact that the flux bundles reside beneath regions where the mantle is seismically faster than average. If we assume that seismic heterogeneity in the lowermost mantle is primarily thermal in origin then seismically fast regions correspond to colder regions, in other words to regions of higher heat flux across the core-mantle boundary. Thus, the evidence from the last 300 years is that flux concentrations occur beneath regions of enhanced heat flux from the core.

Of course, 300 years represents less than one convective turnover time for the core, so additional, longer term evidence of the stationarity of high latitude flux bundles is required. A number of studies have examined whether there is evidence for high latitude flux bundles in paleomagnetic measurements of the field. The evidence is mixed: of recent studies of the time-averaged field over the last 5 Ma, Kelly and Gubbins (1997) find flux bundles at approximately the same locations (at least in the northern hemisphere where the paleomagnetic data coverage is reasonable as opposed to the southern hemisphere where it is extremely sparse) as those seen for the last 300 years; Johnson and Constable (1997) find evidence of nonzonal structure, but not unambiguous evidence of flux bundles, while Carlut and Courtillot (1998) fail to find evidence of any nonzonal structure. Given the poor distribution of measurements, high-latitude flux bundles cannot be ruled out based on these studies (Constable et al., 2000). On intermediate timescales, namely from a 3000-year time average of the field, high-latitude flux bundles are observed again in approximately the same locations as recent observations (Johnson and Constable, 1998), though the more recent model (Constable et al., 2000) indicates that while they may exist in the time-average they are not necessarily present at all times.

Despite the somewhat equivocal evidence from studies of longer time span data, any persistent nonzonal structure that is observed is consistent with that seen in the historical record.

#### Variations in reversal frequency

The chronology of geomagnetic reversals is well-established for roughly the last 150 Ma (see *Geomagnetic polarity reversals*). During that period, the reversal frequency has varied greatly, from as many as eight 134

reversals in a 1-Ma interval around 4 Ma before present to the other extreme of almost 40 Ma between successive reversals during the Cretaceous centered 100 Ma before present. It should be noted, however, that long intervals without reversal are more robustly interpreted as long intervals of predominantly one polarity, since short subintervals of the opposite polarity might be missed. Nonetheless, the record is clear: the frequency of geomagnetic reversal varies greatly, on a timescale, as first pointed out by Cox (1975), of around 50 Ma. As we have seen, this is much longer than the longest timescales commonly associated with magnetic field generation in the core. Cox suggested that these changes in reversal frequency may be due to changes at the core-mantle boundary.

## Geomagnetic reversal paths

A fourth line of evidence, first reported by Laj *et al.* (1991, 1992) for thermal core-mantle interactions comes from the tendency of geomagnetic reversal paths, or more precisely of virtual geomagnetic pole paths, to cluster along one of two separate paths, one corresponding in longitude to the Americas and the other to the eastern part of Asia. Such paths correspond roughly to the position of the static flux bundles (discussed above). This work generated considerable controversy; Love (2000), however, in a very careful analysis, found that the clustering of reversal pole paths is statistically significant at about the 95% confidence level. The fact that reversal pole paths are clustered in a way that corresponds geographically to other evidence of core-mantle interaction lends additional credibility.

## Numerical models

Following the pioneering work of Glatzmaier and Roberts in the 1990s in producing numerical models of the geodynamo (see *Geodynamo*, *numerical simulations*), the effect of thermal core-mantle interactions can be simulated numerically. Each of the three sources of observational evidence for thermal core-mantle interactions can be investigated numerically.

#### The Pacific dipole window

The effect of lateral variations in heat flux at the core-mantle boundary on the long-term secular variation was first studied numerically by Bloxham (2000). By imposing lateral variations in heat flux derived from seismic tomography on a numerical dynamo model he showed that the latitudinal distribution of secular variation was closer to that inferred from observations (than was the case using a homogeneous boundary condition), and that the pattern of secular variation included a Pacific dipole window. In a more recent study, Christensen and Olson (2003) found similar results over a different, but broader, range of parameters.

#### Static flux bundles at the core-mantle boundary

Sarson *et al.* (1997) were the first to study thermal core-mantle interactions and static flux bundles using a numerical dynamo. They showed that the stationarity of flux bundles may be intermittent, a finding that is consistent with earlier studies of the coupling of purely thermal convection to lateral variations in heat flux (Zhang and Gubbins, 1993, 1997). A later study by Bloxham (2002) found behavior consistent with that seen observationally, namely flux bundles at fixed longitudes in the time-average, but with intervals of intermittency in which the bundles are either moved or absent.

## Variations in reversal frequency

Glatzmaier *et al.* (1999) imposed a variety of patterns of heat flux variation on a numerical dynamo model and found differences in the propensity for magnetic reversals, providing compelling evidence that

the frequency of magnetic reversal, at least in their numerical dynamo model, is sensitive to the pattern of heat flux variation. One cautionary note should perhaps be mentioned: the changes in pattern of heat flux variation in their study exceeded those that seem reasonable on the timescale on which the reversal frequency changes. Thus, more investigation is needed to investigate the sensitivity of reversal to smaller, more realistic changes in heat flux pattern.

## Geomagnetic reversal paths

Two studies are of particular note. First, Coe *et al.* (2000) examined the pole path pattern for four of the geomagnetic reversals reported from the numerical modeling of Glatzmaier *et al.* (1999), finding a correlation between the pattern of heat flux variation and reversal pole paths. In a more extensive study, Kutzner and Christensen (2004) found that pole paths tend to cluster in regions of high heat flux and inferred that regions of high heat flux result in intense magnetic flux bundles, which in turn result in an equatorial dipole component biased in that direction.

#### Summary

The evidence for thermal core-mantle interactions is compelling: simple physical considerations argue that it will be an important effect; observations provide evidence of thermal core-mantle interactions on a large range of timescales, from change in reversal frequency to the recent secular variation; and numerical dynamo models provide further support. Perhaps the most important finding to emerge from the study of thermal core-mantle interactions is the simple realization that the dynamics of the core cannot be considered in isolation from the mantle: the two convecting systems are fundamentally coupled.

## CORE-MANTLE COUPLING, TOPOGRAPHIC

Topographic core-mantle coupling results from pressure gradients across bumps at the CMB. Hide (1969, 1977) initiated the study of this mechanism. He discussed how pressure lows and highs result from fluid motions below the core surface. Later, dynamic pressure at the core surface ( $\simeq 10^3$  Pa from peak to trough) has been estimated from geomagnetic secular variation models through core flow modeling. Subsequent research was focused on the strength of the pressure torque by comparison with electromagnetic, viscous, and gravitational torques acting either at the CMB or at the ICB. These research works have often been controversial because of our poor knowledge of the relief at the core-mantle interface (see *Core-mantle coupling topography, seismology*) and of the motions at the core surface. The axial pressure torque acting on the mantle is:

$$\Gamma_p = \mathbf{k} \cdot \int_{\text{CMB}} p(\mathbf{r} \times \mathbf{n}) \, \mathrm{d}S \tag{Eq. 1}$$

where  $\mathbf{k}$  is the unit vector along the rotation axis,  $\mathbf{n}$  is the normal outward to the fluid volume,  $\mathbf{r}$  is the position vector, and p is the pressure. It would vanish if the CMB were spherical ( $\mathbf{n}$  collinear with  $\mathbf{r}$ ). There is an expression analogous to Eq. (1) for the torque acting on the solid inner core.

There are also equatorial components of the pressure torque. Their calculation is straightforward as the acting pressure is due to the centrifugal acceleration associated with a quasirigid equatorial rotation of the outer core. This is the free core nutation (FCN) problem. The FCN results from a tiny difference between the rotation vectors of, respectively, the mantle and the fluid outer core. Because of this misalignment, centrifugal pressure acts on the CMB, of which the meridional sections are ellipsoidal. As a result, the period of the FCN, which is accurately measured because of resonances with lunar forcing, determines the oblateness of the CMB. The remaining part of this entry is devoted to the axial problem.

In reaction to the pressure torque  $\Gamma_p$  acting from the core on the mantle, there is an exactly opposite torque acting on the core from the mantle. As a result, core motions are influenced by the CMB topography. Less obviously, it can be argued that the core motions are arranged in such a way that the strength of the pressure torque is limited. Thus, estimation of the pressure torque and study of the influence of the CMB topography on core dynamics are two intertwined questions (see *Core-mantle coupling topography, implications for dynamics*).

## Geostrophic motions and topographic coupling

Core angular momentum changes in reaction to the torques that act on it. In rapidly rotating and enclosed fluids, angular momentum is carried by motions that are either exactly geostrophic, obeying the leading order force balance between Coriolis and pressure forces, or closely related. Throughout geostrophic circulation, columns of fluid, parallel to the rotation axis, move following geostrophic contours C, which are closed paths on the upper and lower boundaries separated by constant height. Inside the Earth's outer core, the contours C slightly deviate from circles centered on the rotation axis because of topography at the boundaries and generate nearly circular cylinders. For each cylinder, the top and bottom contours are situated either both on the CMB (outside the cylinder tangent to the inner core) or one on the ICB and the other on the CMB (inside this cylinder). Taking the integral over geostrophic cylinders of the momentum equation valid in the frame rotating with the mantle cancels out the leading order terms (Bell and Soward, 1996). Finally, an equation for the geostrophic velocity  $\mathbf{u}_{g}$  is derived:

$$\rho(z_T - z_B) \oint \left(\frac{\partial \mathbf{u}_g}{\partial t} + \rho \frac{\mathrm{d}\Omega}{\mathrm{d}t} (\mathbf{k} \times \mathbf{r})\right) \mathrm{d}\mathbf{l} = \int_{z_B}^{z_T} \left(\oint (\mathbf{j} \times \mathbf{B} + \rho \mathbf{g}) .\mathrm{d}\mathbf{l}\right) \mathrm{d}z,$$
(Eq. 2)

136

where dl is an element of arc length along *C* and  $z_T$  and  $z_B$  denote the *z*-coordinates (parallel to the rotation axis) along, respectively, the top and bottom geostrophic contours. Neglecting the inertial term on the LHS, the RHS gives a generalized version of *Taylor's condition* (*q.v.*). The magnetic force  $\mathbf{j} \times \mathbf{B}$  gives the term that generates *torsional oscillations* (*q.v.*) in reaction to the shearing of the magnetic field lines by the geostrophic motions. It can be shown that Eq. (2) governs the time changes of the kinetic energy of the geostrophic motions, in a frame rotating with the mantle. With spherical boundaries, Eq. (2) can be interpreted also as the equation governing the transport of angular momentum within the fluid outer core and the exchanges with the inner core and the mantle. In presence of topography on the boundaries, Eq. (2) does not, however, give directly the transport of angular momentum (Fearn and Proctor, 1992). This constitutes, arguably, the main difficulty of the studies of topographic core-mantle coupling.

If the solid boundaries were spherical and electrically insulating, core angular momentum would be conserved and the net torque on the core would be zero. This is obviously true but this may also be directly inferred from Eq. (2). Taking into account topography and using a perturbation approach, only the *s* and *z* components of the magnetic and buoyancy forces are involved in the terms that are dependent (linearly) on the topography on the RHS of Eq. (2), while a spherical approximation can be used on the LHS. The constraint of conservation of core angular momentum carried by geostrophic motions does not apply any more.

Taking for the sake of the demonstration insulating solid boundaries in a core model, the only torque left to modify the total core angular momentum is the pressure torque  $\Gamma_p$ . Indeed, the buoyancy and magnetic forces that accelerate the geostrophic motions within the core are unable to account for the exchanges of angular momentum with the mantle. Conversely, when there is a nonzero pressure torque, there are time changes of  $\mathbf{u}_{g}$  and Taylor's condition is not exactly obeyed. Thus, in an average state, fulfilling Taylor's condition, the pressure torque would vanish. In the actual Earth, the different contributions to Eq. (1) probably tend to cancel out also except if the electromagnetic torque acting between core and mantle is strong enough to oppose  $\Gamma_p$ . This explains why it will be difficult to estimate  $\Gamma_p$  from geophysical data. If such a cancelation does not take place and if the height of the topography is of the order of 1 km, the pressure torque is much larger than the torque responsible for the observed changes in the Earth's rotation (Jault and Le Mouël, 1990).

From a theoretical viewpoint, it may not be possible to study separately the different torques acting between core and mantle. As an example, addition of a conducting layer at the bottom of the mantle to the model and inclusion of CMB topography cannot be considered in isolation. Both modify the RHS of Eq. (2). Kuang and Chao (2001, 2003) have adapted a numerical geodynamo model to study topographic coupling. Their solutions are calculated in a spherical shell with boundary conditions modified to mimic the role of the CMB topography. With this approach, the main ingredient of topographic coupling, distortion of the geostrophic contours, is included. Kuang and Chao have verified that, in their model, the different contributions to the pressure torque tend to cancel out.

## Role of the inner core

The main pressure torque acting on the fluid outer core may result from the action of the hydrostatic pressure on the ICB topography if the ICB does not coincide with an equipotential surface of the gravity field. It is unimportant for the outer core since it cancels exactly a gravity torque acting from the mantle on the outer core. On the other hand, pressure and gravity torques acting on the inner core do not cancel out (see *Inner core oscillation; Inner core, rotational dynamics*). Differential rotation between the inner core and the mantle may have some influence on topographic core-mantle coupling because it entails time changes of the geometry of geostrophic contours. If the height of the topography either on the ICB or on the CMB is not negligible, the cylinder tangent to the inner core equator is not of constant height. Then, there are regions void of closed contours separated by constant height on both sides of the tangent cylinder. There, the role of the geostrophic motions is taken over by low-frequency *z*-independent inertial waves, known as Rossby waves (Greenspan, 1968, pp. 85–90).

#### Perspectives

Hopefully, understanding of core-mantle coupling will result from ongoing studies of the propagation of torsional waves within the fluid outer core. Considering the pressure acting on the mantle suffices to calculate the net torque on the mantle but not to estimate how CMB and ICB topographies influence the distribution of geostrophic velocity within the core. Knowledge of the volume forces is required, except in the special case of distortion of the geostrophic contours in the *z*-direction only, which happens when topography is antisymmetrical with respect to the equatorial plane (Jault *et al.*, 1996). Topographical effects have not yet been adequately taken into account in models of torsional waves.

Perhaps, too much weight has been given in this entry on Taylor's condition. Rapid changes in the differential rotation between geostrophic cylinders are definitely opposed by magnetic forces within the core. On the other hand, only viscous coupling and magnetic coupling with the weakly conducting mantle control global oscillations of the fluid outer core with respect to the mantle.

## COWLING, THOMAS GEORGE (1906–1990)

Thomas George Cowling (Figure C45), applied mathematician and astrophysicist, was born on June 17, 1906 at Hackney, London, the second of the four sons of George Cowling, post office engineer, and Edith Eliza Cowling (née Nicholls). His grandparents and their antecedents were nearly all artisans, blue-collar workers, servants, or sailors. Tom was educated at Sir George Monoux Grammar School, from where in 1924 he won an open scholarship in mathematical Exhibition in 1925 and the Scholarship in 1926. A first class degree was rewarded by a three-year post-graduate scholarship at Brasenose, his research supervisor being the cosmologist Edward A. Milne.

Cowling's acumen was quickly recognized. After gaining his D.Phil., he went by invitation to join *Sydney Chapman* (q.v.) at Imperial College as demonstrator. Their collaboration converted Chapman's "skeleton" of a book into a standard text, *The Mathematical Theory of Non-Uniform Gases* (1939), which treats kinetic theory by a systematic attack on the classical Boltzmann equation. Cowling was subsequently assistant lecturer in mathematics at Swansea (1933–1937), and lecturer at Dundee (1937–1938) and at Manchester (1938–1945). From 1945–1948 he was professor of mathematics at Bangor, moving then to his last post as professor in 1970.

Over the three decades 1928–1958, Cowling made outstanding contributions to stellar structure, cosmical electrodynamics, kinetic theory and plasma physics. Recognition came with the Johnson Memorial Prize at Oxford (1935), election to the Royal Society (1947), the Gold Medal of the Royal Astronomical Society (1956) and its presidency (1965–1967), Honorary Fellowship of Brasenose (1966), the Bruce Medal of the Astronomical Society of the Pacific (1985), and the Hughes Medal of the Royal Society (1990).

Tom Cowling married Doris Marjorie Moffatt on August 24, 1935. There were three children: Margaret Ann Morrison, Elizabeth Mary Offord (deceased 1994), and Michael John Cowling, and six grandchildren.

A few years before Cowling began working on stellar structure, Sir Arthur Eddington had published his celebrated *Internal Constitution of* 

Figure C45 Thomas George Cowling.

*the Stars*, in which he pictured a homogeneous star as a self-gravitating gaseous sphere in radiative equilibrium, with its luminosity fixed by its mass and chemical composition. From comparison of his "standard model" with the masses and radii of observed "main-sequence" stars, Eddington inferred that the as yet unknown stellar energy sources must be highly temperature-sensitive. Cowling's careful analysis strengthened Eddington's case—against the criticisms of Sir James Jeans—by showing that the models would nevertheless almost certainly be vibrationally stable. In parallel with Ludwig Biermann, he also showed that a stellar domain that satisfies the Schwarzschild criterion for convective instability and becomes turbulent needs only a very slightly superadiabatic temperature gradient in order to convect energy of the order of a stellar luminosity.

The "Cowling model," with its nearly adiabatic convective core, surrounded by a radiative envelope, is a paradigm for stars somewhat more massive than the Sun, for which energy release by fusion of hydrogen into helium takes place through the highly temperaturesensitive Bethe-Weizsäcker carbon-nitrogen cycle. In low-mass stars like the Sun, hydrogen fusion occurs via the much less temperaturesensitive proton-proton chain, so that the energy-generating core is now radiative; but because of the low surface temperature, there is a deep convective envelope, extending from just beneath the radiating surface. Biermann's calculated depth for the solar convection zone has been confirmed by helioseismology. Biermann also showed that a star of  $\simeq M_{\odot}/4$  would be fully convective. Cowling pointed out that for these stars, the luminosity must still satisfy the condition of radiative transport through the nonconvecting surface layers. Earlier, Milne had argued that the luminosity of all stars should be sensitive to conditions in the surface, rather than depending essentially on radiative transfer through the bulk of the star, as in Eddington's theory. Cowling's work vindicated Eddington's approach for main-sequence stars, while implicitly allowing for such sensitivity in giant stars and pre-main sequence stars, with extensive sub-surface convective zones.

Cowling's other contributions to stellar structure include an important paper on binary stars, and two pioneering papers on nonradial stellar oscillations, foreshadowing today's work in helioseismology.

Simultaneous with his work on stellar structure, Cowling published a series of studies on cosmical magnetism and on plasma physics, culminating in his superbly succinct monograph *Magnetohydrodynamics* (1959, 1976). Together with Biermann, Arnulf Schlüter, and Lyman Spitzer Jr., he did much to clarify the concept of "conductivity" for both fully and partially ionized gases. A lively correspondence with Biermann in the 1930s brought out the requirements of a theory of both the structure and the origin of sunspots, and indeed may be thought of as the genesis of the study of magnetoconvection. While recognizing the seminal contributions of *Hannes Alfvén* (q.v.) to cosmical magnetism ("Alfvén's best ideas are very good indeed"), he had earlier applied his renowned critical faculties to a demolition of Alfvén's theory of the sunspot cycle and defended the pioneering Chapman-Ferraro, quasi-MHD theory of geomagnetic storms against what he regarded as unjust attacks.

In the geomagnetic and in fact in the general scientific world, Cowling is probably best known for his "antidynamo theorem" (see Cowling's Theorem). Sir Joseph Larmor (q.v.) had suggested that motion of the conducting gas across a sunspot magnetic field yields an emf, which drives currents against the Ohmic resistance, and these currents could be just those required by Ampère's law to maintain the assumed field. Cowling began what he expected to be a "relatively routine piece of difficult computation," to see what sort of field could be maintained by the Larmor process. He found instead that for an axisymmetric field, the required condition breaks down at the ring of neutral points. In the absence of an energy supply, the Ohmic decay of the axisymmetric field can be pictured as the steady diffusion of closed field lines into the neutral point. The moving gas drags field lines around meridian planes, but does not generate new ones to replace the disappearing loops-that would require gas to emerge from the neutral point with infinite speed. This qualitative argument can be generalized to apply to fields that are topologically similar to the axisymmetric fields.

For a while, Cowling does seem to have surmised that there was waiting to be proved a much more general antidynamo theorem. Later he felt that too much emphasis was laid on his and other antidynamo theorems: their significance is that those fields that can be dynamomaintained cannot be simple in structure or in mathematical formulation. He illustrated this by showing how one prima facie convincing general algorithm, designed for the construction of the velocity field that will maintain a prescribed magnetic field, when applied to a field which is known to be ruled out by an anti-dynamo theorem yieldsunsurprisingly-"velocities" that are pure imaginary. He appears to have provisionally accepted the now familiar picture by which nonuniform rotation acting on a given poloidal field generates a toroidal field, which in turn yields the required new poloidal flux when acted upon by nonaxisymmetric convective motions-the "a-effect" in current dynamo terminology. While remaining well aware of the lacunae in our present theoretical knowledge, he concluded (1981): "The dynamo theory of the Sun's magnetic field is subject to a number of unresolved objections, but alternative theories advanced so far are open to much greater objections."

In the absence of dynamo action, the high conductivity of stellar plasma yields an Ohmic decay time for a large-scale primeval stellar field that can exceed the lifetime of the star. This "fossil" field picture is inapplicable to the Sun, in which the poloidal field is now known to reverse as part of the solar cycle, but it remains relevant to the observed strongly magnetic stars, convincingly modelled as oblique magnetic rotators. However, for the Earth, the much smaller length scales yield a decay time that is far too short, so that for both the Sun and the Earth, dynamo maintenance appears to be mandatory.

In his autobiographical essay "Astronomer by accident" (1985), Cowling remarks that he and his brothers inherited the "Puritan work ethic" from their nonconformist parents. He remained an active, nonfundamentalist Baptist, though in his later years he confessed to doubts, speaking of "getting closer to mysticism rather than to a religion of set creeds." His puritanism perhaps showed itself in his very high academic standards, which he applied as much to his own work as to that of others, and earned him the nickname "Doubting Thomas." Everyone knew him by sight: his red hair and his great height made him conspicuous. They also looked up to him metaphorically, because of his combination of kindliness and intellectual power.

Cowling's research activity in his later decades was severely hampered by recurring bouts of ill-health, beginning with a duodenal ulcer in 1954. He died in Newton Green Hospital, Leeds on June 15, 1990.

## **COWLING'S THEOREM**

Among the theorems of applied mathematics Cowling's theorem on the impossibility of axisymmetric homogeneous dynamos has played a special role because it has cast in doubt for 40 years the dynamo hypothesis of the origin of geomagnetism. This hypothesis goes back to Larmor (1919; see *Larmor; J.*) who argued that the magnetic field of sunspots could be created by motions in an electrically conducting fluid. He envisioned an axisymmetric model where radial motion into a cylindrical tube of magnetic flux would cause an electromotive force  $\mathbf{v} \times \mathbf{B}$  driving an electric current in the azimuthal direction, which in turn would enhance the magnetic flux in the cylinder. While this model appears to be superficially convincing, Cowling was able to prove that such a dynamo process is not possible.

The proof originally provided by Cowling (1934; see *Cowling*, *T.G.*) is quite simple since he was only concerned with the possibility of the steady generation of a field confined to meridional planes as envisioned by Larmor. A general axisymmetric magnetic field **B** satisfying the condition  $\nabla \cdot \mathbf{B} = 0$  can be described by

$$\mathbf{B} = \nabla A_{\phi} \times \boldsymbol{e}_{\phi} + B_{\phi} \boldsymbol{e}_{\phi} \tag{Eq. 1}$$

where  $e_{\phi}$  is the unit vector in the azimuthal direction and  $A_{\phi}$  is the  $\phi$ -component of the magnetic vector potential **A**. Ohm's law for an electrically conducting fluid moving with the velocity field v can be written in the form

$$\lambda \nabla \times \mathbf{B} = \mathbf{v} \times \mathbf{B} - \nabla U - \frac{\partial}{\partial t} \mathbf{A}$$
 (Eq. 2)

where the last two terms represent the electric field and where the magnetic diffusivity  $\lambda$  is the inverse of the product of magnetic permeability and electrical conductivity of the fluid,  $\lambda = (\sigma \cdot \mu)^{-1}$ . Since we are considering an axisymmetric steady process  $(\partial/\partial t)\mathbf{A}$  vanishes and  $\nabla U$  does not contribute to the  $\phi$ -component of Eq. (2). The latter assumes the form

$$v_r \frac{\partial}{\partial r} C + v_z \frac{\partial}{\partial z} C = \lambda \left( \frac{\partial^2}{\partial r^2} C + \frac{\partial^2}{\partial z^2} C - \frac{1}{r} \frac{\partial}{\partial r} C \right)$$
(Eq. 3)

where a cylindrical coordinate system  $(r, \phi, z)$  has been used and  $C(r,z) \equiv rA_{\phi}$  has been introduced after multiplication of the equation by r. The condition that the magnetic field is generated locally requires that it decays towards infinity at least like a dipolar field, i.e., in proportion to  $(r^2 + z^2)^{-3/2}$ . The function C(r, z) thus must decay at least like  $(r^2 + z^2)^{-1/2}$ . Since, on the other hand, C vanishes on the axis, r = 0, it must assume at least one maximum or minimum at a point  $(r_0, z_0)$  at which  $(\partial/\partial r)C = (\partial/\partial z)C = 0$  can be assumed. Such a point in the meridional plane is sometimes called "neutral line." Because at a maximum or minimum usually  $(\partial^2/\partial r^2)C + (\partial^2/\partial z^2)C \neq 0$  holds, a contradiction to Eq. (3) is obtained. In the case of "flat" maxima or minima where  $(\partial^2/\partial r^2)C + (\partial^2/\partial z^2)C$  may vanish a similar contradiction can be constructed, but this requires a more technical approach. It should be noted that the above argument does not require a solenoidal velocity field,  $\nabla \cdot \mathbf{v} = 0$ , as Cowling had originally assumed. For a generalization of Cowling's original theorem, which emphasizes its topological nature, see Bullard (1955; see Bullard, E. C.). Backus and Chandrasekhar (1956) later refined Cowling's proof by eliminating the possibility of an axisymmetric dynamo with a finite component  $B_{\phi}$ .

For geophysical and astrophysical applications it is important to consider the possibility of axisymmetric dynamos caused by varying magnetic diffusivity or by time-dependent processes. The former possibility was eliminated by Lortz (1968) while the latter problem motivated Braginsky (1964) to seek a new mathematical approach based on energy arguments. Braginsky also introduced the spatial configuration of a finite axisymmetric domain V of constant electrical conductivity surrounded by an insulating space outside. For his proof of the impossibility of time-dependent axisymmetric dynamos he had however to assume a solenoidal velocity field. For the domain V, Hide (1979) introduced as a new definition for a dynamo that the magnetic flux intersecting the surface  $\partial V$  of V remains finite as the time t tends to infinity,

$$\oint_{\partial V} |\boldsymbol{B} \cdot \boldsymbol{d}^2 S| \neq 0 \quad \text{for} \quad t \to \infty.$$
(Eq. 4)

Hide and Palmer (1982) tried to prove on this basis Cowling's theorem under rather general conditions. In view of their novel approach it is unfortunate that their proof turned out to be incomplete (Ivers and James, 1984; Núñez, 1996). The efforts of Lortz and coworkers were thus required to arrive at mathematically rigorous conclusions about the impossibility of the generation of axisymmetric magnetic field by time dependent and not necessarily solenoidal velocity fields. For references and details of the mathematical issues we refer to the reviews of Ivers and James (1984) and Núñez (1996).

Cowling (1955) had already realized that the ideas of the proof for the impossibility of an axisymmetric dynamo could easily be applied to prove the impossibility of two-dimensional dynamos for which the magnetic field depends only on two of the three coordinates of a cartesian system. Since the cartesian case is somewhat simpler to deal with many of the mathematical problems have first been explored in this geometry. The 1955 Cowling paper is particularly important in its showing that—because of the presence of non-Hermitian operators—the apparently general kinematic dynamo formalism developed by Elsasser (1947 and earlier papers referred therein; see *Elsasser; W.*) does not guarantee real valued velocities. Cowling illustrates this by showing that the two-dimensional model yields purely imaginary velocities.

It is of interest to note that dynamos with small deviations from axisymmetry can readily be realized. The theory of spherical dynamos developed by Braginsky (1976; see *Dynamo, Braginsky*) is based on a small perturbation of an axisymmetric configuration. A purely axisymmetric dynamo has been obtained by Lortz (1989) by allowing for a small anisotropy of the magnetic diffusivity tensor. It thus appears that in spite of its early negative influence Cowling's theorem has stimulated the understanding of dynamo action and the creation of ingenious solutions for the problem of magnetic field generation.

## COX, ALLAN V. (1926–1987)

Allan Cox was one of the preeminent geophysicists of his generation. He made many important scientific contributions to the field of paleomagnetism and to the study of plate tectonics. His untimely death at the age of 61 was a loss to Stanford University, his home institution, and to the geophysics community.

Cox was born in Santa Ana, California, in 1926 as the son of a house painter. He attended the University of California at Berkeley where he started his education as a chemistry major. He only went to Berkeley for one quarter before he dropped out and joined the merchant marine. His work in the merchant marine allowed him time for one of his great loves, reading over a wide range of topics. After three years in the merchant marine, he returned to Berkeley, again as a chemistry major. One of his life defining experiences at that time was spending summers in Alaska with geologist Clyde Wahrhaftig of the U.S. Geological Survey. These summer jobs gave Cox a strong love of geology. When he returned to Berkeley to continue his education at the end of the summer, he found chemistry dull by comparison and his grades suffered. This led to the loss of his student deferment from the military draft and he ended up in the army for two years. When he came back to Berkeley after the army, strongly motivated to succeed at his studies, he changed his major to geology. In 1955, he earned his bachelor of arts from Berkeley in geology. He continued his education with graduate work in geology at Berkeley. His initial intent was to study ice and rock glaciers, the objects of his summer field work with Wahrhaftig, but instead he decided to work with John Verhoogen on rock magnetism. At that time Verhoogen was one of the few Berkeley faculty members who was receptive to the idea of continental drift. This gave Cox an early exposure and interest in the field that would become plate tectonics.

Cox received a master of arts in 1957 and his PhD from Berkeley in 1959 and went to work at the U.S. Geological Survey in Menlo Park, California. At the Survey he worked with another rock magnetist, Dick Doell, on the paleomagnetic record of geomagnetic field reversals. For this work, Cox and Doell needed some way to accurately date the rocks carrying paleomagnetic records of reversed and normal geomagnetic field polarity, so they convinced the U.S. Geological Survey to 140

hire Brent Dalrymple who could use the radiogenic decay of K to Ar to determine the age of igneous rocks being studied paleomagnetically. The research team of Cox, Doell, and Dalrymple made important contributions to Earth science by unraveling the record of polarity intervals of the geomagnetic field over the past 5 Ma. They traveled to far corners of the globe to collect igneous rocks of various ages, measured their paleomagnetism at their laboratory in Menlo Park, conducted demagnetization experiments to isolate the primary magnetization of the rocks, and dated the rocks radiogenically. There was spirited competition with other researchers conducting similar research at this time, particularly an Australian team consisting of Tarling, Chamalaun, and McDougall, based at the Australian National University. The two teams would make friendly wagers about who would discover the next polarity interval in the quest for the full revelation of the geomagnetic polarity time scale. The bets would be paid off, usually in cocktails, at the next professional meeting. The geomagnetic timescale for the past 5 Ma was completed by 1969 and was crucial to the seafloor spreading interpretation of the seafloor magnetic anomalies that were discovered to be parallel to the mid-ocean ridges at about this time.

In 1967, Allan Cox moved from the U.S. Geological Survey to nearby Stanford University in Palo Alto, California, and became the Cecil and Ida Green Professor of Geophysics. At Stanford he studied various aspects of paleomagnetism with his graduate students, contributing to the understanding of many topics, including the transition of the geomagnetic field between polarity states, the characteristics of geomagnetic field intensity, the statistics of polarity interval lengths, the rock magnetics of seafloor basalts and sedimentary rocks, vertical axis rotations of tectonic blocks, and the structure of a plate's apparent polar wander path. He developed a strong interest in the paleolatitudinal motion of the tectonostratigraphic terranes that were just being recognized by geologists at that time.

In 1979, he became dean of Stanford's School of Earth Sciences and showed a gift for being an administrator. During his stint as dean he kept up his teaching and his research and stayed involved with undergraduates, through undergraduate research projects and helping design the lighting for the student theatre. He was viewed as the paramount example of a true teacher-scholar, excelling equally at teaching, research, and service to Stanford University and his professional societies. He also served his community in the hills to the west of Palo Alto, studying with fellow faculty members and students the effects of logging on soil erosion and watersheds and publishing a small book on the subject, *Logging in Urban Counties*.

Allan Cox had a productive scientific career, publishing over 100 scientific journal articles and two textbooks on plate tectonics, *Plate Tectonics and Geomagnetic Reversals* and *Plate Tectonics, How it Works* with Robert B. Hart. He also received many professional honors. He was elected to the National Academy of Sciences, the American Philosophical Society, and the American Academy of the Arts and Sciences. He was president of the American Geophysical Union from 1978–1980. He received the Day Medal of the Geological Society of America, the Fleming Medal of the American Geophysical Union, and the Vetlesen Medal of Columbia University.

He died in a bicycle accident on January 27, 1987, running off the road in the hills west of Stanford and into a redwood tree. Tragically, his death was ruled a suicide, probably brought on by failings and crises in his personal life.

## **CRUSTAL MAGNETIC FIELD**

## Introduction

Magnetic minerals in the rocks in the upper lithosphere of the Earth and other differentiated planetary bodies having dynamos generate magnetic fields when the minerals are in a cooler environment than their individual Curie temperatures. These magnetic fields are useful for studying crustal materials for a variety of applications. The most widely known example of the utility of the field is its role in deciphering the process of seafloor spreading through the recognition of alternately normally and reversely magnetized rock stripes on the ocean floor (see Magnetic anomalies, marine; Magnetic anomalies for geology and resources). In continental regions, the use of crustal magnetic field is well-known to Earth scientists because the short-wavelength part of the field closely correlates with the near-surface geologic variations. Crustal magnetic field is thus a proxy for crustal geology and is useful in understanding the structure and composition of the crust as well as its evolution especially when surficial sediments and other geologic formations obscure subsurface geology. Readers interested in the details of the methods on processing, analysis, and interpretation of the entire spectrum of crustal magnetic fields should consult the books by Blakely (1995) and Langel and Hinze (1998).

Magnetization is a complex phenomenon and for rocks it is dependent on a variety of conditions the rocks are exposed to-beginning with their formation, through their tectonic evolution, and exposure to their surroundings and the ambient conditions. A part of the magnetization of the rocks has the memory of these past conditions (based on the strength and direction of the past magnetic field at the time when the rocks are formed or chemically altered, its environmental history/metamorphism, etc.): this memory is retained as components known as "remanent magnetization" (see Magnetization, remanent and Magnetization, natural remanent (NRM)). The present conditions (magnitude and direction of the surrounding ambient magnetic field, temperature, and mineral chemistry) to which magnetizable minerals in the rocks are exposed are reflected in their "induced magnetization." A vector sum of the induced magnetization and all retained remanent components leads to "total magnetization" of rocks, which causes the magnetic field in the neighborhood of the rocks. This field attenuates with increasing distance from the rocks, adds to the fields originating from the surrounding rocks, and "perturbs" the fields at the observation location caused by the planetary dynamo, electrical currents in the ionosphere and the magnetosphere (the external fields), and induction due to conductivity structure of the planetary interior (see Core, electrical conductivity and Mantle, electrical conductivity, mineralogy). The perturbing field is traditionally called the "anomalous" field and this is the crustal magnetic field.

The field of the planetary dynamo and the external fields vary spatially as well as in time (see *Geomagnetic secular variation* and *Geomagnetic spectrum, spatial*), and models estimating them at the location and time of observations are required to extract the crustal magnetic field from the raw magnetic field observations. Because the conductivity structure of the Earth is not well-known, its contribution is customarily not explicitly removed when deriving the crustal magnetic field, but efforts are underway to estimate and remove the nonmagnetization-related effects from the observed magnetic field in areas where the conductivity variation is large and the geometry is known (e.g., ocean-continent conductivity contrast; see *Coast effect* 

of induced currents). The typical model describing the core-field dynamo is called the International Geomagnetic Reference Field (IGRF) (q.v.). However, this does not include the external fields and, therefore, stationary magnetometer basestations tracking the time variations of the external field are employed in a local region of surveys (see Aeromagnetic surveying); these time-varying external fields are then removed from the survey observations to construct the magnetic anomaly field. To reduce the effects of imperfect and incomplete reference models and any remaining inconsistencies in the derived anomaly field, it is typical to perform surveys with tracks crossing each other (also called tie-lines) so that the anomaly mismatches at the cross-over locations could be minimized subject to assumptions regarding the nature of the spatiotemporal variations of the external field and the induction effects in the region. Deployment of base stations is not always feasible where surveys are made along tracks longer than a few hundred kilometers (typically over the oceans, but also for continental surveys designed for the determination of the long-wavelength anomaly field). A recently developed specialized model, known as the comprehensive model (CM) (Sabaka et al., 2002), is useful to estimate and remove these noncrustal magnetic field components from such regional survey data. The CM describes the core field and its variation, the long-wavelength variation of the external fields during the magnetically quiet periods, and the first-order induced fields in the Earth using the permanent observatory records beginning 1960s, augmented by fields measured by satellites to fill the large spatial gaps in the magnetic observatory coverage in many parts of the world. Since the CM is a temporally continuous model in comparison to the piece-wise continuous IGRF, it is also effective in minimizing survey base-level mismatches noticeable when neighboring surveys are combined (see examples in Ravat et al., 2003).

On Earth, in the near-surface environment, crustal field generally has magnitude range of a few hundred nanoteslas (nT, an SI unit of magnetic field strength) - much smaller compared to the coregenerated magnetic field of 24000-65000 nT (see Main field maps). However, over magnetically rich iron formations the magnitude of the crustal field above the Earth's surface can exceed 10000 nT regionally, for wavelengths of a few hundreds of kilometers (e.g., Kursk iron formations in Ukraine). Locally, the magnitude of the anomalies can be stupendously large: for example, ground magnetic surveys over parts of Bjerkreim-Sokndal layered intrusion in Rogaland, Norway, where hemo-ilmenitic rocks having remanent magnetization up to 74 A/m have been measured, a nearly 30000 nT anomaly trough spans the distance of only 500 m (McEnroe et al., 2004). In such places, even compass needles are rendered useless in their usual magnetic northpointing purpose because they are attracted by the magnetism of the neighboring rocks rather than the Earth's core-generated magnetic field. The sensitivity of commonly available field magnetometers is better than 0.1 nT (see Aeromagnetic surveying) and the relative precision of the measurement (which depends partly also on the relative precision of spatial coordinates and the time of measurements) nearly approaches this number in carefully executed surveys. Thus, it is possible to resolve reliably very small spatial changes in magnetic field especially over elongated geologic sources (e.g., dikes or faults). Thus, a magnetic map consists of patterns associated with geology and can be interpreted with fractal magnetization and pattern recognition/characterization concepts (e.g., Pilkington and Todoeschuck, 1993, in Blakely, 1995; Maus and Dimri, 1994; Keating, 1995); this is discussed further in the interpretation methods section.

## Examples of the utility of the field

How the crustal magnetic field is used by Earth scientists and the superb subsurface detail reflected in it are best conveyed using simple visual correlations of high-resolution magnetic and geologic maps. Figure C46/Plate 7c shows such a map from the poorly exposed Archean age province of western Australian cratons under the Precambrian

and recent cover rocks. In the figure, the magnetic map is superimposed partly by the geological map prepared by Geological Survey of Western Australia and Geoscience Australia from surface outcrops and mining information. Considerable gold workings have been developed in the greenstone formations that form the linear magnetic highs in the shape of an ovoid in the center of the map (this structure is common when domal uplifts have been partly eroded). Aeromagnetics in this case shows clearly the lateral extent of these greenstone formations under the sedimentary cover. In addition, numerous fractures, faults, dykes, as well as textures and patterns that reveal the clues to the origin and evolutionary history of the Archean craton are quite evident in this image. Generally, the correlation of magnetic anomalies with geology requires an intervening step called the reduction to pole (q.v.) because the anomalies are skewed with respect to their sources and have differently displaced positive and negative lobes depending on the magnetic latitude and the direction of remanent magnetization. Another way of avoiding the skewness issue when comparing with geology is to map the field into magnetic property variation (susceptibility and/or magnetization) as done in the next example.

The second example illustrates the utility of the other end of the crustal magnetic anomaly wavelength spectrum. The greatest advantage of looking at the long-wavelength portion of the crustal magnetic field is that it is uniformly collected by satellites and to a large degree processed similarly over the entire world. One of the most important aspects of the interpretation of the satellite-altitude magnetic field, overlooked by most geologists and geophysicists, leading to its misinterpretation, is that all wavelengths shorter than 500 km are reduced below 1 nT level at the altitude of measurement (about 400 km) and so this field contains virtually no near-surface geologic information unless the near-surface geology itself happens to be a reflection of the structure and composition of the deep crust; therefore, the correlations of these long-wavelength anomalies with geology should not be normally sought. On the other hand, this long-wavelength magnetic field contains an integrated effect of the entire magnetic portion of the lithosphere whereas most geologic/geophysical observations (including near-surface magnetic surveys) are collected over limited areas, processed differently with different methods and then compiled into a regional database-a process that inherently introduces a longwavelength corruption of the database. Moreover, near-surface geologic samples usually only have limited amount of information about the deep crust. In addition, the present amount and distribution of many data sets that can probe the deep crust (e.g., seismic, electromagnetic, etc.) is not adequate in their spatial resolution to differentiate evolutionary domains of the continents. And finally, all physical properties do not change similarly from one region to the next in the bulk sense and therefore each property has something unique to contribute to our knowledge of the Earth's crust. The main point of this second example is that the bulk magnetization variation is sensitive to a number of changes that occur from one geologic domain to the next and as a result, it is able to delineate some major crustal formation provinces in the United States. This type of knowledge is only possible through a compilation of extensive and time-consuming geochemical analyses of samples throughout the continents. Figure C47a (Plate 6d) shows geologic provinces based on the latest igneous activity in the United States (Van Schmus et al., 1996). In the western portion (for example, the western margin of the Inner Accretionary Belt in Figure C47a and Plate 6d), the geochemical age boundaries well-document the nature in which the continent accreted during the Middle Proterozoic times (1.9-1.6 Ga); however, in the eastern part, later igneous activity of the eastern and southern Granite-Rhyolite provinces (EGR (1470  $\pm$  30 Ma) and SGR (1370  $\pm$  30 Ma)) obscure the fundamental accretionary boundaries. It is only through the analyses of Nd isotope data, the crustal formation age boundary could be defined (shown by a dashed line Nd in Figure C47a and Plate 6d; Van Schmus et al., 1996) and shown by a white dashed line in Figure C47b and Plate 6d). The magnetization variation plotted in Figure C47b (Plate 6d) is the integrated effect of magnetic

**Figure C46/Plate 7c** A low-altitude, high-resolution aeromagnetic map of a part of the Archean craton in Western Australia depicting the power of remotely sensed magnetic anomalies in peeling off the sedimentary cover. Pixel size is 25 m which makes it possible to observe subtle variations in the textures of the buried craton. The aeromagnetic image is courtesy of Fugro Airborne Surveys Limited. The example is courtesy of Colin Reeves.

property over the thickness of the magnetic layer; it is based on CHAMP satellite's MF3 crustal magnetic field model (Maus *et al.*, 2004), which is much higher resolution data than its predecessors. The depth integrated magnetic property variation is clearly able to delineate the Nd boundary and reasonably well enclose the Middle Proterozoic province to the west where it is not affected by later tectonic activity reducing the thickness of the magnetic layer (e.g., Rio Grande Rift (R) and Basin and Range Province (BR)). Since the depth integrated magnetic property map is available for the whole world, it could be used to understand better the evolution of the less understood parts of Africa, Antarctica, Asia, Australia, and South America.

In general, the depth integrated magnetic property variation is a good reflection of large changes in magnetic properties of the bulk crust in the continents in locations where the crustal thickness does not vary significantly and also of places where the magnetic crust is thinner compared to the surrounding regions either because the heat flow is high (as in the Rio Grande Rift) or because much of the crust involves nonmagnetic rocks (south of Oklahoma-Alabama transform (T in Figure C47b/Plate 6d) which was the Precambrian continental boundary) and sometimes because of the effect of regional remanent magnetization.

#### The interpretation methods

The main purpose of the analysis of the crustal magnetic field is to gain knowledge of the crustal geology and its geometry, tectonics, and the evolution of the crust through time. A number of methods have been developed over the past two centuries that allow geophysicists to work toward this goal. The methods fall into two broad categories: qualitative and quantitative methods. Qualitative methods use patterns, magnitude, and wavenumber characteristics of the variation of the magnetic field to identify, group, and contrast adjacent regions into geologic domains, subdomains, and cross-cutting features. For example, referring to Figure C46/Plate 7c, the central region has a significantly different magnetic character than the territories on the west and the east and they can be identified as separate geologic domains on the basis of magnetic pattern. Magnetic highs associated with greenstone belts have significantly different signature than the surrounding magnetic highs, reflecting the structural and compositional variations of the craton. One can also identify, due to their linearity (and high wavenumber nature), the dikes and faults that cut across all the geologic domains and the ones that terminate at the edge of the domains, indicating relative timing of the geologic events. Differences in wavenumber content usually also imply differences in depths to magnetic sources-higher wave numbers nearly always arising from narrow sources reaching closer to the surface. Qualitative correlations among magnetic and other geologic/geophysical information is also immensely useful in the process of interpretation. Many qualitative interpretation tools have their foundation in potential field theory and mathematical computations of various quantities (e.g., regional/ residual separation, upward/downward continuation and other filtering techniques), but they are analyzed and interpreted subjectively.

Quantitative methods of analyses can also be subdivided into various categories, but generally the purpose is to generate a physical model resembling geology either through iterative matching of magnetic anomalies from hypothesized magnetic blocks (called "forward modeling" when interpreters judge the changes to be made and "inverse modeling" when matrix inversions and numerical schemes are formulated to judge the adequacy and nature of the changes) (Blakely, 1995) or by coming up with particular characteristics of the

**Figure C47/Plate 6d** a, Middle Proterozoic (1.9–1.6 Ga) crustal provinces in the United States: bounded on the north and west by Mojave Province (Mv), Cheyenne Belt (CB), and continuing up to the Killarney region (k in the northeast) of Ontario. SGR and EGR are southern Granite-Rhyolite and eastern Granite-Rhyolite provinces. *Dashed line* (Nd) represents inferred southeastern limit as defined by Nd isotopic data which bounds the Middle Proterozoic crustal provinces on its southeastern margin and divides SGR and EGR provinces (from Van Schmus *et al.*, 1996). b, Depth integrated magnetic contrasts over the United States. *Orange/reds* are the relative highs in the susceptibility variation and *blue/light greens* depict relative susceptibility lows. *White continuous* and *dashed lines* (Nd) show the Middle Proterozoic provinces in the United States. Mv from part "a" is excluded from the Middle Proterozoic region because presently this region is governed by the high heat flow related to the Basin and Range province (BR), which has decreased the magnetic thickness of the crust and hence it does not appear as a magnetic high. R, Rio Grande Rift; CB, Cheyenne Belt; K, Kentucky magnetic anomaly; T, Oklahoma-Alabama transform.

nature of the sources (e.g., depths to the top, center or bottom (see *Euler deconvolution*)) through analysis of widths, slopes, and amplitudes of isolated anomalies and their derivative fields from different concentrated geometries (e.g., Analytic Signal method, *Euler deconvolution* (q.v.) method in Blakely, 1995; Salem and Ravat, 2004), through the analysis of spectral properties of the field (the Spector

and Grant method, the wavenumber domain centroid method of Bhattacharyya and Leu in Blakely, 1995; Fedi *et al.*, 1997) through anomaly attenuation rates and shape factors (see references in Salem *et al.*, 2005), bounds on physical property contrasts (ideal body theory of Parker, 1974, 1975 in Blakely, 1995). Unconstrained modeling is usually not useful in the interpretation of magnetic anomalies because

of nonuniqueness of potential fields (which theoretically allows infinite number of different configurations to reproduce the same anomaly) and the only recourse is to employ constraints derived from corollary information (e.g., geologic mapping, borehole information, depths from seismic surveys, etc.) that reduce the ambiguity and lead to meaningful solutions for the particular geologic situation. Nonetheless, when all these aspects of interpretation are carefully applied and limitations assessed, magnetic field provides one of the most valuable tools for insights into the geology and geophysics of the crust.

# D

## D" AND F-LAYERS

D'' is the rather obscure name for the lowermost mantle adjacent to the liquid core. The encyclopedia contains several articles on the properties of D'' because of its potential influence on the geodynamo. F is the name for the boundary layer at the bottom of the outer core, where liquid core material freezes and differentiates. K.E. Bullen, in 1940–1942, defined the layers of the Earth on the basis of extensive seismological studies linked to probable compositional and mineralogical models. He labelled the layers A to G from the top down, with A the crust, B the upper mantle, C the transition zone, D the lower mantle, E the liquid core, F the layer around the inner core, and G the solid inner core itself (see *Earth structure, major divisions*).

The F-layer was originally proposed to explain a transition region at the bottom of the outer core, introduced by H. Jeffreys in 1939, in which the P-wave velocity decreased with depth. A similar structure was proposed by Gutenberg (1959). Bullen's F-layer was 150 km thick with P-velocity decreasing by about 10% (Bullen and Bolt (1985), p. 317; Lay and Wallace (1995), p. 305). The evidence for Jeffrey's transition zone and the dramatic change in seismic velocity were removed when seismic arrays made possible the measurement of slowness (arrival direction): energy thought to be refracted in the F-layer around the inner core was in fact being scattered from anomalous structure in the lowermost mantle (Doornbos and Husebye, 1972; Haddon and Cleary, 1974).

Region D was therefore separated into D", the lowest few hundred kilometres of the lower mantle, and D', the rest of the lower mantle. Region F was abandoned for lack of seismological evidence, but the name remained in use in geomagnetism to denote the boundary layer around the inner core, Braginsky (1963) having already proposed a theory of *energy sources for the geodynamo* (q,v) based on freezing and differentiating of the liquid close to the inner core. Ironically, the only parts of Bullen's original nomenclature in use today is D", not part of the original list, and F, which no longer exists.

The properties of D'' are described in the next four articles. It is thought to be a thermo-chemical boundary layer with large variations in both temperature and composition that may influence the geodynamo (see *Core-mantle coupling; Electromagnetic; Thermal; and Topographic*). Freezing at the inner core boundary is now thought to result in a thin mushy zone at the top of the inner core (see *Chemical convection*).

## D" AS A BOUNDARY LAYER

A *boundary layer* is a thin region (usually situated near a boundary) in a fluid or deformable body that has unusual structural properties. In self-gravitating bodies such as Earth, these regions are characterized by large gradients of temperature or composition or both. The lithosphere is a well-known example of a boundary layer; it is characterized by both a large gradient of temperature and by long-lived chemical heterogeneities (including the continents). The D" layer near the base of Earth's mantle is believed to have properties complementary to those of the lithosphere, including a large temperature gradient and chemical variations. The focus of this article is on the causes and consequences of its thermal structure; its compositional structure is the subject of a separate entry (see D'', *composition*).

#### 146

## D" as a thermal boundary layer

Originally the D'' layer was identified as a distinct region immediately above the Core-mantle boundary (CMB) by its seismic properties (see D'', seismic properties), and these remain our principal source of information on the structure of this region of Earth's interior (Loper and Lay, 1995; see Earth structure, major divisions). Its character as a thermal boundary layer follows from the requirement that the core be cooling at a sufficient rate (see Core-mantle boundary, heat flow across) so that the outer core is in a state of convective motions sufficiently vigorous to drive the geodynamo. In the bulk of the mantle, the upward transfer of heat associated with core cooling is accomplished by convection: upward movement of hot material and downward movement of cold. Since vertical motions are inhibited near the base of the mantle by the strong density contrast between the mantle and the core, vertical transport of heat from the core must be accomplished primarily by thermal conduction in the lowermost part of the mantle. Large temperature gradients are required to conduct the requisite heat (see Mantle, thermal conductivity); this is the essence of a thermal boundary layer.

The average temperature contrast across the D" layer can be estimated by two complementary methods. The first involves extrapolation of the temperatures across the mantle and the core. These extrapolations start from known fixed points and assume that adiabatic temperature gradients exist in the bulk of the mantle and the core. The fixed point in the mantle is the phase transition at 410 km depth, while that in the core is the inner core boundary where the outer core material is at its freezing point. The greatest uncertainty in this calculation is the amount that the freezing temperature is depressed due to impurities in the outer core. Estimates of the temperature contrast obtained from extrapolation range from 200 to 1600°C.

The second method for estimating the temperature contrast across the D'' layer is to use a crude approximation of the equation of heat conduction:

$$q = kA(\Delta T)/(\Delta z)$$

where q is the total heat transferred across the CMB, k is the thermal conductivity, A is the area of the CMB,  $\Delta T$  is the temperature contrast across the D'' layer, and  $\Delta z$  is its thickness. Knowing the other factors, this may be solved for  $\Delta T$ . The most uncertain factor in this formula is  $\Delta z$ .

The heat that is transferred from the core has two effects on the material comprising the D" layer: it makes the material less dense, leading to convective motions which transfer the heat upward through the mantle, and it reduces the viscosity. The thermal and dynamical structures of the D" layer are governed by the equations of conservation of mass, momentum, and energy, with the latter two being strongly coupled through the dependence of viscosity on temperature. A simple and plausible pattern of convective motion consists of a very slow descent of cold mantle material toward the CMB nearly everywhere and horizontal motion very close to the CMB toward a small number of discrete sites, from which warm mobile material rises into the mantle, forming thermal plumes (Stacey and Loper, 1983). Thermal diffusive thickening of the D" layer is balanced by the downward motion, leading to a layer of (nearly) steady thickness. Due to the strong variation of viscosity with temperature, the D" layer has a double structure. Most of the temperature contrast occurs across the thicker portion, in which motions are predominantly downward. Lateral motion is confined to a thinner layer close to the CMB, which is hottest and hence has lowest viscosity.

Lateral (geographic) variations in the temperature of the descending material causes lateral variations in the thermal structure of the D" layer and consequently lateral variations in the rate of heat transfer from core to mantle (see *Inhomogeneous boundary conditions and the dynamo*). By means of these variations the mantle provides some control on the structure of convection in the core, and of the Earth's magnetic field. In particular, variations in the thermal structure of the

D'' layer on the timescale typical of mantle convection ( $10^8$  years) are the most plausible cause of the observed changes in the frequency of reversals on that timescale.

## D", ANISOTROPY

Dynamic processes within the Earth can align minerals and inclusions. The resulting rock fabric leads to seismic anisotropy, which means that seismic velocity at a position varies as a function of the direction of wave propagation. In contrast, isotropy refers to the case where velocity is not directionally dependent. For reference, seismic heterogeneity (or inhomogeneity) refers to variation in velocity with position. Conventional seismic imaging techniques (e.g., travel-time tomography) invert data for the isotropic velocity heterogeneity of the mantle, and as such offer insights into thermal and chemical structures. There are though a growing number of methods for estimating seismic anisotropy. As anisotropy results from deformation processes, such analyses offer added insight into the dynamical nature of the Earth. Although we are still in the early stages of mapping anisotropy, it appears that it is most pronounced in the boundary layers of the Earth, regions where deformation is greatest. One such boundary layer is the D" region (see D'' as a boundary layer; Core-mantle boundary).

The lowermost mantle boundary layer, referred to as the  $D^{\prime\prime}$  region or layer, marks the boundary region between the solid silicate (rocky) mantle and the liquid iron core. This region, which extends to a few 100 km above the Core-mantle boundary (CMB), is the site of the most dramatic variations in velocity structure in the lower mantle (see D'', seismic properties). Proposed explanations for the anomalous properties of D'' include the effects of a phase change in the region, iron infiltration from the core, primordial material from early mantle differentiation, and subducted material pooling at the CMB. Numerous arguments suggest that mantle plumes may originate in D". The thermochemical nature of this region will influence thermal, gravitational, topographic, and electromagnetic core-mantle coupling, which in turn influence the dynamo, changes in the length of the Earth's day, and inner core development (see Core-mantle coupling; Core-mantle boundary, heat flow across). Hence, studies of D" anisotropy offer insights into the region's influence on large-scale Earth processes.

There are three primary difficulties in studying D'' anisotropy. The first concerns the complexity of seismic wave propagation in anisotropic media. The second involves removing the competing effects of anisotropy from other regions of the mantle. The third lies in the interpretation of anisotropy mechanisms.

## Wave propagation in anisotropic media

P- and S-wavefronts emanating from a point source in an isotropic homogeneous medium are spherical. The ray direction (direction of energy transport) is normal to the wavefront, the particle motion of the P-wave is also normal to the wavefront, and the particle motion of the S-wave is tangential to the wavefront and normal to the ray (transverse). The elasticity of an isotropic medium is described by two independent parameters (e.g., the Lamé parameters).

In contrast the elasticity of an anisotropic medium is parameterized by 21 independent elastic parameters. Three independent waves propagate and in a homogeneous anisotropic medium; their wavefronts are not spherical. The ray direction is in general not perpendicular to the wavefront and the particle motion of the P-wave and two S-waves are no longer normal and tangential to the wavefront, respectively. The most unambiguous indicator of anisotropy is the observation of two independent and orthogonally polarized shear waves. As a shear wave in an isotropic medium impinges on an anisotropic region it will split into two shear waves. The two shear waves will continue to propagate separately upon leaving the anisotropic region, retaining a "memory" of the anisotropy. Such splitting is described by the time separation between the two shear waves,  $\delta t$ , and the polarization of the fast shear wave,  $\phi$  (Silver, 1996; Savage, 1999). Such analysis has been used extensively to map anisotropy in the uppermost mantle. Should these two waves encounter another anisotropic medium, they will again split, spawning four independent shear waves. Consequently wave propagation in heterogeneous anisotropic media becomes complicated and it can be difficult to isolate regions of anisotropy.

The number of independent elastic parameters required to describe wave propagation in anisotropic media is further reduced by the symmetry of the medium. For example, a single crystal of olivine is orthorhombic in symmetry and its elasticity is described by nine elastic parameters. A commonly assumed style of anisotropy is transverse isotropy, which is a form of hexagonal symmetry and is described by five elastic parameters. Such a medium with a vertical axis of symmetry is commonly referred to as having vertical transverse isotropy (VTI) symmetry or radial anisotropy. A characteristic of wave propagation in such media is that the fast and slow shear waves are polarized in either the horizontal direction (SH) or the vertical plane (SV). Mechanisms for such anisotropy include the periodic horizontal layering of contrasting materials or the alignment of crystals in a horizontal glide plane with no fixed slip direction.

## Evidence for anisotropy in D"

A range of indicators suggest that the lowermost mantle is anisotropic. The decay of phases diffracted along the core-mantle boundary show dramatic regional variations and Doornbos *et al.* (1986) first sought to explain this in terms of VTI anisotropy in the D'' region (see reviews in Lay *et al.*, 1998 and Kendall and Silver, 1998).

D" anisotropy has been more clearly documented through observations of splitting in shear wave phases that travel hundreds of kilometers through this region (S, ScS and Sdiff; Figure D1) (see Seis*mic phases*). The magnitude of the splitting,  $\delta t$ , varies considerably (0 to >7 s) with both region and path length through D" (Kendall and Silver, 1998; Lay et al. 1998). Although this is the site of the largest shear wave splitting magnitudes in the Earth, the splitting is accrued over long path lengths and estimates of anisotropy in the region are 0–3% (( $v_{\text{fast}} - v_{\text{slow}}$ )/ $v_{\text{ave}}$ , where v refers to shear wave velocity). To date, analysis has primarily concentrated on measuring the separation between shear wave arrivals on the transverse and radial components of a three-component seismometer. In other words, the polarization of the fast shear wave,  $\phi$ , is either in the vertical plane or the horizontal direction (SV vs. SH). Such analysis implicitly assumes VTI anisotropy as more general forms of anisotropy would yield fast and slow shear wave energy on both the radial and transverse components. Recently, Panning and Romanowicz (2004) have inverted shear wave data to produce a global map of D" VTI anisotropy (Figure D2/Plate 11c). Future directions involve developing techniques to invert more general forms of anisotropy (i.e., nonVTI).

A difficultly in measuring D" anisotropy is ruling out the effects of anisotropy in shallower parts of the mantle. For example, estimating splitting in SKS phases is a now standard technique for studying upper mantle anisotropy (see Silver, 1996; Savage, 1999). Any interpretation of D" anisotropy must be correct for near-source and near-receiver anisotropy (see Kendall and Silver, 1998). Analysis of SKS splitting at permanent stations provides a correction for near-receiver anisotropy, although care must be taken as this may be directionally dependent. Using very deep earthquakes can mitigate near-source anisotropy, as the transition zone and middle mantle are thought to be largely isotropic (Mainprice *et al.*, 2000). Alternatively, relative changes in shear wave splitting in phases that turn above and below D" can be used to isolate the anisotropy to the lowermost mantle.

The style of anisotropy in high velocity and hence probably colder regions of D" is quite consistent. Here shear wave energy on the transverse component leads that on the radial component. Regional studies of D" beneath the Caribbean, Siberia, Alaska, Australia and the Indian Ocean suggest a roughly VTI anisotropy. Recently, detailed analysis has shown that the anisotropy beneath the Caribbean is not purely VTI: the orientation of the symmetry axis varies up to  $20^{\circ}$  from the vertical (Garnero *et al.*, 2004). In warmer and more ambient regions the style of D" anisotropy appears to be more complex and the magnitude more variable. Specifically, the form of anisotropy

**Figure D1** Seismic phases used to analyze D" anisotropy. UMA refers to upper mantle anisotropy. The SdS phase reflects off a discontinuity that lies at the top of the D" region. At distances beyond  $100^{\circ}$ , the phase S and ScS merge and diffract along the CMB ( $S_{\text{diff}}$ ).

#### D", ANISOTROPY

**Figure D2/Plate 11c** Map of seismic S-wave anisotropy ( $\xi = V^2_{SH}/V^2_{SV}$ ) in D" based on a global waveform tomography inversion for a 3D model of radial anisotropy (VTI) (from Panning and Romanowicz, 2004). Also shown are areas of detailed regional analysis of D" anisotropy: white indicates regions wherein D" horizontally polarized S-waves (SH) are faster than a vertically polarized S-waves (SV); red shows regions where D" appears to be isotropic; green shows a broad region of D" beneath the Pacific where the style of anisotropy appears to be complex and quite variable.

beneath the Pacific appears to vary in style and magnitude over relatively short distances. Furthermore, D'' anisotropy is not ubiquitous; regions beneath parts of the Pacific and Atlantic Ocean appear to be isotropic.

Cumulatively, these results suggest that anisotropy correlates with regional variations in other properties of D" (see D", seismic properties). Although we are still in the early stages of mapping out the magnitude and orientation of such anisotropy, we can loosely group the observations into categories based on regional characteristics. One is associated with regions where slabs are predicted to subduct into the lower mantle. Such regions are characterised by high D" shear velocities and a more VTI style of anisotropy. Another category involves sites of inferred mantle upwelling, for example, beneath Hawaii. Such regions are characterised by lower than average shear velocities and a more complex style of anisotropy. Finally, initial results suggest that more ambient regions of D" appear to be isotropic.

## Causes of D" anisotropy

A range of mechanisms can cause anisotropy, including the preferred alignment of crystals, grains, or inclusions, and the fine-scale layering of contrasting materials. As the mantle convects, rock deformation will be accommodated by mechanisms such as dislocation, diffusion, grain boundary migration, and dynamic recrystallization (Karato and Wu, 1993). Dislocation glide and creep mechanisms are effective in aligning crystals and producing a lattice preferred orientation (LPO). In order to evaluate such effects in the lower mantle we need to know the minerals present, their single-crystal elastic properties, and how they deform. We are still a long way from knowing all of this information, but recent advancements in laboratory experiments and theoretical calculations are offering new insights. Candidate minerals for LPO anisotropy include perovskite, magnesiowustite, columbite (Stixrude, 1998), and the recently discovered post-perovskite phase (Murakami *et al.*, 2004) (see *D*", *composition*). In high-velocity regions, post-perovskite and

magnesiowustite are likely candidates for D'' anisotropy and perovskite is a likely candidate for D'' anisotropy in low-velocity regions.

Alternatively, the anisotropy may be associated with well-ordered subseismic scale heterogeneity. Oriented inclusions or layering can effectively generate anisotropy if there is sufficient contrast in material properties. For example, aligned melt-filled tabular inclusions generate anisotropy very effectively (Kendall and Silver, 1998).

It seems that the physical process responsible for the anisotropy beneath paleoslab regions is different from that beneath regions of mantle upwelling. The infiltration of core material into the D" region could lead to inclusions of low-velocity material. Should these inclusions be aligned, they may provide an explanation for the anisotropy beneath the central Pacific. This is a region for which there is evidence for an ultralow velocity zone at the base of the mantle and it has been argued that these may be due to the presence of partial melt (see *ULVZ*, *ultralow velocity zone*). Alternatively, the preferred orientation of perovskite could explain the anisotropy. With either mechanism the magnitude and orientation of the anisotropy must vary over short length scales.

There are a number of arguments that the anisotropy in high-velocity regions is associated with the accumulation of paleoslab material in D'' (Kendall and Silver, 1998). Regions of anisotropy beneath the Caribbean, Alaska, northern Asia, Australia, and the Indian Ocean correlate with predicted CMB locations of the slabs. The high isotropic shear velocities of this region can be explained by the retained slab thermal anomaly and the high strains associated with the slab material colliding with the rigid CMB can align constituent crystals or inclusions.

In summary, there are clear regional variations in the style of D'' anisotropy that are very likely associated with different physical processes. In a sense, these variations are analogous to those observed between continental and oceanic regions in the upper mantle boundary layer. As our knowledge of D'' mineral physics grows and new seismic arrays provide improved coverage, studies of D'' anisotropy will offer new insights into this important but somewhat enigmatic region.

## D", COMPOSITION

Both the mantle and the core of the Earth are fundamentally affected by the properties of the material at the base of the mantle. This region controls the heat flow between the core and the mantle; it may be the source region for mantle plumes; and it is the lowermost window through which the magnetic field of the Earth must propagate to reach the surface. That the base of the mantle differs seismically from the overlying mantle material was recognized nearly a century ago by

Gutenberg (1913). The D" zone was originally defined as a distinct zone by Bullen (1949) as the layer with anomalously low increases in seismic velocity with depth in the lowermost several hundred of kilometers of the mantle. Since the importance of mantle convection was recognized, the chemical composition of this lowermost ~300 km of Earth's 2900 km-thick mantle has widely been viewed as approximately equivalent to that of the overlying lower mantle, with its seismic properties perturbed by a large increase in temperature distributed over the lowermost few hundred kilometers of the mantle. The superadiabatic gradient associated with the basal boundary layer of the Earth's convecting mantle likely involves a gradual temperature increase of  $\sim$ 1000 K to perhaps as much as 2000 K (if the layer is internally stratified) across the D" zone. Such shifts in temperature can produce decreased gradients of seismic velocities across this zone, a result that generally agrees with laterally averaged seismic models of Earth's mantle, such as the Preliminary Reference Earth Model (PREM: Dziewonski and Anderson, 1981).

However, improvements in seismic observations have driven a reassessment of the possible roles of chemical differentiation and chemical heterogeneity within D". The specific seismic observations include: a sporadic seismic discontinuity involving an increase of  $\sim 1-3\%$ in shear and perhaps in compressional velocity at heights usually 200-300 km above the core-mantle boundary (CMB); a laterally heterogeneous zone 5-40 km above the CMB with decreases in compressional and shear velocity of the order of 10% and 30%, respectively (the ultralow velocity zone, or ULVZ); two large-scale slow structures beneath Africa and the western Pacific spanning lateral dimensions of  $\sim$ 2000 km and extending to heights of  $\sim$ 1000 km above the CMB, with shear decrements of  $\sim 3\%$  or larger; and pervasive and laterally varying anisotropy within the D" layer (see Gurnis et al., 1998; Lay et al., 1998; and D", seismic properties, and D", anisotropy). The chemical characteristics of D" have thus emerged as a multidisciplinary problem, incorporating the anomalous seismic characteristics of this layer, the somewhat ill-constrained properties of Earth materials at the extreme conditions of the CMB (pressure of 135 GPa and temperature of 3500-5000 K), and the effects of changes in chemistry on the electromagnetic properties of the deep mantle, and thus on the geomagnetic field.

The seismic observations of structural complexity within D" have driven a broad range of proposals of possible chemical changes that might be present within this region. These possibilities include: descent of melts from the overlying mantle, enriching this zone in incompatible and volatile elements; interaction of material with the underlying core, producing iron enrichment, and contributions from subducted slab material. Additionally, a different chemistry of this region might have been created early in the history of the planet, through early differentiation processes or perhaps even during planetary accretion. All such proposed changes in chemistry must not dramatically alter the seismic velocity or density in this region from that within the lowermost mantle: seismic travel-time and normal mode constraints show that the bulk of D" can only differ in velocity and density by a few percent from that within the deep mantle (see Earth structure, major divisions). This constraint is, however, relaxed in the lowermost 5-40 km of the mantle, where dramatic changes of seismic wave velocities have been observed.

From a geomagnetic perspective, the importance of the chemistry of the lowermost mantle lies primarily in its effect on the propagation of Earth's magnetic field through the basal layer of the mantle. If the electrical conductivity of the lowermost mantle is markedly elevated from that of the overlying material, through enrichment in iron, the presence of partial melt, or both, then temporal variations of the magnetic field could be attenuated within such a layer (see *Mantle, electrical conductivity, mineralogy*). Moreover, any electromagnetic coupling between the core and mantle would generate a torque on the overlying mantle: such a torque has been associated with shifts in the nutation of the Earth and changes in the length of day (e.g., Buffett, 1992). If high conductivity zones were heterogeneously distributed near the base of 150

Earth's mantle, then the mantle could exercise a structural control on changes in virtual geomagnetic pole positions during reversals of the polarity of Earth's magnetic field, potentially forcing the reversing pole to follow geographically preferred paths (Aurnou *et al.*, 1996).

#### **Core-mantle chemical interactions**

The most straightforward way to determine the composition of D" would be to analyze samples derived from this region. However, the ability to geochemically sample D" directly via surface volcanism is controversial. For such sampling to occur, an upwelling would have to transit nearly 3000 km of Earth's mantle and retain a chemical signature that could be unambiguously associated with its basal origin. It is possible that a portion of Earth's hot spots may originate from D'', and as such might be expected to carry a geochemical signature of this region or perhaps even of the underlying core. Some evidence exists that some hot spots and flood basalts carry anomalously high <sup>187</sup>Os/<sup>183</sup>Os ratios (e.g., Walker et al., 1995). The radiogenic parent of <sup>187</sup>Os is <sup>187</sup>Re: Re is a strongly siderophilic (iron-loving) element and is thus anticipated to be strongly enriched in Earth's core. Re enrichment is similarly observed in iron meteorites. In contrast, Os is generally lithophilic, partitioning into silicates. Thus, elevated <sup>187</sup> Os/<sup>183</sup>Os ratios are associated with the sampling of Re-rich regions. The most parsimonious explanation for such ratios is that some hot spots and flood basalts may record a geochemical signature of interaction with Earth's core. The amount of chemical interaction necessary to generate the observed ratios is not large, but it nevertheless may provide prima facie evidence for chemical interaction between Earth's core and mantle.

How might such core-mantle chemical interactions occur? A direct means for producing such interactions is through chemical reactions of the silicate of the lowermost mantle with the liquid iron-rich alloy of the outer core. Such reactions, which involve oxidation of core-derived iron and reduction of mantle silicon, can be described using chemical formulae such as

$$(Mg_xFe_{1-x}) SiO_3 (mantle material) + 3[(1-x) - s]Fe$$
  
=  $xMgSiO_3 + sSiO_2 + [(1-x) - s]FeSi$   
+  $[3(1-x) - 2s]FeO.$ 

Here, s is the amount of silica produced in the reaction and (1-x) is the amount of iron in the reacting mantle material. Such reactions have been both experimentally verified to occur and are thermodynamically driven to the right by a negative volume change of the reaction (e.g., Knittle and Jeanloz, 1991). The intriguing aspect of these reactions is that the products involve both iron-free silicates, which are both likely to be of low density and electrical conductivity, and relatively high density, high electrical conductivity iron alloys. Accordingly, core-mantle reactions can lead to a suite of reaction products with highly heterogeneous physical properties. The key questions associated with such core-mantle reactions are mechanical in nature: over what length-scale such reactions occur at the CMB, how efficiently reaction products are entrained within flow of the overlying mantle or underlying core (exposing fresh mantle material to reaction), and whether the low-density products are able to separate from the high-density products. In short, whether the mantle develops a thin reacted rind at its base, or whether reacted zones can be dynamically entrained into the overlying mantle, producing an enrichment of iron alloys and replenishment of the reacting zone in the lowermost mantle is ill-constrained. The possibility that topographic effects might be important in enhancing such chemical reactions has been suggested (e.g., Jeanloz and Williams, 1998): any topography on the CMB involves either silicate material intruding into iron or vice versa (see Core-mantle boundary topography). In such cases, the gravitational effects that drive the separation of the core and the mantle material

are locally relaxed, with core fluid prospectively being able to infiltrate the mantle material without traveling against gravity.

## Subduction and D"

The role of slab (and particularly oceanic crust) enrichment in D" has frequently been invoked as a possible cause of geochemical heterogeneity in this region. If ancient oceanic crust is sequestered in D", then this zone would be enriched in Ca, Al, and Si relative to the overlying mantle. Moreover, volatile elements such as hydrogen and carbon that were retained within the slab during its transit through the mantle might also be more abundant in this zone. A compelling case for the existence of such slab-related enrichment would require several separate lines of evidence: first, seismic evidence that slabs penetrate to CMB depths; second, a sufficiently elevated density of subducted material that it would stably reside for long times within D"; and third, a possible mechanism by which oceanic crust can efficiently separate from its underlying depleted mantle. Each of these lines of evidence is not fully developed: seismic tomography shows that slab-related seismic anomalies thicken substantially as they enter into the lower mantle, but these anomalies do not appear to be easily tracked into the lowermost 500-1000 km of the mantle. As the full slab is comprised of oceanic crust overlying depleted mantle material, the chemistry of the slab as a whole lies close to that of the bulk mantle. Therefore, a means by which oceanic crust can delaminate from its depleted complement and accumulate within D" is required if the dregs of ancient crustal subduction are a major chemical component of the lowermost mantle. Accordingly, while slabs may generate geochemically distinct regions within D", the available evidence neither requires nor precludes the presence of ancient slabs within D".

## Partial melting

Partial melting and associated melt segregation are well known means of geochemical differentiation in the shallow regions of the planet. Thus, the likely existence of partial melt in the lowermost regions of Earth's mantle may imply that enrichment in incompatible elements-those elements that partition strongly into silicate liquids relative to solids-occurs at these depths. The idea that partial melt exists in the lowermost mantle is driven by the observation that decrements of  $\sim 10\%$  in compressional wave velocity and  $\sim 30\%$  in shear velocity exist in heterogeneously distributed zones in the lowermost 5-40 km of the Earth's mantle-the ultralow velocity zones (ULVZ, q.v.). Such decrements likely require 6-30% partial melt (with the amount depending on how the melt is distributed) entrained in parts of the lowermost mantle (Williams and Garnero, 1996). The stable retention of melt at the base of Earth's mantle (rather than it buoyantly rising to the top of Earth's mantle) is probably produced by two tandem, complementary effects. First, the dramatic increase in temperature within D" relative to the overlying mantle (see D'' as a boundary layer) may produce sufficiently high temperatures that the base of the mantle lies above its solidus-the temperature at which melting initiates in multicomponent systems. Second, melts at pressures corresponding to those at the base of the mantle may be denser than their coexisting solids, due to both structural effects associated with highly densified amorphous structures and the preferential partitioning of iron into silicate liquids. Indeed, the available constraints on the ULVZ indicate that this region has an increase in density relative to the overlying mantle material of about 10% (Rost et al., 2005): a result fully consistent with a marked enrichment in iron, with the additional iron most likely being oxidized. Thus, melts likely stably stratify near the base of the mantle, and any partial melt that occurs in the deep lower mantle may descend into D", enriching this zone in both volatile elements (H and C), and likely incompatible major elements such as Fe, Ca, and Al. Additionally, radiogenic heat-producing elements such as K and U might be enriched within the CMB region.

However, the melting behavior of the mantle material at the extreme pressures and temperatures of the CMB is not yet well-constrained, so the geochemical consequences of partial melting and melt segregation are largely inferred based on experiments at substantially less extreme conditions. The key point about the geochemical effects of partial melting in D" is that they are not exclusive of either core-mantle reactions or the presence of slab-derived components within D". Coremantle reactions may lower the melting point of mantle material and partial melt could facilitate the transfer of reacted material away from the CMB. Similarly, if the melting temperature of ancient oceanic crust (or, indeed, any portion of the slab) is lower than that of normal mantle material, then slab-derived melts could descend into D". As such, enrichment of D" in slab-related geochemical components could be driven by partial melting processes. Lastly, the importance of partial melting in D'' is likely to have been far greater earlier in Earth history. If secular cooling of Earth's mantle has occurred over the age of the Earth, then partial melt is anticipated to have been more abundant in the deep mantle early in Earth history, and today's D" could (at least partially) represent the solidified residue of partial melt.

#### Primordial chemical layering

A rather different genesis for a chemically distinct D" was proposed by Ruff and Anderson (1980). They proposed that the composition of the lowermost mantle might differ markedly from that of the overlying material due to effects associated with Earth's accretion. Such primordial layering might have arisen through early accretion of material enriched in Ca, Al, and Ti. These elements are abundant in the initial condensates of the protoplanetary nebula, and the idea was simply that these elements might have heterogeneously accreted to the center of the protoEarth during the earliest stages of planetary accretion. Subsequently, they might have been displaced to the region surrounding the core due to the gravitational instability of subsequently accreted dense, iron-rich material. The dilemma is that this layer must not only persist through impacts of planetary-sized objects on the early Earth, but also endure without mixing throughout Earth history: both the lack of a clearly global discontinuity at the top of D'' and the generally similar seismic properties of the bulk of D" to the overlying mantle make such broadscale, profoundly chemically distinct, and primordial layering unlikely. However, if primordial layering does persist within D", it may be less likely to be associated with accretionary effects, and more likely to be produced by differentiation processes within a primordial magma ocean. Such a magma ocean is widely postulated to have existed early in Earth history due to accretional heating associated with giant impacts on the early Earth. In this sense, "primordial" chemical differentiation of D" could operationally differ little from the effects of partial melting of Earth's deep mantle over the course of Earth history.

However, such early chemical differentiation may also be affected by the presence within the deep mantle of a recently discovered post-perovskite phase [Murakami et al., 2004]. This ultrahigh pressure phase of (Mg,Fe)(Si,Al)O<sub>3</sub> may be the dominant mineral within D", and its pressure of onset appears to correspond with the depth of the seismic discontinuity often viewed as the top of D'' (see D'', seismic properties). Little is known about the chemical behavior or affinities of this CaIrO3-structured phase, beyond the likelihood that the transition to this phase has a positive Clapeyron slope. However, depending on the degree to which D" has equilibrated with the overlying mantle material, D'' could be enriched in elements that are more compatible within the post-perovskite structure than within the silicate perovskites of Earth's lower mantle. Speculatively, if iron preferentially partitions into this phase, then a net iron enrichment of D" could arise through progressive equilibration between D" and the overlying mantle. Such equilibration could be generated through selective transport of material across the phase boundary, with progressive fractionation of compatible (and perhaps heavy) elements into the lowermost mantle.

Core-Mantle Boundary Topography D" as a Boundary Layer D", Anisotropy D", Seismic Properties Earth Structure, Major Divisions Mantle, Electrical Conductivity, Mineralogy

## D", SEISMIC PROPERTIES

Across most of Earth's lower mantle, P- and S-wave seismic velocities increase with depth in a fashion consistent with adiabatic selfcompression of uniform composition material, and there is relatively little lateral variation in seismological structure (see *Earth structure, major divisions*). However, the lowermost few hundred kilometers of the mantle, called the D" region, has been recognized since the 1940s as having anomalous seismic properties, with reduced seismic velocity gradients with depth and strong lateral variations in structure. This prompted designation of D" as a distinct layer in the early labeling of Earth's shells. Seismological characterization of inhomogeneity of the D" region has advanced dramatically in recent decades, and the unusual seismic properties of D" are now commonly interpreted as manifestations of complex thermal and chemical boundary layers at the base of the mantle (see D'' as a boundary layer). This region is of importance to the Mantle and the core dynamical systems.

At a depth of 2891 km below the surface, the core-mantle boundary (CMB) separates the two principal chemical layers of the Earth, the molten metallic-alloy outer core and the highly viscous silicate- and oxide-mineral mantle (see Core-mantle boundary). The contrast in density between the mantle rock and the core alloy exceeds the density change from air to rock at Earth's surface, and the contrast in viscosity is comparable to that between rock and ocean water. The superadiabatic temperature contrast from the core into the mantle is estimated to be as high as 2000°C, possibly exceeding that across the lithospheric thermal boundary layer, and there is heat flow of 2-10 TW across the boundary (44 TW flows through the Earth's surface) (see Core-mantle boundary, heat flow across). Over time, dense materials in the mantle are likely to have concentrated in D", while light dross, expelled from the core may have accumulated at the CMB (see D'', *composition*). The D" boundary layer is relatively accessible to seismic imaging, and its seismic properties are discussed here (also see D", anisotropy; D" as a boundary layer; D", composition; ULVZ, ultralow velocity zone). Garnero (2000), Lay et al. (1998a), and many papers in Gurnis et al. (1998) provide reviews of ongoing research topics and conceptual models for processes occurring in D".

#### One-dimensional seismic velocity models for D"

One-dimensional global seismic velocity models, such as the Preliminary Reference Earth Model (PREM) of Dziewonski and Anderson (1981), usually have reduced velocity gradients in the deepest 150 km of the mantle, reflecting the global departure of D" velocity structure from that of the overlying lower mantle. For several decades, efforts have been made to interpret the low (or even negative) velocity gradients in such average models of D'' structure as the result of a superadiabatic temperature increase across a thermal boundary layer; large temperature increases above the CMB can be reconciled with the one-dimensional models (see D" as a boundary layer; Core-mantle boundary, heat flow across). However, studies over the past half century have established that there is a very substantial heterogeneity in D" on a wide variety of scale lengths; thus, there is no meaningful "average" structure for the region useful for a robust interpretation of the boundary layer. It appears more useful to discuss the seismic properties of D" by emphasizing the lateral variations in structure, as is the case for the surface boundary layer.

#### Large-scale seismic velocity patterns

Seismic tomography has been applied to develop three-dimensional seismic velocity models for the entire mantle for over 15 years. This method extracts three-dimensional P-wave and S-wave velocity fluctuations relative to one-dimensional reference models by inversion of massive data sets with crossing raypaths for which seismic wave arrival times are measured, exploiting the localized sensitivity of seismic waves to velocity structure around the path on which they propagate through the Earth. These three-dimensional velocity inversions indicate that heterogeneity in the mid-lower mantle is relatively weak, but that in the lowermost 300-500 km of the mantle heterogeneity increases with depth, becoming stronger in D" than anywhere else in the Earth except for the uppermost mantle where major thermal, chemical, and partially molten heterogeneities are known to exist. The most surprising aspect of the D'' seismic velocity heterogeneity is that it is dominated by large-scale patterns, with large continuous volumes of high- or lowvelocity material having scale lengths of hundreds to thousands of kilometers. This predominance of large-scale variations is observed in both S-wave and P-wave velocities, as indicated by the representative models for lateral variations in D" structure shown in Figure D3a/Plate 11a.

S-wave velocity variations (dVs) relative to the global average velocity in D'' (Figure D3a/Plate 11a.) are positive (relatively high

**Figure D3/Plate 11a,b** Maps of S velocity (a) and P velocity (b) variations relative to the global average values in D" at a depth near 200 km above the CMB in representative global mantle seismic tomography models. S velocity variations are from Mégnin and Romanowicz (2000) and P velocity variations are from Boschi and Dziewonski (2000). Positive values (blue) indicate higher than average velocities and negative values (red) indicate lower than average velocities. The scale bars differ: S velocity variations are 2–3 times stronger than P velocity variations. Large-scale patterns dominate, suggesting the presence of coherent thermal and chemical structures.

velocity) beneath the circum-Pacific, with relatively low-velocity regions found under the central Pacific and south Atlantic/Africa. High-velocity regions are likely to be at lower temperature than lowvelocity regions, although chemical differences may contribute to the variations. Recent tomographic models have  $\pm 4\%$  S velocity variations in D", two or three times stronger than those found in the midlower mantle, and comparable to the  $\pm 5-8\%$  variations at depths near 150 km in the upper mantle. While mid-mantle variations tend to have more spatially concentrated heterogeneities, there is a significant degree of radial continuity of velocity anomaly patterns throughout the lower mantle, possibly linking subduction zones at the surface to high velocity regions in D" and hot spot distributions at the surface to low velocity regions in D".

P-wave velocity variations, dVp, in current tomographic models (Figure D3b/Plate 11b) involve  $\pm 1.0-1.5\%$  fluctuations, with low-velocity areas beneath the southern Pacific and south Atlantic/Africa and high velocities under eastern Eurasia. There is not a strong increase in P velocity heterogeneity in D" relative to that in the overlying mantle as there is for S-wave velocity, which can be attributed to the expected greater sensitivity of S velocity to strong thermal variations in a hot thermal boundary layer.

As apparent in Figure D3/Plate 11a,b, there is a general spatial correlation between S- and P-wave velocity patterns, as expected for temperature-induced variations, but in some regions, such as beneath the northern Pacific, this correlation breaks down. In other regions, such as beneath the central Pacific, the S-wave variations are much stronger than the P-wave variations even though both have the same sign. The decorrelation of dVp and dVs and the variation in their relative strengths provide strong evidence that thermal variations alone cannot explain the large-scale patterns of seismic velocity heterogeneity, so there is likely to be chemical heterogeneity present in D"

(Masters *et al.*, 2000). In fact, if bulk sound velocity variations, dVb, are estimated from P and S arrival times, they are found to have anticorrelation with dVs on very large scale, which requires bulk modulus and shear modulus to have opposite sign perturbations. It is important to recognize that the patterns in Figure D3/Plate 11a,b are relative to the global average velocities at D" depths, and that these averages do not necessarily define "normal" mantle structure. This results in uncertainty in interpretations of the velocity fluctuations (for example, high-velocity regions may be anomalously low temperature, perhaps due to cool down-wellings that have disrupted an overall hot boundary layer, or low-velocity regions may be anomalously hot regions, perhaps partially melted, within a chemically distinct, high-velocity layer). Resolution of finer scale seismic properties in D" is pursued in order to overcome this baseline uncertainty of seismic tomography imaging.

## Seismic velocity discontinuities in D"

The presence of several percent lateral variations in S and P velocities concentrated within the lowermost mantle suggests the possibility of rapid velocity increases and/or decreases at the top of the D" region. Various seismic observations suggest that rapid increases in velocity with depth are indeed present at depths from 130-300+ km above the CMB in many regions. Rapid shear velocity increases of 1.5-3% are found over intermediate-scale (500-1000 km) regions, with velocity structures and spatial sampling as indicated in Figure D4. While the PREM model shows a smooth velocity increase with depth in the lower mantle, with D" being suggested only by a drop in rate of velocity increase with depth 150 km above the CMB, other shear velocity models obtained for localized regions have an abrupt increase in velocity near the top of the D''region. The velocity discontinuities are required to account for observed S-wave reflections that precede the reflections from the CMB. Similar models are obtained for localized regions for P-waves, usually with a smaller velocity increase of 0.5-1%. The increase in velocity may be distributed over a few tens of kilometers or it may be very sharp, and in some regions it can vary in depth by as much as 100 km over lateral scales of just 200 km. Wysesssion et al. (1998) review many observations and models for this D" seismic velocity discontinuity. While localized onedimensional models are undoubtedly oversimplified, they do strongly suggest that some regions of D" appear to effectively be layered, with thermally and compositionally distinct material.

Comparison of Figure D3a/Plate 11a and Figure D4 suggests that the S velocity discontinuity is commonly observed in areas of high S-wave velocity in D". An abrupt increase in velocity with depth is not expected for a thermal boundary layer structure, so most interpretations of this correlation invoke the notion of localized ponding of cool subducting lithospheric slabs that have sunk to the lowermost mantle, retaining enough thermal and chemical anomalies to account for the high seismic velocity and strong radial gradients. Alternatively, chemically distinct high-velocity material may be present in these regions, perhaps involving ancient accumulated material concentrated during core formation or segregated oceanic crustal materials that have accumulated over Earth history. The observation of a weak and variable S velocity increase beneath the central Pacific, a relatively lowvelocity region far from any historical subduction zone, complicates any attempt to interpret the velocity discontinuity as the result of recent slab thermal anomalies.

A possible explanation for the D" seismic discontinuities has been provided by the discovery in 2004 of a phase change that occurs in magnesium silicate perovskite, MgSiO<sub>3</sub>, the dominant mineral structure in the lower mantle (Murakami *et al.*, 2004). At pressure and temperature conditions close to those at the top of D", a slightly denser post-perovskite mineral is expected to form, with a relatively strong increase in shear modulus and a small or even negative change in bulk modulus. This is expected to occur preferentially in lower temperature regions of D", which may account for the intermittence of the D" reflections. The effects of chemistry on this phase transition and its implications for boundary layer dynamics are active areas of research.

**Figure D4** Representative S velocity models obtained from waveform modeling of data from localized regions of the lowermost mantle (top), and a map of regions with large-scale (>500 km) coherent structures having S velocity increases of 2.5–3%, 130–300 km above the CMB (bottom). The S velocity models are one-dimensional approximations of the local structure, and in most regions it appears that there is substantial variability in the depth and strength of the velocity increase on 100–300 km lateral scale-lengths. Most regions with clear S-wave velocity discontinuities have high S-wave velocities in D" (Figure D3/Plate 11a,b) and underlie regions of extensive subduction of oceanic lithosphere in the past 200 Ma, but the central Pacific is an important exception.

## Low-velocity provinces in D"

The central portions of the largest regions with very low shear velocity seen in Figure D3a/Plate 11a appear to have very strong decreases in velocity from above and laterally. For example, the low-velocity region beneath the southern Atlantic and Africa has been modeled as having an abrupt 1 to 3% decrease 250–300 km above the CMB, with average velocities in D" that are 3-5% lower than for PREM (Figure D5). It appears that these are distinctive low-velocity regions, and having abrupt lateral boundaries (e.g., Wen *et al.*, 2001). The sub-African province appears to thicken to 800 km or so beneath the continent, with a thin

Figure D5 Two massive provinces with thick regions of low S velocity exist in the lower mantle: under the southern Pacific and under the southern Atlantic/Africa/southern Indian Ocean (bottom). A cartoon sketch of the latter feature is shown (top), with a 200–300 km thick layer in D" having an abrupt decrease in velocity of 1 to 3% overlying a layer with average velocity decreases of 3 to 5%. Under Africa this low velocity body appears to extend upward to as much as 800 km above the CMB, and it may have an ultralow velocity zone (ULVZ) just above the CMB. It has sharp lateral boundaries in D" and in the mid-mantle. The low S velocity province under the central Pacific is not yet well imaged, but appears comparable in size and strength of velocity reductions.

region of ultralow velocity right above the CMB (see below). Lateral gradients on the margins of the low-velocity province are very abrupt, on the scale of tens of kilometers, both in D'' and in the upward extension into the lower mantle.

The large low-velocity provinces are commonly assumed to be very hot regions, and have been called Superplume provinces, under the assumption that they are sources of upwelling flow rising from a hot thermal boundary layer at the CMB. Indeed, they do underlie large regions of low velocity in the lower mantle as well as concentrations of hot spot volcanoes at the surface, some having distinctive chemical anomalies. However, the strong lateral gradients and apparent endurance of these structures suggest that there is distinctive chemical composition associated with the low-velocity provinces, and the extent to which thermal and chemical buoyancy trade-off is not yet established. P velocity anomalies of the low S velocity provinces are much smaller, suggesting the possibility of partial melting of these regions, which raises the possibility that these are simply the hottest (and partially molten) regions within a global chemically distinct layer. The strong temperature increase expected across the D" region may approach or exceed the eutectic solidus of lower mantle mineral assemblages, allowing partial melting to take place in the boundary layer (Lay et al., 1998a).

Detected ULVZ presence (light) and absence (dark)

Figure D6 Seismic velocity models for PREM and the central Pacific region, where an ULVZ is detected right above the CMB (top). The ULVZ structures in various regions have P velocity drops of 4 to 10% and S velocity drops of 12 to 30%. The map (bottom) shows regions where ULVZ features have either been observed (light gray) or are not observed (dark gray). In general, regions with ULVZ in D" tend to be found in regions of low S velocities (Figure D3a/Plate 11a).

#### Ultralow velocity zones in D"

The most dramatic seismic velocity reductions that have been detected in D'' are associated with very thin layers or lumps of material just above the CMB that are called ultralow velocity zones (ULVZs) (see ULVZ, ultralow velocity zone). Figure D6 shows P and S velocity models characteristic of a region with a ULVZ (the central Pacific). This region, which is lower velocity than PREM over a 200-300 km thick D" region, has a thin layer 10 to 40 km thick and laterally quite extensive (500-1000 km across), with P velocity reductions of 4 to 10% and S velocity reductions of 12 to 30%. In some regions, such as under Iceland, the ULVZ appears to be in a localized mound a few hundred kilometers across, but with comparably strong velocity reductions to the more extensive areas of ULVZ under the Pacific (Garnero et al., 1998). Comparing Figure D6 and Figure D3a/Plate 11a indicates that ULVZs are commonly found within the margins of large-scale low-velocity regions, including at least portions of the major low S velocity provinces. Existence of a melt component in the ULVZs is the likely explanation for their strong velocity effects. The melt may involve either core-material that has infiltrated into the mantle, or partial melting of mantle material. In either case ULVZs are likely to involve thermochemical anomalies, probably with iron enrichment that causes the melt component to be dense, concentrated near the CMB (see: D", composition; Core-Mantle boundary; ULVZ, ultralow velocity zone).

#### Seismic velocity anisotropy in D"

As is the case for upper mantle structure, the velocity structure in D'' is anisotropic, with seismic velocities being dependent on the direction of propagation and the polarization of ground shaking (see D", anisotropy). This results in shear wave splitting, where an S-wave will separate into two components with orthogonal polarization, one traveling slightly faster than the other. By measuring the polarizations and travel-time difference between the fast and slow S-waves, it is possible to determine the anisotropic characteristics of the medium. The results of such analyses of S-wave splitting for phases traversing D" are summarized in Figure D7. In most cases, the data indicate S velocity models in which horizontally polarized (SH) vibrations travel with 1 to 3% higher velocities than vertically polarized (SV) vibrations for raypaths grazing horizontally through the D" region. This behavior is consistent with vertical transverse isotropy (VTI), which can result from hexagonally symmetric minerals with vertically oriented symmetry axes or from stacks of thin horizontal layers with periodic velocity fluctuations (Lay et al., 1998b). The regions with the best documented cases for strong VTI in D" tend to have higher than average S velocities (Figure D7 and Figure D3a/Plate 11a). There are observations favoring slightly tilted (nonvertical) transverse isotropy, which results in weak coupling of the SH and SV signals (the fast wave is close to

**Figure D7** Examples of shear velocity models (top) proposed for various regions of D" where the velocity structure has been found to be anisotropic, and a map (bottom) showing locations where relatively strong (>1%) vertical transverse isotropy has been detected in D" (dark shading) or where weak or nonexistent anisotropy has been observed (light shading). The velocity models, which are compared to the PREM reference structure, have a few percent higher velocities for horizontally polarized S-waves (SH) than for vertically polarized S-waves (SV), which is consistent with vertical transverse isotropy. S-wave anisotropy in D" has been detected in regions with high S velocities (Figure D3a/Plate 11a) and strong D" S velocity discontinuities (Figure D4), and in regions with low S velocities and weak, or nonexistent S velocity discontinuities.

the SH polarization), as well as limited regions where SV signals are found to propagate faster than SH signals (such as in the low S velocity region of the central Pacific). Obtaining mineralogical and dynamical explanations for anisotropy in the lowermost mantle are areas of active research (see: D'', *anisotropy*). There is great interest in improving the characterization of D'' anisotropy because it has the potential to reveal actual deformation processes occurring in the boundary layer.

## Discussion and conclusions

The diverse seismic properties of D" appear to reflect the presence of thermal and chemical boundary layers at the base of the mantle. There is a predominance of large-scale structures and the strength of heterogeneities at intermediate and large-scales appears to be significantly greater than in the overlying lower mantle. Small-scale (<10 km) heterogeneities also appear to be present, but are not clearly more pronounced than in rest of the lower mantle. Interpretation of the seismic properties of D" involves many uncertainties, and a wide spectrum of scenarios and processes have been advanced to account for the observations. Thermal variations in D" play an important role in determining the heat flux boundary condition on the core dynamic regime, along with the possible role of D" as a source of upwelling thermal plumes, so perhaps the greatest current challenge is to identify the relative contributions to the seismic properties of thermal versus chemical heterogeneity.

## DELLA PORTA, GIAMBATTISTA (1535–1615)

Born at Vico, Italy, sometime in October or November 1535, Giambattista Della Porta may well have been self-educated. He was fascinated by the esoteric philosophies of the Renaissance, and his *Magia Naturalis* (1558) became famous for the bewildering mixture of scientific, occult, and classical material that it contained, and was translated into English in 1658.

Magia Naturalis, Book VII, discusses "The Wonders of the Lodestone" in 56 short chapters. Its particular value comes from the rich and abundant stock of classical and medieval references to magnetism contained within it, which in many ways provides us with the first history of this branch of science. Della Porta seems to have taken the innately occult "vertue" of the lodestone pretty well as read, though he was always keen to narrate his own experiments, which were usually performed with the intention of testing one legend or another.

Della Porta inquires on a number of occasions in his narrative into why lodestones attract iron. Most remarkably, he mentions that Epicurus in classical Greece ascribed this attractive force to *atoms* coming from the stone (Chapter 2), though most of his reported explanations are mystical and analogous to the power of Orpheus's music, which could allegedly attract and transfix humans.

Of course, *Magia Naturalis* recounts all kinds of tricks that could be performed with magnets, such as "How to make an army of sand fight before you" (Chapter 17), whereby magnetized sand, arranged into ranks and battle array on a table top, could be made to move and collide by the skilful manipulation of lodestones under the table. He also relates stories from classical literature of ancient temples having roofs sheathed in lodestone, so as to make the statue of the goddess within seemingly hang in the air (Chapter 27). On the other hand, Della Porta's experiments exploded the classical myth that onions and garlic destroyed the power of the lodestone, finding that "breathing and belching upon the Loadstone after eating of Garlick, did not stop its vertues" (Chapter 48). He tried similar experiments to test the power of goat's blood and diamonds upon the "*vertue*" of stony and metallic magnets.

However, the lodestone's power was found to be totally destroyed by placing it in a powerful fire, during which the heated lodestone gave off dark blue flames and a stink of sulfur (Chapter 51).

But Della Porta gave lots of advice on practical subjects, such as how to best magnetize the needles of mariners' compasses (Chapter 36), and even suggested how the compass might be employed to find the longitude at sea (Chapter 38) by utilizing the needle's prior recorded deviation from true north on different parts of the Earth's surface. For instance, in the sixteenth century the needle pointed to true north in the Azores, to west of the meridian in the Americas, but to the east of it in Europe. Della Porta's writings on magnetism must be seen as part of his wider visionary and occult view of nature. For *Magia Naturalis* was immensely influential, and in addition to the tests and experiments which he reported, Book VII is especially important as a history of magnetism from antiquity to the sixteenth century.

Giambattista Della Porta's wider magical and occult beliefs led to an encounter with the Inquisition some time before 1580, but he seems to have otherwise lived as a devout Catholic. He became, being married, a lay brother with the Jesuit Order in 1585 and devoted himself to the movement for the reformation of the Roman Catholic Church. Over the last 30 years of his life, in addition to his scholarly activities he worked in a variety of charitable capacities amongst the poor of Naples. He died in Naples on 4 February 1615.

# DEMAGNETIZATION

The multicomponent nature of the remanent magnetization of rocks was recognized early in paleomagnetic research. The natural remanent magnetization (NRM) is the vector sum of several magnetizations generated over the geological history of the rocks. Recognition of the multivectorial nature of NRM, understanding of the magnetization acquisition mechanisms and magnetization types, and development of techniques for separation of magnetization components became part of the fundamental principles for paleomagnetic research and for the success of the multiple applications in geology, geophysics, and related fields (e.g., Irving, 1964; McElhinny, 1973; Tarling, 1983). The various magnetization components are acquired over the rock history since formation by processes related to burial, tectonic deformation, heating, metamorphism, metasomatism, fluid circulation, and weathering, which result in formation of new magnetic minerals, chemical reactions (oxidation, reduction), grain size changes, etc. The magnetization acquired at the time of formation of the rock (i.e., cooling below the blocking temperatures of a volcanic or intrusive rock, deposition of sediments, or a metamorphic event) is referred as primary magnetization, with all other components acquired at later times representing secondary components. Secondary components may be added through formation of new magnetic minerals or through partial or total overprints on existing mineral phases. The acquisition modes and magnetic carriers for the various NRM components, which may be thermal, chemical, or viscous magnetizations residing on iron-titanium oxides, iron sulfides or iron oxyhydroxides, result in characteristic spectra of coercivities, blocking temperatures and solubility. Demagnetization techniques (or cleaning techniques) that use application of alternating magnetic fields, temperature or chemical leaching exploit differences on those characteristics, expecting that each magnetic component is characterized by a particular (and discrete) coercivity, temperature, or solubility spectrum. The temporal changes of direction and intensity at any given location on the Earth s surface resulting form secular variation and polarity reversals of the Earth magnetic field and/or changes of the orientation of a rock unit relative to the ambient field direction cause that in general each generation of NRM components present a distinctive magnetization direction. The separation and interpretation of NRM components make use of laboratory demagnetization techniques, methods for determination of vector components and field and consistency tests.

Demagnetization techniques test the stability of the magnetic minerals that carry the remanent magnetization and provide information on their properties. The standard demagnetization techniques are the thermal and alternating field (AF) demagnetization, which make use of the application or progressively higher temperatures or alternating fields. Chemical demagnetization is a technique used for sedimentary rocks, which exploits the solubility of magnetic minerals. Application of low temperatures has also been employed as a demagnetization technique; it involves successive cooling of samples from room temperature down to liquid nitrogen temperature.

Alternating field demagnetization has been used since early in the development of the paleomagnetism (As and Zijderveld, 1958; Creer, 1959; Kobayashi, 1959). Alternating field demagnetization investigates the coercivity spectrum by application of successively stronger alternating fields to the domain grains of a sample, which is placed in a zero direct field setting. The technique takes the domains around successively larger hysteresis loops at each peak demagnetizing field, which are then slowly reduced as the alternating field strength is decreased to zero (magnetic domains of lower coercivity are locked to different orientations). For single domain grains the relaxation time  $\tau$  is directly related to the coercive force  $H_c$ .

Multidomain grains present low coercivities, and the technique can provide information on the presence of a given assemblage of grains with different domain states (Evans and McElhinny, 1969; Dunlop and West, 1969; Stacey, 1961).

Paleomagnetism Rock Magnetism

# DEPTH TO CURIE TEMPERATURE

#### Introduction

The Curie temperature or Curie point is the temperature at which a ferromagnetic mineral loses its ferromagnetic properties. At temperatures above the Curie point the thermal agitation causes the spontaneous alignment of the various domains to be destroyed/randomized so that the ferromagnetic mineral becomes paramagnetic. The term Curie point is named after the French scientist Pierre Curie who discovered that ferromagnetic substances lose their ferromagnetic properties above this critical temperature. This discovery has had great utility in providing information about the deep crust of the Earth that lies below direct human access.

The interior of the Earth is considerably hotter than the surface. Depth to the Curie temperature is the depth at which crustal rocks reach their Curie temperature. Although paramagnetism and diamag*netism* contribute to the magnetism of rocks, it is the ferromagnetic minerals that are the dominant carriers of magnetism in rocks (Langel and Hinze, 1998). The dominant ferromagnetic minerals are the irontitanium oxide and iron sulfides (q.v.). Generally the depth to Curie isotherm is calculated indirectly from analysis of magnetic anomalies; however in a rare case this depth was physically reached in a drilled core. The German Continental Deep Drilling Program drilled a 9.1-km deep core and its petrophysical properties showed that the most abundant ferrimagnetic mineral at this site is monoclinic pyrrhotite (see iron sulfides), which disappeared below about 8.6 km, and below this depth, hexagonal pyrrhotite with a Curie temperature of 260°C was the stable phase (Berckhemer et al., 1997). Thus the depth to the Curie temperature of the predominant pyrrhotite was physically reached (as the drilled core reached in situ bottom hole temperature of around 265°C).

## Utility

Magnetite with a Curie temperature of 580°C is the dominant magnetic mineral in the deep crust within the continental region (Langel and Hinze, 1998). Below the Curie isotherm depth the lithosphere is virtually nonmagnetic. From the analysis of the crustal magnetic field (q.v.), the depth below which no magnetic sources exist can be estimated. The remotely sensed magnetic (surface, airborne, satelliteborne) measurements thus indirectly provide an isothermal surface within the lower crust that in turn can be translated into geothermal gradients of the region. The nationwide geothermal resources project of Japan, initiated in the early 1980s, was perhaps the first systematic attempt to use Curie point depth estimates from the magnetic data as an integral part of a nationwide geothermal exploration program for such a large area (Okubo et al., 1985). Estimates were made for temperature gradients and utilizing available heat flow data very meaningful average thermal conductivities were determined. The depth to Curie temperature can also provide an understanding of the thermal structure; e.g., in volcanic areas convective heat transfer complicates the determination of the thermal structure from heat flow measurements alone and determination of Curie point depths from magnetic data can prove to be helpful for understanding the thermal structure. From a magnetic analysis of the Tohoku arc, Japan, Okubo, and Matsunaga (1997) find that the Curie isotherm varies from 10 km in the volcanic province of the back arc to 20 km or deeper at the eastern limit of Tohoku. They find that the boundary between the seismic and aseismic zones in the overriding plate correlates with the inferred Curie isotherm, indicating that the seismicity in the overriding plate is related to temperature.

The magnetic method estimates the depth to the bottom of the magnetized layer. Due to the inherent uncertainties of these Curie temperature depths, supporting independent evidence is desirable. Possibilities include the comparison with deep seismic soundings, gravity surveys, and petrological studies. In case the estimated Curie temperature depth correlates with a velocity or density boundary, it is likely to reflect a vertical change in composition. Rajaram et al. (2003) applied a series of high pass filters to the aeromagnetic data of Southern India and inferred that below the exhumed crust of the Southern Granulite terrain the magnetic crust is thin (compared to the Dharwar craton) being confined to 22 km; at this depth there is a change in the seismic velocity in the seismic reflection/refraction profiles implying a compositional change being responsible for the lack of magnetic sources below 22 km. The depth extent of magnetic sources has become synonymous with the depth to the Curie temperature though in reality they may represent either a petrological or temperature boundary. Magnetization measurements and petrological studies indicate that ferromagnetic minerals are generally not present in the mantle, at least in the continental region (Langel and Hinze, 1998) implying that the Moho is a magnetic boundary.

#### Method

Magnetic anomalies contain contributions from the ensemble of sources lying above the Curie isotherm. The depth extent of magnetic sources is often determined by spectral analysis of magnetic data. This is done by either examining the shape of isolated magnetic anomalies or by examining statistical properties of patterns of magnetic anomalies. Spector and Grant (1970) pointed out that the anomaly due to an ensemble of sources, represented by a large number of independent rectangular parallelepipeds, has a power spectrum equivalent to that of a single average source of the ensemble and the depth to the top of the body,  $z_t$ , can be estimated from the slope of the log power spectrum. A limited depth extent of the body is predicted to lead to a maximum in the power spectrum, and the wave number of this maximum  $k_{max}$  is related to the bottom of the magnetic source,  $z_b$  (depth to the Curie isotherm) thus:

$$k_{\max} = \frac{\log z_b - \log z_t}{z_b - z_t}$$

For a magnetic survey of dimension *L* the smallest wavenumber is the fundamental wavenumber  $k = 2\pi/L$  (Blakely, 1995). Thus,  $k_{\text{max}}$  should be at least twice this to be able to resolve a peak in the spectrum and this suggests that the survey dimension must be at least

$$L \ge \frac{4\pi(z_b - z_t)}{\log z_b - \log z_t}$$

For a survey conducted 1 km above the top of magnetic sources, the survey dimension must be at least 160 km for sources extending to 50 km depth. It often turns out, however, that continental scale magnetic compilations do not have a maximum in the power spectrum indicating a flaw in the underlying assumptions. Indeed, it is very difficult to estimate the depth to the bottom of the magnetic sources, as the spectrum is dominated at all wavelengths by the contribution from the shallower parts.

To avoid this complication, one calculates the centroid depth,  $z_0$ , either from isolated anomalies or by using methods based on Spector and Grant's statistical model and the inferred depth to the Curie temperature is then obtained as  $z_b = 2z_0 - z_t$  (Okubo *et al.*, 1985).

The method adopted by Spector and Grant (1970) assumes that the magnetization has no spatial correlation; however there are evidences to the contrary. Pilkington and Todoeschuck (1993) from a statistical analysis of susceptibility and aeromagnetic fields indicate that the magnetization and resulting fields are correlated over large distances and can be described as a self-similar random process. Such processes have a power spectrum proportional to some power of the wavenumber, called the scaling exponent (fractal dimension), and the degree of correlation is indicated by the magnitude of this exponent. Maus et al. (1997) find that the limited depth extent of the crustal magnetization is discernible in the power spectra of magnetic anomaly maps of South Africa and Central Asia. From the theoretical power spectrum of a slab using fractal methods, they estimate the Curie temperature depths to lie between 15 and 20 km, with large uncertainties due to the inaccurately known scaling exponent of the crustal magnetization. They conclude that for reliable estimates of the depth to the Curie temperature, magnetic anomalies over an area of at least 1000 km  $\times$  1000 km are required.

Magnetic anomalies, long wavelength (q.v.), measured by satellites are generally inverted using an equivalent source model (see Langel and Hinze, 1998). The observed magnetic anomaly is inverted by a least squares method for an array of equal area dipole sources at the surface of the Earth. A common assumption is that the magnetization arises from induced magnetization only. The magnetization is proportional to the effective susceptibility and the thickness of the magnetized crust, which in turn is a measure of the depth to the Curie temperature. Using inverse models incorporating a priori ocean-continent magnetization contrasts, Purucker et al. (1998) generated global integrated susceptibility maps from Magsat (q.v.), which can be interpreted in terms of thermal characteristics of the crust. Purucker and Ishiara (2005) have used a further refined model using CHAMP (q.v.)data and find for the subduction region of the 2004 great Sumatran earthquake that the subducting plate is descending so quickly that its temperature does not reach the Curie point, resulting in thickened magnetic crust due to the subducting slab.

#### Conclusions

Magnetic anomalies derived from *aeromagnetic surveying* (q.v.) have been used to estimate the depth and configuration of the Curie isotherm for over half a century. Estimates of depth to the Curie temperature can provide valuable insights in the assessment of geothermal energy, calculation of thermal conductivity, and geodynamic evolution. However, unknown mineralogical and statistical properties of the source magnetization have a strong effect on the accuracy of Curie isotherm depth estimates by magnetic methods. These estimates should therefore be interpreted in the context of independent geological, geophysical, and geothermal information. Estimating depth to Curie temperature on a regional scale from long wavelength anomalies requires that large areas of survey data be used for the calculations. There is still no consensus on the minimum survey area required to arrive at a reliable estimate of the Curie isotherm depth. Also, in the Fourier domain, one works with square grids of data, which can pose a problem due to the shape of the continents e.g., Indian peninsula. However, in the absence of any direct method to observe Curie depth, estimates from magnetic anomalies will continue to provide valuable information. New global magnetic anomaly maps, compiled from all available marine and aeromagnetic data and combined with CHAMP (q.v.) and upcoming Swarm satellite magnetic maps, using spherical cap harmonics (q.v.), will provide a valuable basis for future global estimates of the Curie isotherm.

# **DIPOLE MOMENT VARIATION**

The present geomagnetic field is approximately that expected from a dipole located at the center of the Earth and tilted by about 11° relative to the rotation axis. The magnetic moment associated with such a dipole can be inferred from measurements of magnetic field strength. Systematic measurements of relative field strength revealing latitudinal variations were made by De Rossel on the D'Entrecasteaux expedition (1791–1794), but the moment was not evaluated directly until the 1830s when *Gauss* (*q.v.*) carried out the first spherical harmonic analysis using absolute measurements of field strength made at geomagnetic observatories. Although the dipole moment has decreased by about 10% since then, the current value of  $7.78 \times 10^{22}$  Am<sup>2</sup> is close to the average for the past 7 ka ( $7.4 \times 10^{22}$  Am<sup>2</sup>). A broad range of geomagnetic and paleomagnetic observations indicates that both these values are higher than the longer-term average, but probably not anomalously

high, and that the current rate of change seems not atypical for Earth's history. Changes in the dipole moment occur on a wide spectrum of timescales: in general, changes at short periods are small, and the greatest variations are those associated with excursions and full reversals of the geomagnetic field.

#### Dipole moments and their proxies

How the dipole moment is estimated depends on the information available. The geomagnetic dipole moment *m* can be computed directly from the degree 1 Gauss coefficients,  $g_1^0, g_1^1$ , and  $h_1^1$ , of a *spherical harmonic* (*q.v.*) field model via

$$m = \frac{4\pi a^3}{\mu_0} \sqrt{\left(g_1^0\right)^2 + \left(g_1^1\right)^2 + \left(h_1^1\right)^2},$$

with *a* the average radius of the Earth, and  $\mu_0$  the permeability of free space. This clearly distinguishes the dipole from *nondipole field* (*q.v.*) contributions. When there are insufficient data to construct a field model, *p* can be calculated as a proxy for *m* using a single measurement of magnetic field strength *B*,

$$p = \frac{4\pi a^3}{\mu_0} \frac{B}{\sqrt{1+3\cos^2\theta}}$$

When  $\theta$  is the geographic colatitude at which **B** is measured, *p* is known as a virtual axial dipole moment (VADM). This is the equivalent moment of a magnetic dipole aligned with the rotation axis that would generate the observed value of **B**. Often the magnetic inclination *I* is used to derive the magnetic colatitude  $\theta_m$  via the relationship

$$\tan I = 2 \cot \theta_{\rm m}$$

When  $\theta_m$  is used in place of  $\theta$ , the result is known as a virtual dipole moment (VDM). In principle, the VDM might take account of the tilt of the dipole axis, but the effect is complicated by the contribution of the nondipole field present in any instantaneous measurement. VADM and VDM are most often used in comparing paleomagnetic data to account for gross geographic variations in field strength. Temporal and spatial averages of *p* are sometimes referred to as paleomagnetic dipole moments (PDMs); the hope is that such averages will remove the influence of nondipole field contributions, but recent work indicates the possibility of substantial bias. Paleomagnetic measurements of field strength can be absolute or relative variations with time. Absolute measurements require a thermal origin for the magnetic remanence, while the relative variations commonly acquired from sediments must be tied to an absolute scale. A review of current paleointensity techniques can be found in Valet (2003).

Cosmogenic radioisotopes such as  ${}^{14}C$ ,  ${}^{10}$  Be, and  ${}^{36}$ Cl are produced in the stratosphere at a rate that is expected to follow a relationship approximately inversely proportional to the square root of Earth's dipole moment (Elsasser *et al.*, 1956). Thus, cosmogenic isotope records can serve as a proxy for relative dipole moment changes. Production rates are also affected by solar activity, but such changes seem largest on timescales short compared with the dipole moment variations. For  ${}^{14}C$ , the effects of exchange of CO<sub>2</sub> between atmosphere and ocean must be considered, resulting in substantial smoothing and delay in the recorded signal.

#### Direct estimates for the period 0-7 ka

Today, the most complete mapping of the magnetic field is achieved using magnetometers on board satellites (e.g., Ø*rsted* (*q.v.*) and *CHAMP* (*q.v.*)) that orbit Earth at an altitude of several hundred kilometers. These data are sufficiently dense and accurate that, when combined with observatory measurements, it is possible to obtain spherical harmonic models and detect changes in Earth's dipole moment of the order of  $10^{18}$  A m<sup>2</sup> on timescales as short as a day. Such short-term variations (and at least some of the changes up to periods as long as or longer than the solar cycle) do not reflect changes in the internal part of the magnetic field, but stem from fluctuations in strength of the solar wind. The solar wind modulates the strength of the external ring current that exists between about 3 and 6 Earth radii and is the source of induced magnetic field variations in Earth's moderately electrically conducting mantle. Short-term variations in dipole moment presumably also arise in Earth's core, but will be attenuated by passage through the electrically conducting mantle. On timescales of months to several tens of years, it remains a challenge to separate variations of internal and external origin.

For longer term changes in dipole moment, we turn to models constructed from the historical and paleomagnetic record. An excellent *time-dependent model of the main magnetic field* (*q.v.*) is available for A.D. 1590–1990 (Jackson *et al.*, 2000) but is artificially scaled prior to 1832. Early attempts to extend knowledge of the dipole moment back in time used proxy VDMs and VADMs from archeomagnetic artifacts and lava flows for the past 50 ka (McElhinny and Senanayake, 1982) and indicated that 2000 years ago, the dipole moment was almost 50% higher than today. Time-varying spherical harmonic models now exist for the past 7 ka, and these allow separation of dipole and nondipole variations. Directional data used in these models come from archeomagnetic artifacts, lava flows, and high deposition rate sediments. For intensity, only absolute measurements from archeomagnetic samples and lava flows were included. The resolution

**Figure D8** Comparison of estimated dipole moment *m* (continuous curve) with VADM proxies, *p*, (circles) for the past 7 ka, each based on the same archeomagnetic intensity data. Square gives the dipole moment from spherical harmonic analysis in 2002.

depends on the accuracy of the dating and the quality of the observations, which is lower than for direct measurements, and also more heterogeneous, but the dipole moment agrees well with that inferred from historical data in the overlapping time range. Figure D8 shows the dipole moment for the period 0–7 ka, along with VADM calculated for the same data. The estimated dipole moment *m* is systematically lower than the VADM, but still shows almost a factor of two in variability. The differences are consistent with geographical and temporal bias in sampling of the nondipole field by the available VADMs (Korte and Constable, 2005).

# Proxy records from sediments for 10 ka–1 Ma timescales

On longer timescales, the view of dipole moment variation is far less complete, although the situation is steadily improving. There are no direct estimates of *m*, so we must rely on VADMs or some other proxy. Relative paleointensity variations in sediments are available from a large number of marine sediment cores (again, see Valet, 2003) at a variety of locations and a range of time intervals. Global stacks and averaging of these records have been used as a proxy for dipole moment variation, initially for the time interval 0-200 ka and more recently for 0-800 ka (the SINT800 record). Longer stacked records will undoubtedly be forthcoming. Detailed analyses of the stacking process have been conducted with simulations of probable noise processes applied to output from numerical dynamo simulations. These show that although individual sedimentary records may be of low quality and inconsistent with others from nearby sites, such techniques can recover long-term variations in dipole moment. The resolution of changes in the record is primarily limited by the quality of the age control and correlations among cores, which depends on sedimentation rate and other environmental factors, but for SINT800 is probably around 20 ka. Regional stacks for the North and South Atlantic regions have better temporal resolution because of higher average sedimentation rates. Some researchers hope to use dipole moment or regional paleointensity variations as a stratigraphic correlation tool, but large local variations in the nondipole field may prevent this from being a useful approach.

The absolute calibration of relative variations in global dipole moment remains difficult, but the general pattern is well understood for the past few million years at a resolution of a few tens of thousand years. For the past 800 ka, a mean value of  $5.9 \times 10^{22}$  A m<sup>2</sup> is estimated for the global dipole moment, about 25% lower than its current value. SINT800 shows unequivocally (Figure D9) that there are repeated large but irregular changes in VADM over the past 800 ka: the standard deviation is a little more than 25% of the mean for the entire record (almost certainly an underestimate of the true field variability because of heavy averaging). Excursional geomagnetic field

Figure D9 Variations in virtual axial dipole moment inferred from globally distributed marine sediments. Upper curve gives average VADM, lower curve is one standard error in the mean. More details are given in Valet (2003).

behavior in field direction (most recently the Laschamp excursion at about 40 ka), are concurrent with low values of VADM, although the converse is not necessarily true, and the lowest value corresponds to the Matuyama-Brunhes geomagnetic reversal. The exact number of excursions cataloged during the Brunhes normal chron ranges from about 6 to 12 depending on the extent to which one requires global correlations among records. Paleointensity records from volcanics almost exclusively support the notion that excursions are associated with large decreases in geomagnetic intensity, and the idea that geomagnetic reversals are accompanied by a decrease of 80% or 90% in dipole moment is essentially undisputed. Independent support for sedimentary relative paleointensity variations is provided by the general agreement with proxy dipole moment variations derived from the cosmogenic isotopes  $^{10}$ Be and  $^{36}$ Cl.

# Proxy records from TRMs and longer timescale variations

In principle, absolute paleointensity measurements on bulk samples and single crystals derived from lava flows and submarine basaltic glass provide the highest quality measurements of the geomagnetic field. The picture that emerges for VADM variations is slowly clarifying as the number of results steadily increases, and it becomes possible to evaluate the quality of the available data through the implementation of consistency checks on laboratory work, and replicate data on specimens from the same sample. Over the time interval 0–160 Ma, the average dipole moment is estimated as  $4.5 \times 10^{22}$  A m<sup>2</sup> with a standard deviation of  $1.8 \times 10^{22}$  A m<sup>2</sup>. The data are reasonably approximated by a lognormal distribution (Tauxe, 2006).

It remains hard to make definitive statements about very long-term changes in dipole moment, because of the large geographic (1 standard deviation is about 18% for the present field) and temporal variability in *p*. The relationship between average intensity and reversal rate is still unclear, although at  $8.1 \times 10^{22}$  A m<sup>2</sup> the average VADM for the Cretaceous Normal Superchron is high and also highly variable (1 standard deviation =  $4.3 \times 10^{22}$  A m<sup>2</sup>, Tauxe and Staudigel, 2004)). Other times during the Cenozoic show a weak correlation between average field strength and polarity interval length, although for short intervals, this may reflect a significant contribution to the average from the low dipole strength during reversals. Higher average intensities are also correlated with greater variability in VADM, indicating that dipole and nondipole variations may be covariant. It is clear that the average dipole moment depends on the time interval used for the calculation.

Some researchers have inferred correlations between changes in Earth's orbital parameters and geomagnetic field variations. There is to date no undisputed demonstration of such a relationship. Another outstanding question concerns the very ancient geomagnetic field. The field is known to have existed at 3.5 Ga and reversals have been documented from as early as 1.5 Ga (Dunlop and Yu, 2004), but there are so few data that it is not known whether the early field was really dipolar. Many more data are needed to test exciting hypotheses such as whether the nature of geomagnetic field variations changed with the formation and growth of the inner core.

# **DYNAMO WAVES**

Dynamo waves are oscillating solutions of the induction equation of *magnetohydrodynamics* (q.v.), which typically involve magnetic field fluctuations on global scales (possibly including global reversals), and fluctuate with periods related to the timescale of magnetic diffusion (i.e., ca.  $10^3-10^4$  years, for the Earth). They arise as oscillatory solutions of the kinematic *dynamo problem* (q.v.): the linear problem for the generation of magnetic field subject to the inductive action of a specified flow. The concept of dynamo waves can be extended beyond the linear regime, however, as the oscillatory behavior is often retained in nonlinear solutions; and in scenarios involving fluctuating velocities, such waves are invoked by several proposed mechanisms for geomagnetic reversals (see *Reversals, theory*).

In this usage, dynamo waves should be distinguished from other forms of *magnetohydrodynamic waves* (q.v.), including *Alfvén waves* (q.v.), and magnetic *torsional oscillations* (q.v.). The behavior of the magnetohydrodynamic waves is determined jointly by the induction equation and the hydrodynamic equation of motion (including the magnetic Lorentz force). As such, the magnetohydrodynamic waves involve various additional timescales (e.g., the inertial and rotational timescales). Whereas magnetohydrodynamic waves are typically considered as perturbations to the basic state of the geodynamo (although they may retain an important role in the basic generation mechanism, as in the *Braginsky dynamo* (q.v.), dynamo waves are part of the fundamental dynamo mechanism.

#### Axial waves

The idea of dynamo waves goes back to the earliest work on homogeneous dynamos by Parker (1955), where the generative term in the induction equation, later called the "alpha"-effect, was first formulated (see *Dynamos, mean field; Dynamo, Braginsky*). Subsequent early work elucidated the behavior of the resulting equation in axisymmetric 162

systems, and it is in such axial geometries that dynamo waves remain most studied. Given the predominantly axisymmetric character of the geomagnetic field, the importance of the axial modes is clear; and much recent work, despite being fully three-dimensional, continues to focus on these aspects of the solutions. Solving the alpha-effect induction equation in a simplified Cartesian geometry, Parker (1955) found that the most easily excited solutions were normally oscillatory, reversing sign via recurring waves of magnetic activity. This observation was soon corroborated by other authors, and extended to axisymmetric spherical geometries (e.g., Roberts, 1972). The generic behavior of such axisymmetric, mean field dynamos is now well established, and is summarized by Moffatt (1978) and Parker (1979). Different characteristic behavior is obtained if the inductive action of differential fluid rotation-the so-called "omega"-effect-is responsible for part of the field generation (in "alpha-omega" dynamos), or if the alpha effect is the source of dynamo action alone (in "alpha<sup>2</sup>" dynamos). The simplest dipole solutions of alpha<sup>2</sup> dynamos tend to be stationary, whereas the corresponding solutions of alpha-omega dynamos tend to be oscillatory (i.e., involving dynamo waves).

It is worth noting, however, that this generic behavior tends to rely upon the spatial distributions of the alpha- and omega-effects being smooth; different behavior is possible with strongly localized forms. In some cases, alpha<sup>2</sup>-dynamos can also produce dynamo waves (e.g., Giesecke *et al.*, 2005). There are also various ways in which the oscillations of alpha-omega dynamos can be stabilized; "meridional circulation"—i.e., axisymmetric flow on planes of constant meridian, or longitude—being the most celebrated example (see Braginsky, 1964; Roberts, 1972). The situation is further complicated by the possible competition between distinct symmetries of solutions: dipole and quadrupole (see *Symmetry and the geodynamo*). Oscillatory dipole solutions frequently coexist with stationary quadrupole solutions, and *vice versa*. The nonlinear interaction of the various modes may therefore be rather complex.

The smaller number of three-dimensional kinematic studies which have described dynamo waves are broadly consistent with the characteristic behavior outlined above (e.g., Gubbins and Sarson, 1994; Gubbins and Gibbons, 2002); although no longer purely axisymmetric, these solutions typically retain strong axial symmetry and reverse by a similar mechanism. (Gubbins and Gibbons note, however, that the additional freedom available in three dimensions strongly increases the preference for stationary solutions, rather than dynamo wave solutions.) Willis and Gubbins (2004) also considered the kinematic growth associated with time-periodic velocities in three dimensions; some of their solutions exhibited more complex dynamo wave solutions (see *Dynamos, periodic*).

Much of the early work cited above was more motivated by the *solar dynamo* (q.v.) than by the geodynamo, and the concept of dynamo waves remains more developed in the solar context. (Wave solutions are more clearly relevant to the Sun, given the oscillatory nature of the *Sun's magnetic field* (q.v.). It was already noted by Braginsky (1964), however, that an isolated dynamo wave might model a geomagnetic reversal; and this insight has been the basis of many kinematic reversal mechanisms (see *Reversals, theory*). The interaction of dynamo waves with more steady states—typically studied using mean field dynamo models—have also been used to model other aspects of the geodynamo; e.g., Hagee and Olson (1991) used nonlinear solutions, combining modes of both steady and oscillatory character, to model aspects of *geomagnetic secular variation* (q.v.).

In axisymmetric geometries, the dynamo waves progress via the movement of regions of alternately signed magnetic flux, appearing near the equator and migrating towards the pole (or *vice versa*) to replace the magnetic flux originally there; one such sequence constitutes a field reversal (i.e., half an oscillation). The sense of migration—poleward or equatorward—depends upon the relative signs of the alpha- and omega-effects. At the surface of the dynamo region, this migration is exhibited by bands of oppositely signed radial field; in terms of external field models, the process involves the coupled

oscillations of the various zonal multipole terms. In three-dimensional calculations, the migration can also be seen in the motion of local, nonaxisymmetric, surface flux patches. In the solar case, this migration ties in well with the observed sunspot cycle (sunspots being associated with intense magnetic flux). In the case of the Earth, the motion of flux patches of reversed polarity has been proposed as a possible mechanism for a global reversal, on the basis of both observations and theory (e.g., Gubbins, 1987; Gubbins and Sarson, 1994).

Oscillatory features in the output of numerical dynamo models (see *Geodynamo, numerical simulations*) have occasionally been considered with such dynamo wave interpretations in mind (e.g., Glatzmaier and Roberts, 1995); but the three-dimensional simulations are extremely complex, and such identifications remain tentative. The numerical solution analyzed in detail by Wicht and Olson (2004) reversed polarity via a form of dynamo wave; but this solution, which reversed polarity periodically, is not particularly Earth-like. Takahashi *et al.* (2005) analyzed the surface morphology of their numerical reversal in terms of migrating flux patches, but the wave this represents appears to be rather complex.

#### Nonaxial waves

Following on from the earliest axisymmetric work, most studies of dynamo waves have concentrated on the axial waves discussed above; but other forms of waves are quite generally possible. The most frequently discussed alternatives oscillate via the simple rotation of a nonaxisymmetric field pattern, typically dominated by equatorial field patches (including the equatorial dipole). Such solutions have been studied in nonaxisymmetric solutions of mean field models (e.g., Rädler et al., 1990), and in direct three-dimensional calculations: both kinematic (e.g., Holme, 1997) and dynamic (e.g., Aubert and Wicht, 2004). Such waves may be more relevant to other planets than to the Earth, but they may also have some relevance to the geomagnetic secular variation, where they might explain such features as the westward drift (q.v.) of field. (Such secular variation may alternatively, however, be explained by other forms of magnetohydrodynamic waves (q.v.); or else may arise from corotation with the drifting velocity associated with rotating convection (q.v.).)

# DYNAMO, BACKUS

In 1919, *Larmor* (q.v.) speculated that the flow of a conducting fluid could generate a magnetic field. At the Earth's surface, the observed magnetic field is largely axisymmetric, but in 1934, however, *Cowling* (q.v.) published a proof stating that a two-dimensional magnetic field could not be generated by a two-dimensional flow. For a while it seemed plausible that a generalized antidynamo theorem might exist and another mechanism would have to be sought. Worries were eventually allayed in 1958 with the appearance of two positive examples—the rotor dynamo of *Herzenberg* (q.v.), and the stasis dynamo of Backus. Although Bullard and Gellman (1954) had already appeared to have working dynamos, the generated magnetic fields were later shown to be artifacts of insufficient numerical resolution, Gubbins (1973). The existence proof of Backus (1958) bypasses this difficulty by considering a time-dependent flow. Allowing sufficient periods of stasis, the truncation of higher order modes can be rigorously justified.

A magnetic field can be expressed in terms of toroidal and poloidal components  $\boldsymbol{B} = \boldsymbol{T} + \boldsymbol{P} = \nabla \wedge (T\hat{\boldsymbol{r}}) + \nabla \wedge \nabla \wedge (P\hat{\boldsymbol{r}})$ . Upon substitution into the induction equation

$$\frac{\partial \boldsymbol{B}}{\partial t} = \nabla \wedge (\boldsymbol{u} \wedge \boldsymbol{B}) + \lambda \nabla^2 \boldsymbol{B}, \tag{Eq. 1}$$

where  $\lambda$  is the magnetic diffusivity, it becomes apparent that poloidal field must be created by stretching of a toroidal field and *vice versa*. Although originally formulated in terms of topological arguments, Cowling's negative result rested on the impossibility of creating an axisymmetric poloidal field with an axisymmetric flow. The mechanism of toroidal and poloidal exchange, however, formed the basis for the first dynamos shown to exist by analytical methods. Backus (1958) considered the generation of a nonaxisymmetric poloidal field in a sphere of radius *R* filled with an incompressible fluid. An axisymmetric flow within the sphere is punctuated by periods of stasis; exterior to the sphere the medium is assumed to be electrically insulating.

The proof begins by considering the first few natural decay modes of a stationary conducting sphere. The leading toroidal mode  $T_1$ decays more quickly than the leading poloidal mode  $P_1$ , because boundary conditions confine toroidal fields to the sphere. Therefore, the cycle starts in the situation where only the poloidal mode is present and is normalized by the energy norm,  $||P_1|| = 1$ . A small residual field R may also be present. A large toroidal field is then drawn out from  $P_1$  by stretching it with a burst of toroidal field is then drawn out from A period of stasis is then required to remove almost all but the leading poloidal mode P. By applying a very rapid solid body rotation, it is always possible to align P with the the original, resulting in the field  $\gamma(P_1 + R')$ . The cycle is sketched in Figure D10.

Backus proceeds to derive a number of criteria that must be satisfied to ensure that the multiplier  $\gamma$  is greater than unity, and such that if the starting residual is no greater than some small value,  $|| \mathbf{R} || \le \varepsilon$ , then the proportion of resulting residual field remains small,  $|| \mathbf{R}' || \le \varepsilon$ . One of the inequalities that emerges early in the proof, a *bounding theorem* (*q.v.*) for dynamo action is frequently expressed as

$$R'_m \ge \pi^2,\tag{Eq. 2}$$

where the magnetic Reynolds number  $R'_m = RU'/\lambda$  is defined in terms of the maximum difference in flow velocities over the sphere. To satisfy the remaining criteria, however, the bound (Eq. (2)) is greatly exceeded by Backus' chosen flow.

The flow specified by Backus (the Backus dynamo) is axisymmetric with toroidal and poloidal components

$$\boldsymbol{u}_T = \hat{\boldsymbol{\phi}} \lambda^{-1} r^2 (1 - r^2) \sin \theta \cos \theta, \qquad (\text{Eq. 3})$$

**Figure D10** Generation and decay of toroidal and poloidal energies,  $E_T$  and  $E_P$ , over one cycle of the Backus dynamo.

$$\boldsymbol{u}_{P} = \hat{\boldsymbol{r}}r^{2}(1-r^{2})^{2}\sin^{2}\theta\cos\theta - \hat{\boldsymbol{\theta}}r^{2}(1-r^{2})(1-2r^{2})\sin^{2}\theta.$$
(Eq. 4)

The initial toroidal jerk lasts a short time  $\tau \lambda = 0.015$  with  $\lambda^{-1} = 8 \times 10^9$ . The poloidal component of the flow persists for unit time, so  $t_1 = 0.985$ , and the stasis period is  $t_2 = 0.2105$ . After applying a solid body rotation, the flow amplifies the leading poloidal mode initially aligned with the axis. The proportion of residual field at the beginning and end of the cycle is less than  $\epsilon = 1.047 \times 10^{-3}$ .

Although the flow is axisymmetric, *Cowling's theorem* (*q.v.*) is not violated as the generated field is nonaxisymmetric. The dimensional time- and space-averaged velocity corresponds to approximately  $4 \times 10^2$  cm s<sup>-1</sup> for the Earth. The historical record of secular variation suggests that typical velocities near the core-mantle boundary are closer to  $4 \times 10^{-2}$  cm s<sup>-1</sup>. The constraints of physical plausibility were relaxed in order to establish a successful dynamo, but the rigorous analysis of Backus has stood the test of time. Together with the Herzenberg dynamo, the Backus dynamo demonstrated conclusively that velocity fields are capable of generating a magnetic field.

## DYNAMO, BRAGINSKY

The Braginsky dynamo—due to Stanislav Iosifovich Braginsky (sometimes spelled Braginskii, or Braginskiy), and first presented in Braginsky (1964a)—was the first model rigorously to show how a dominantly axisymmetric magnetic field could be generated via the homogeneous dynamo mechanism. The key part of Braginsky's analysis elucidates a mechanism for generating dipolar field from azimuthal field; in this respect, the mechanism follows the more heuristic treatment of Parker (1955) and predates the "two-scale" (or turbulent) mechanism developed by Steenbeck *et al.* (1966) (see *Dynamos, mean field*). Unlike these other approaches, Braginsky's analysis was formulated in terms of the magnetic inductive action of large-scale nonaxisymmetric "waves" of a form excited in the Earth's core. The analysis behind this theory produced many additional insights into the *magnetohydrodynamics* (*q.v.*) of the Earth's core.

## Nearly axisymmetric magnetic field generation

Although the geomagnetic field is observed to be dominantly axisymmetric (i.e., symmetric about the rotation axis, as exemplified by the dominantly axial dipole field), Cowling's theorem (q.v.) shows that a purely axisymmetric system cannot maintain a dynamo. While the generation of azimuthal field from dipolar field is relatively straightforward, via the shearing action of nonuniform azimuthal flow (or "differential rotation"), the converse generation of dipolar field from azimuthal field cannot be sustained within such a system. This seemingly rules out a large class of appealingly simple models, and instead requires the consideration of fully three-dimensional systems. Braginsky's analysis circumvented this problem by considering (in a mathematically rigorous way) a "nearly axisymmetric" system, allowing for small deviations in axisymmetry in both flow and magnetic field. Because of the high electrical conductivity of the Earth's core-which is built into the analysis-these asymmetries, although weak, can combine to influence the axisymmetric field significantly. The net effect is to augment the azimuthally averaged equations for the magnetic field with an additional term (arising from the nonaxisymmetric fields); it is this term that allows the sustenance of the axisymmetric field (thus evading Cowling's theorem, as it would apply to the purely axisymmetric system). This term is in the form of what was later to be called an "alpha effect", similar to that obtained from the analysis of Mean field dynamos (q.v.); it allows the generation of dipolar fields from azimuthal fields. (Braginsky originally denoted this generation term as "Gamma"-as did the earlier, influential, but more schematic analysis of Parker (1955)-but the "alpha" nomenclature has now become the norm.) Together with the so-called "omega" effect, describing the generation of azimuthal field from dipolar field by differential rotation (and thus "completing the cycle"), this allows for a working dynamo.

This analysis required a remarkable appreciation of the magnitudes of several components of the coupled field and flow within the core (with the same scalings applying to both magnetic field and flow field). The azimuthal parts of the axisymmetric fields dominate; the nonaxisymmetric fields are somewhat weaker, and the nonazimuthal parts of the axisymmetric fields (including the dipolar part of the magnetic field) are weaker still. (Technically, these scalings are formulated in powers of the inverse square root of the magnetic Reynolds number; see Dynamos, kinematic, for a definition of this nondimensional number.) Although seemingly intricate, this scaling is consistent with the highly conducting nature of the core fluid, and is supported by many later calculations and observations (although the relative dominance of the various components of fields remains somewhat controversial). Notably, this scaling implies that the axial dipole part of the field, which dominates at the Earth's surface, is actually the weakest part of the field within the Earth's core. (This causes no difficulties for the theory, however, as Braginsky's analysis requires the stronger components of field to remain confined within the core. Indeed, one gratifying consequence is that it naturally produces a weak nonaxisymmetric field in the exterior; i.e., it naturally explains the slight tilt observed in the Earth's dipole field.) It is notable that this analysis makes the Braginsky dynamo inescapably of "alpha omega" character, with the "omega" effect mechanism (and the azimuthal fields) inevitably stronger than the "alpha" effect (and the dipolar, or meridional, fields). This need not be a problem regarding applicability to the Earth, as azimuthal differential rotation is relatively easily excited in rotating convective systems (see Thermal wind); but it has interesting consequences for the resulting behavior of the dynamo.

Braginsky's original analysis relied on the identification of a number of "effective fields", to simplify the appearance of the azimuthallyaveraged equations. These essentially amount to "changes of variables" in the representations of the dipolar magnetic field and of the meridional component of flow (which has a similar geometry to the dipole field, but is confined within the core), to isolate the parts actively involved in the generation mechanism. Such effective variables were found to remain useful when the mathematical analysis of field generation was continued to the next order (Tough, 1967). As Braginsky noted in 1964b, the surprising elegance of this simplification suggests an underlying physical mechanism, and this was later identified by Soward (1972), working in a "pseudo-Lagrangian" framework: the terms needed to give the effective variables can be related to the transformations needed to map streamlines of nearly axisymmetric flow onto axisymmetric, circular, paths about the rotation axis. The development of Soward (1972) reviewed in Moffatt (1978)—also makes the relation between the Braginsky dynamo mechanism and the mean field dynamo mechanism clearer.

While Braginsky (1964a) initially considered the generation associated with a single wave of nonaxisymmetric flow and field-which might contain more than a single azimuthal mode, but which must rotate at a common angular velocity-the analysis was soon extended to allow for arbitrary combinations of waves, and also to allow for oscillations of the axisymmetric meridional flow and dipolar field on timescales similar to that of the waves (Braginsky, 1964b); the generative effect of the waves effectively sums, once the appropriate new effective quantities are allowed. It is worth noting that to obtain a nonzero generation term, the nonaxisymmetric flow of any of these waves must have some preferred sense of direction; it cannot be mirror symmetric about any plane of constant azimuth. The convective rolls which make up this flow must therefore have a spiral planform. Fortunately such spiraling flows can be excited in convective systems like the Earth's (see Rotating convection, non-magnetic). As Braginsky noted, this requirement explains why the Bullard-Gellman dynamo (q.v.) cannot truly sustain dynamo action, at least in the nearly axisymmetric limit. Sarson and Busse (1998) more explicitly address the importance of spiraling in this limit.

Braginsky (1964a,b) also considered the effect of surfaces where the tangential velocity is discontinuous, or where the axisymmetric azimuthal flow vanishes; he showed that concentrated, or "resonant", generation of field can occur on such surfaces, and analyzed the form of such generation.

# Kinematic dynamo action and nonlinear developments

If a particular velocity field is assumed, as in a kinematic dynamo (q.v.), the detailed dynamo action associated with that flow can be investigated. The mechanics of such kinematic dynamo action were immediately investigated in the axisymmetric system obtained by Braginsky (1964a,b), assuming specific simple forms of the differential rotation, meridional circulation, and generation coefficient "alpha" relevant to that system; Braginsky considered such models both analytically in a plane (Cartesian) geometry approximation (1964b), and numerically in spherical geometry (1964c). Both sets of calculations recover the result, shown by Parker (1955), that "alpha omega" dynamos tend to produce oscillatory magnetic fields; a good model for the solar dynamo, but not for the mainly steady field of the geodynamo. Braginsky found, however, that the presence of meridional circulation could alter the behavior so as to favor stationary solutions. Furthermore, his dynamo equations naturally contain a source of meridional circulation, in terms of the effective meridional circulation described above. Even in the absence of significant "true" meridional circulationand the meridional circulation in the Earth is thought to be weak-the effective meridional circulation associated with non-axisymmetric waves, or with axisymmetric oscillations, remains present to stabilize the dynamo oscillations. Braginsky (1964b,c) also identified in this effect a possible mechanism for reversals (see Reversals, theory): fluctuations in the convective state of the dynamo will naturally lead to fluctuations in the (effective) meridional circulation; and if the latter becomes too weak, the dynamo will become oscillatory, reversing polarity via dynamo waves (q.v.) until a more normal convective state is resumed. In a notable subsequent corroboration, the relation of the

axisymmetric system to the full three-dimensional kinematic dynamo problem was explored by Kumar and Roberts (1975). They prescribed a three-dimensional velocity field (including a nonaxisymmetric wave component), and investigated its kinematic dynamo action, both via direct three-dimensional calculations and via the analogous axisymmetric system obtained from the prescriptions of Braginsky (1964a) (with the generation term and effective meridional circulation being explicitly calculated). In a suite of calculations near to this highly conducting, nearly axisymmetric limit, they found very satisfactory agreement.

The calculations of Braginsky (1964a,b,c) were all concerned with kinematic dynamo action, although Braginsky (1964d) contemporaneously considered the full nonlinear problem of the *magnetohydrodynamics* (*q.v.*) of the Earth's core (requiring the form of the flow to be self-consistently derived). Given the remarkable success of the kinematic development, considerable work was expended in trying to extend the nearly symmetric analysis into the nonlinear regime. Despite some initially promising results—Tough and Roberts (1968) showed that the effective variables described above retain some relevance in the nonlinear problem—such developments proved very difficult. At the level of expansion of the foregoing analysis, the nonlinear modifications did not prove to support dynamos; and attempts (Braginsky *et al.*,) to make progress with modified scalings, theoretically capable of nonlinear dynamo action, also encountered difficulties. Roberts (1987) discusses these efforts.

In the absence of a full nonlinear theory, the Braginsky dynamo model was nevertheless extended into the nonlinear regime in a series of "intermediate" models; these assumed a given form of the generation term "alpha", as motivated by the above, and thus allowed the nonlinear dynamics of the system to be investigated within a numerically tractable axisymmetric system. Notable amongst such models is the "model Z" *dynamo* (*q.v.*), originally presented in Braginsky (1975).

## Historical context

The Braginsky dynamo mechanism was of great historical importance. It was the first rigorous elucidation of a mechanism that could sustain a nearly axisymmetric field such as the Earth's, and arguably remains a mechanism more appropriate to the Earth than the two-scale, or turbulent, dynamos frequently studied following the work of Steenbeck *et al.* (1966) While the difficulty of analytic work on the nearly axisymmetric system has limited much further development, the qualitative understanding provided by Braginsky's analysis remains hugely important. Although the current widespread availability of computers capable of simulating three-dimensional dynamo action (see *Geodynamo: numerical simulations*) may naively appear to have marginalized such theories, the results of such large-scale calculations cannot easily be appreciated without the appropriate theoretical guidance.

The importance of Braginsky's contributions to our understanding of the magnetohydrodynamics of the Earth's core is difficult to overstate. The four papers published in 1964 (all were submitted between April and June of that year) constituted a huge advance in the theory of the geodynamo. In addition to the work described here on magnetic field generation, they further advocate the importance of *chemical convection* (*q.v.*), and address the effects of the core conditions on turbulence (see *Core Turbulence*). Later work by Braginsky investigated these varied topics in more detail, and his continued elucidations of the magnetohydrodynamics of geodynamo—most recently in Braginsky and Roberts (1995)—has remained enormously influential.

# DYNAMO, BULLARD-GELLMAN

The Bullard-Gellman dynamo, presented by *Edward Crisp Bullard* (q.v.) and Harvey Gellman in a pioneering paper of 1954, was the first convincing quantitative model for dynamo action in a fluid sphere. It prescribed a specific velocity, intended as a highly idealized model of the motion in the Earth's core, and considered the kinematic growth of magnetic field produced by this flow (see *Dynamos, kinematic*).

Bullard and Gellman considered this problem both theoretically and computationally. In terms of the dynamo explanation for the Earth's magnetic field, this work was ground-breaking in several respects.

The study was formulated using the mathematical framework of vector *spherical harmonics* (q.v.). In representing the magnetic field and the velocity in this form—and in analyzing the induction equation determining the time-evolution of magnetic field in the same terms—Bullard and Gellman introduced the formalism most commonly used for dynamo theory today. (A similar treatment had earlier been proposed by Elsasser (1946), but Elsasser had used vector spherical harmonics to represent the magnetic vector potential, rather than the magnetic field itself; and the former option constitutes an unsuitable choice of gauge. Takeuchi and Shimazu (1953) were also engaged in a parallel development.)

At the time, the plausibility of homogeneous fluid dynamos was far from clear; no examples were known, and *Cowling's theorem* (q.v.)seemed to shed doubt on the whole concept. The formalism developed by Bullard and Gellman elucidated the practical possibilities of such dynamos. Regardless of their conclusions for the specific velocity model they proposed, their analysis made the mechanisms of kinematic dynamo action the possible subject of detailed study. Indeed, one of the first rigorously proven examples of dynamo action in a sphere the "stasis" dynamo of Backus (1958)—relies explicitly on the spherical harmonic decomposition developed by Bullard and Gellman.

In choosing to work with a highly idealized flow—which could be represented by a simple, concrete set of vector spherical harmonics— Bullard and Gellman inspired a long series of subsequent investigations into the abstract possibilities of kinematic dynamo action. Many later kinematic dynamos were direct developments of the original Bullard-Gellman flow (e.g., Lilley, 1970; Kumar and Roberts, 1975; Sarson 2003), and many insights into dynamo action were obtained from this "family" of models.

The form of flow they chose-consisting of two distinct parts-was motivated by considerations both of kinematic dynamo action and of the fluid dynamics of the Earth's core. One constituent was an axisymmetric azimuthal flow, of nonuniform angular velocity ("differential rotation"); such a flow, of a form easily excited in a rotating fluid, can shear dipolar magnetic field into azimuthal field. Since Cowling's theorem had shown a purely axisymmetric system to be incapable of sustained dynamo action, a nonaxisymmetric constituent was also included; this involved radial motions, schematically emulating buoyancy-driven convection in the core. Although this component was chosen in a particularly simple form (for reasons of computational convenience), Bullard and Gellman clearly anticipated more "columnar" structures, in line with the Proudman-Taylor theorem (q.v.); they correctly noted that the dynamo action of such structures would be similar to that of the flow they adopted. Their paper explicitly discusses how this constituent of flow might act to create dipolar field from azimuthal field, along the lines elucidated by Parker (1955) and later formalized in the theory of mean field dynamos (q.v.).

Even with this relatively simple velocity, the kinematic dynamo problem remains technically daunting (involving the solution of an infinite set of coupled differential equations), and Bullard and Gellman ultimately addressed its solution computationally. In doing so, their work was one of the very first attempts to solve a physical problem governed by partial differential equations numerically. Their calculations were made using the automatic computing engine (ACE) computer of the UK National Physics Laboratory, one of the world's first programmable computers. In this respect, their work is a clear precursor of the large number of numerical simulations now routinely carried out in geodynamo theory (see Geodynamo: numerical simulations). Bullard and Gellman's numerical scheme uses a purely spectral treatment of the angular variations (i.e., it considers each term in the vector spherical harmonic decomposition separately, requiring the explicit consideration of all possible mutual interactions) and a finite difference discretization in radius. In this it does not differ greatly from many modern treatments (although the use of purely spectral expansions for

nonlinear interactions is now considered less efficient than alternative techniques).

The 1954 paper also contains a number of other significant contributions. Perhaps most famously, it contains an "*antidynamo theorem*" (q.v.) stating the impossibility of dynamo action by flows with no radial component (i.e., confined to radial surfaces). The paper also contains significant discussion of the essential magnetohydrodynamics of the problem, and some detailed analysis of the applicability of the work to the Earth.

Despite their many insights and advances, the positive dynamo action Bullard and Gellman tentatively deduced from their calculations was later shown to be an artifact of the low numerical resolution possible at the time (a possibility which the authors themselves had been careful to acknowledge). Nevertheless, the Bullard-Gellman dynamo introduced many methods for solving the induction equation in spherical geometry, took several major steps towards validating the dynamo explanation of the geomagnetic field, and can justly be considered the forerunner of many later computational models. For all these reasons, it stands as an important milestone in the development of dynamo theory.

## DYNAMO, DISK

It is generally believed that the Earth's magnetic field results from some form of electromagnetic induction, producing electric currents flowing in the Earth's fluid, electrically conducting outer core (see *Geodynamo*). The details of the process are not known and several questions have not been answered, such as how the field reverses its polarity. The partial differential equations that govern the generation of the field are complex, nonlinear, and contain physical quantities whose values in the Earth's core are not known with any certainty. Various mathematical models have therefore been proposed, which might simulate reversals of the field.

One of the simplest is the homopolar disk dynamo suggested by Bullard (1955). It is based on the Faraday disk generator and consists of an electrically conducting disk that can be made to rotate on an axle by an applied torque. If the disk rotates in an axial magnetic field, a radial EMF will be produced between the axle and the edge of the disk. If this were all, the EMF would be balanced by an electric charge distribution on the edge and surfaces of the disk and no current would flow. However, if one end of a stationary coil coaxial with the disk and axle is joined to the edge of the disk by a sliding contact (a brush) and the other end is joined to another sliding contact on the axle, a current will flow through the coil and an axial magnetic field will be produced. The system becomes a dynamo when the rotation is fast enough that the induced field becomes equal to the field required to produce it. No external source of field or current is then required and no part of the system needs to be ferromagnetic.

The system can be represented by two nonlinear ordinary differential equations. If the disk is driven by a constant torque G, the equation of motion is

$$C\dot{\omega} = G - MI^2 \tag{Eq. 1}$$

where *C* is the moment of inertia of the disk,  $\omega$  its angular velocity, *I* the current and  $2\pi M$  the mutual induction of the coil and disk. The equation governing the current is

$$L\dot{I} + RI = M\dot{\omega}\dot{I} \tag{Eq. 2}$$

where L and R are the inductance and resistance of the coil, respectively.

Since Eq. (1) is quadratic in *I* and Eq. (2) linear and homogeneous in *I*, the dynamo can produce a current in either direction. It cannot, however, switch from one direction to the other, since, if *I* is zero, so is *I*. In order to produce reversals, another term must be introduced into Eq. (2) so that *I* is not proportional to *I*. This has been achieved in two ways. *Rikitake* (q.v., 1958) suggested using two coupled disk dynamos in series (see Figure D11) and Malkus (1972) suggested an impedance between the brush and the coil and a shunt connected across the coil of a single dynamo to introduce a phase difference. Malkus' suggestion was investigated by Robbins (1977). Bullard and Gubbins (1973) studied the case when the disks oscillated periodically as a model of dynamo action by gravity waves in a stable core and

 $I_2$ Disc 1  $I_1$  $I_2$  $I_2$  $I_2$ Disc 2

Figure D11 Coupled system of two disk dynamos (after Rikitake, 1958).

found that a single disk dynamo would not generate a magnetic field but that two coupled disk dynamos would, provided the oscillation frequency were not too large.

A number of people have investigated the properties of disk dynamos for values of various parameters and have shown that the system may oscillate randomly between two states, which would correspond to reversals of the geomagnetic field (Figure D12). Such behavior has been found in many other fields and is called chaos. As with other nonlinear systems displaying chaotic motion, the behavior of disk dynamos depends critically on initial conditions. In some models, the amplitude of the oscillations grows monotonically with time—when the amplitude exceeds some particular value, the system flips to the opposite polarity (Figure D12). Hide (1995) questioned the assumption that dissipation due to mechanical friction can be neglected compared with Ohmic effects and suggested that friction may even prevent dynamo action by destroying any initial transients in the system. He demonstrated this for the Rikitake double disk dynamo by adding an extra term  $-k\omega_1$ , to the right hand side of Eq. (1) for one disk dynamo, and  $-k\omega_2$  to the similar equation for the second disk dynamo. The development of the system depends on the values of the parameters and, for some values, chaotic oscillations are inhibited and a dynamo cannot function.

Figure D12 Oscillations of the current in the coil of a single disk dynamo with an impedance between the brush and the coil and a shunt connected across the coil (after Robbins, 1977). The three plots form one continuous time sequence.

Figure D13 Plot of the current on the Robbins dynamo with brown noise excitation (after Crossley *et al.*, 1986). The three plots form one continuous time sequence.

Crossley *et al.* (1986) investigated the Robbins (1977) dynamo when another component was added into the equations of motion to simulate irregularities in the hydrodynamics of the Earth's core. These irregularities could be due to fluid dynamical turbulence, variations in the material properties, or physical and chemical processes. They represented this "noise" by adding a small time-dependent term to the constant driving torque. Three different types of noise were investigated. Figure D13 shows variations in the current for the Robbins dynamo with the addition of "brown" noise (random walk). An interesting result of their models is that the addition of some noise into the system can either add to or reduce the excursions of the magnetic field attributed to the nonlinear behavior of the equations of motion.

Hide and his coworkers have investigated more sophisticated selfexciting disk dynamo systems. In one study (Hide *et al.*, 1996), they considered a nonlinear electric motor connected in series with the coil of a single disk dynamo. They found that if the torque *T* on the armature of the motor is proportional to the current *I*, multiple periodic as well as chaotic persistent fluctuations are possible, but if *T* is proportional to  $I^2$ , persistent fluctuations are completely quenched.

The study of disk dynamos, which began as a search for models of the Earth's magnetic field, has led to the study of sets of nonlinear ordinary differential equations with important applications to other areas of geophysical fluid dynamics.

Geodynamo Rikitake, Tsuneji (1921–2004)

# DYNAMO, GAILITIS

The Gailitis dynamo is a simple flow pattern in an electrically uniformly conducting ( $\sigma$ ) incompressible fluid for which there is a simple mathematical proof that it can generate magnetic field. In that sense, it resembles the *Backus* (*q.v.*), *Herzenberg* (*q.v.*), and *Ponomarenko* (*q.v.*) *dynamos*. Together they supported the belief in dynamo theory at a time when neither experiment nor computation was able to demonstrate dynamo action in uniform fluid conductor.

#### Geometry

The Gailitis flow is stationary, with axial symmetry, and with velocity  $\mathbf{v}$  in meridian planes only. In the Gailitis (1970) version the whole flow is concentrated in two toroidal eddies. In each of them the fluid rotates round the bent central line like a ring vortex as shown on Figure D14. The exterior is a stationary conductor to infinity.

#### Self-excitation

As in Herzenberg's dynamo, each eddy alone cannot excite magnetic field but both together can. The lower vortex excites the upper one and vice versa. At an appropriate flow speed, the mutual excitation supports a steady magnetic field. As the flow is axisymmetric, the field has to have angular dependence  $B_{\varphi} \sim \exp(im\varphi)$ . The integer *m* cannot be zero because of *Cowling's anti-dynamo* (*q.v.*) theorem.

## Mathematics

For mathematical simplicity, both vortices are assumed to be thin and the motion is assumed to be being fast:

$$R \ll \max(a, z_0)$$
 and  $Rm = \mu_0 \sigma \int_0^R (r/R)^2 v \,\mathrm{d}r \gg 1$ 

At high *Rm*, field-lines are semifrozen to the moving fluid, hence the field pattern inside any vortex has the asymptotic form  $B_{\varphi} = \rho b \exp(im\varphi)/a$  (field proportional to the length of field-line) and  $B_r = -irmb \exp(im\varphi)/(2a)$  (from div B = 0). As the upper vortex is a mirror reflection of the lower one, at self-excitation the normalization factors *b* in each vortex have the same magnitude but may differ in sign. Inserting these expressions on the right side of the induction equation written in the integral form gives

$$\mathbf{B}(\mathbf{r}) = \frac{\mu_0 \sigma}{4\pi} \int \frac{\mathrm{d}^3 r'}{|\mathbf{r} - \mathbf{r}'|} \mathrm{curl}[\mathbf{v}(\mathbf{r}') \times \mathbf{B}(\mathbf{r}')],$$

Figure D14 Flow concentrated in two toroidal eddies. The fluid rotates round the bent central line like a ring vortex.

and integrating over the first vortex volume (outside  $\mathbf{v} = 0$ ) with  $\mathbf{r}$  fixed at the second vortex, the left side leads to the excitation condition  $Rm = \pm (a/R)^2 T_m(z_0/a)$ .  $T_m(z_0/a)$  is a standard integral. Computed values are given in Figure D15. The dynamo generates a field with different values of *m* depending on  $z_0/a$ . The dominant value of *m* is the one with lowest  $T_m(z_0/a)$ . The sign of *Rm* determines the flow direction. If the flow is directed as on Figure D14, the generated  $B_{a}$  in both vortices is in the same direction. If the flow

**Figure D15** Computed values of the induction equation. The dynamo generates a field with different values of *m* depending on  $z_0/a$ .

**Figure D16** Computer simulation thick vortices in a sphere. Shown is the simplest possible polynomial velocity distribution. direction is opposite to that in Figure D14 the  $B_{\varphi}$  in the upper vortex is opposite to that in the lower vortex. The absolute value of Rm remains the same.

## **Thick vortices**

The thinness of the vortices is not essential for dynamo action. Computer simulation of a pair of thick vortices in a sphere works equally well. For the simplest possible polynomial velocity distribution (Figure D16) the critical  $Rm = \mu_0 \sigma v_{\text{max}} R$  is 1735 (Gailitis, 1995). As for thin vortices, the absolute magnitude of the critical Rm remains unchanged when the flow direction is altered.

# Helicity

The Ponomarenko relies on helicity (v.curl v). The Gailitis dynamo has zero helicity, like the "second order" spatially periodic dynamos because the flow lies in meridian planes: there is no azimuthal motion. On the other hand, the critical Rm = 1735 for Gailitis is two orders of magnitude higher than for Ponomarenko. Adding some azimuthal flow to the thick vortices flow also lowers the critical Rm more than by an order of magnitude. The Gailitis dynamo therefore demonstrates that helicity is not strictly necessary for dynamo action but is helpful.

# DYNAMO, HERZENBERG

## Definition of the model

Human-made dynamos are complex multiconnected devices, but those operating in Nature have to function in geometrically simple (usually almost spherical) bodies of electrically conducting fluid, such as Earth's core. During the early development of dynamo theory, it seemed possible that no motion within such a simple "homogeneous" system could maintain a magnetic field, a feeling reinforced by some antidynamo theorems; see *Antidynamo and bounding theorems* and *Cowling's theorem*. Theoreticians sought either to strengthen antidynamo theorems until it could be proved that *homogeneous dynamos* could not exist, or to devise specific examples that worked. In these endeavors, it was simplest to focus on the electrodynamics, assuming that the velocity V of the conductor is given, and to ignore the dynamical questions of how V is maintained and how a magnetic field **B** would affect it; see *Dynamos, kinematic*. It is then irrelevant whether

 ${\bf V}$  is dynamically possible or not; it is necessary only to find a  ${\bf V}$  that can sustain a nonzero  ${\bf B}.$ 

The first two kinematic dynamos were devised in 1958, one of which is described here; see also *Dynamo, Backus*. These models proved that the search for a general antidynamo theorem was in vain. In 1958, electronic computers were not sufficiently powerful to find homogeneous dynamos. Moreover, numerical integrations could not provide the mathematical "rigor" that the subject demanded in the face of the anti-dynamo theorems. Backus and Herzenberg had to provide demonstrations by rigorous mathematical analysis. In each case, this depended on an ingenious asymptotic argument based on the smallness of a well-chosen parameter.

In essence, the Herzenberg dynamo consists of two spherical rotors,  $\mathcal{R}_1$  and  $\mathcal{R}_2$ , each of radius *a*, embedded in an infinite conductor of the same magnetic diffusivity,  $\eta$ , with which they are in perfect electrical contact; see Figure D17. The rotors turned steadily with angular velocities,  $\boldsymbol{\omega}_1$  and  $\boldsymbol{\omega}_2$ , different in direction, but having the same magnitude:  $\boldsymbol{\omega} = |\boldsymbol{\omega}_1| = |\boldsymbol{\omega}_2|$ . Their centers are denoted by  $O_1$  and  $O_2$  where  $\overrightarrow{O_1O_2} = \mathbf{R}$ . Provided a suitably defined *magnetic Reynolds number*, Rm, is large enough, the rotors can re-enforce one another magnetically in the sense that the magnetic field,  $\mathbf{B}_1$ , created by  $\mathcal{R}_1$  (as it rotates in the field,  $\mathbf{B}_2$ , produced by  $\mathcal{R}_2$ ) will be large enough for  $\mathcal{R}_2$  (rotating in the field  $\mathbf{B}_1$ ) to be able to generate the required  $\mathbf{B}_2$ . A suitable magnetic Reynolds number is

$$Rm = \omega a^5 / \eta R^3. \tag{Eq. 1}$$

The model can sustain a magnetic field if Rm attains a critical value, Rm<sub>c</sub>, of order unity. Since V is time-independent, **B** is then steady (the DC dynamo) or oscillatory (the AC dynamo). Herzenberg, following the general trend of the times, sought DC dynamos only. The small parameter of Herzenberg's analysis is a/R, or equivalently  $\eta/\omega a^2$ , since  $\eta/\omega a^2 = \text{Rm}^{-1}(a/R)^3$  and Rm = O(1).

Dynamos conceptually similar to Herzenberg's have been proposed for binary stellar systems, the magnetic field created by one star providing the field needed by the other star to produce the field required by its partner (Dolginov and Urpin, 1979; Brandenburg *et al.*, 1998).

## Ideas behind Herzenberg's evaluation of Rm<sub>c</sub>

In 1949, Bullard wrote a seminal paper on induction by spherical rotors, and Herzenberg (1958) made ingenious use of his results; see also Herzenberg and Lowes (1957). Herzenberg's analysis succeeds because of two basic simplifications. First, the rotors are well separated;  $R \gg a$ .

**Figure D17** The Herzenberg dynamo model. Two spherical rotors,  $\mathcal{R}_1$  and  $\mathcal{R}_2$ , are embedded in an infinite medium of the same electrical conductivity with which they are in perfect electrical contact. Their centers  $O_1$  and  $O_2$  are separated by **R**, a distance large compared with their radii *a*. They rotate with angular velocities  $\boldsymbol{\omega}_1$  and  $\boldsymbol{\omega}_2$  about directions lying in the planes indicated by the *dashed rectangles*.

Second, they are rapidly rotating;  $R_{\omega} \equiv \omega a^2/\eta \gg 1$ . Order one values of Rm arise as the product  $R_{\omega}(a/R)^3$  of one very large number and one very small one.

To evaluate the field **B**<sub>1</sub> produced by the rotation of  $\mathcal{R}_1$ , it is necessary to know, throughout  $\mathcal{R}_1$ , the field **B**<sub>2</sub> created by  $\mathcal{R}_2$ . This field is almost uniform, because of the remoteness of  $\mathcal{R}_2$  implied by the first simplification ( $R \gg a$ ). More precisely, **B**<sub>2</sub> can be expressed in a rapidly convergent Taylor expansion as

$$\mathbf{B}_2(\mathbf{x}) = \mathbf{B}_2(\mathbf{O}_1) + \mathbf{x} \cdot (\nabla \mathbf{B}_2)\mathbf{O}_1 + \cdots, \qquad (\text{Eq. 2})$$

where **x** is the position vector from O<sub>1</sub>. For  $r = |\mathbf{x}|$  of order *a*, the ratio of successive terms in Eq. (2) is of order  $a/R \ll 1$ , and it might seem at first sight that only the first term in the expansion Eq. (2) is needed, but this is not the case as is shown below.

The second simplification reduces the complications of evaluating  $B_1$ . The field  $B_2$  is split into two parts,

$$\mathbf{B}_2 = \overline{\mathbf{B}}_2 + \mathbf{B}_2',\tag{Eq. 3}$$

where  $\overline{\mathbf{B}}_2$  is symmetric with respect to the direction of  $\boldsymbol{\omega}_1$  and  $\mathbf{B}'_2$  is the remaining asymmetric part. This separation of  $\mathbf{B}_2$  can be achieved by defining cylindrical coordinates  $(s, \phi, z)$ , with *z*-axis parallel to  $\boldsymbol{\omega}_1$ . The  $\phi$ -independent components of Eq. (2) then define  $\overline{\mathbf{B}}_2$ :

$$\overline{\mathbf{B}}_2 = A_1^{(1)} \widehat{\boldsymbol{\omega}}_1 + a^{-1} A_2^{(1)} [3(\widehat{\boldsymbol{\omega}}_1 \cdot \mathbf{x}) \widehat{\boldsymbol{\omega}}_1 - \mathbf{x}] + \cdots, \qquad (\text{Eq. 4})$$

where  $\widehat{\boldsymbol{\omega}}_1 = \boldsymbol{\omega}_1 / \boldsymbol{\omega}$  and

$$A_1^{(1)} = \widehat{\boldsymbol{\omega}}_1 \cdot \mathbf{B}_2(\mathbf{O}_1), \quad A_2^{(1)} = \frac{1}{2}a \ \widehat{\boldsymbol{\omega}}_1 \cdot [\widehat{\boldsymbol{\omega}}_1 \cdot (\nabla \mathbf{B}_2)\mathbf{O}_1]. \quad (\text{Eq. 5})$$

The advantage of the division in Eq. (3) becomes apparent when the fields  $\mathbf{B}'_1$  and  $\overline{\mathbf{B}}_1$  induced by  $\mathbf{B}'_2$  and  $\overline{\mathbf{B}}_2$  are compared. In the frame of reference moving with a point on the surface  $S_1$  of  $\mathcal{R}_1$ , the inducing field is highly oscillatory, and the induced currents are therefore confined to a thin "skin" at  $S_1$ . These currents shield the interior of  $\mathcal{R}_1$  almost completely from the inducing field  $\mathbf{B}'_2$ . Since they cancel each other out within  $\mathcal{R}_1$ , the fields  $\mathbf{B}'_1$  and  $\mathbf{B}'_2$  must have similar magnitudes everywhere near  $\mathcal{R}_1$ . This is in sharp contrast to  $\overline{\mathbf{B}}_2$  and  $\overline{\mathbf{B}}_1$ . Since  $\overline{\mathbf{B}}_2$  is steady in the frame rotating with  $\mathcal{R}_1$ , there is no skin of eddy currents at  $S_1$ , and the induced field  $\overline{\mathbf{B}}_1$  is proportional to  $\omega$ ; see Eq. (6) below. (This is sometimes called "the omega effect"; see *Magnetohydrodynamics*.)

In short, even though  $\overline{\mathbf{B}}_2$  and  $\mathbf{B}'_2$  are comparable in magnitude,  $\overline{\mathbf{B}}_1 = O(R_{\omega}\overline{\mathbf{B}}_2) = O(R_{\omega}\mathbf{B}'_1) \gg \mathbf{B}'_1$ . The  $\mathbf{B}'_1$  part of  $\mathbf{B}_1$  can therefore be ignored.

The Bullard (1949) theory shows that the first term in Eq. (4) creates a quadrupolar field; the second produces a combination of dipolar and octupolar fields, of which the latter can be discarded since, for  $r \gg a$ (where **B**<sub>1</sub> is required in order to evaluate the field **B**<sub>2</sub> generated by the rotation of  $\mathcal{R}_2$ ), the octupolar field is smaller than the dipolar field by a factor of order  $(a/R)^2$ . For  $r \gg a$ ,

$$\mathbf{B}_{1} = \mathbf{R}_{\omega} \left\{ \frac{2}{15} A_{2}^{(1)} \frac{a^{2}}{r^{3}} \left( \widehat{\boldsymbol{\omega}}_{1} \times \mathbf{x} \right) - \frac{1}{5} A_{1}^{(1)} \frac{a^{3}}{r^{5}} \left( \widehat{\boldsymbol{\omega}}_{1} \cdot \mathbf{x} \right) \left( \widehat{\boldsymbol{\omega}}_{1} \times \mathbf{x} \right) \right. \\ \left. + \mathbf{O} \left( A_{3}^{(1)} \frac{a^{4}}{r^{4}} \right) \right\}, \tag{Eq. 6}$$

 $\mathbf{B}'_1$  having been ignored (see above). The necessity of retaining the second term in Eqs. (2) and (4) is now apparent. For n > 1 the part of  $\mathbf{B}_1$  created by the  $A_n^{(1)}$  term is of order  $\mathbb{R}_{\omega}A_n^{(1)}(a/R)^n$  at the rotor  $\mathcal{R}_2$ , and in particular it is of order  $\mathbb{R}_{\omega}A_2^{(1)}(a/R)^2$  for n = 2. The uniform field  $A_1^{(1)}$  however makes a contribution to  $\mathbf{B}_1$  only of order  $\mathbb{R}_{\omega}A_1^{(1)}(a/R)^3$ . It follows that the  $A_1^{(1)}$  and  $A_2^{(1)}$  are equally effective in inducing field but that,

172

to leading order, all terms not shown in the expansions of Eqs. (2) and (4) can be ignored.

The coordinate-independent way (6) of writing **B**<sub>1</sub> is due to Gibson and Roberts (1967); see also Moffatt (1978). It eases the task of computing  $A_1^{(2)}$  and  $A_2^{(2)}$ , defined at O<sub>2</sub> in analogy with Eq. (5). For example, on substituting **x** = R in Eq. (6), it is seen that

$$A_1^{(2)} = \Lambda \left[ A_1^{(1)} \cos \Theta_1 - \frac{2R}{3a} A_2^{(1)} \right],$$
 (Eq. 7)

where

$$\Lambda = \frac{1}{5} R_{\omega} \left(\frac{a}{R}\right)^3 \widehat{\mathbf{R}} \cdot \left(\widehat{\boldsymbol{\omega}}_1 \times \widehat{\boldsymbol{\omega}}_2\right) = \frac{1}{5} Rm_c \sin \Theta_1 \sin \Theta_2 \sin \Phi,$$
(Eq. 8)

and  $\hat{\mathbf{R}} = \mathbf{R}/R$ . Here  $\Theta_i$  is the angle between  $\boldsymbol{\omega}_i$  and  $\mathbf{R}$ , and  $\Phi$  is the angle between the plane defined by  $\boldsymbol{\omega}_1$  and  $\mathbf{R}$  and the plane defined by  $\boldsymbol{\omega}_2$  and  $\mathbf{R}$ . Similarly  $A_2^{(2)}$  is obtained by setting  $\mathbf{x} = \mathbf{R}$  after operating on Eq. (6) with  $\nabla$ .

Analogous expressions for  $A_1^{(1)}$  and  $A_2^{(1)}$  are obtained by reversing **R** and the roles of  $\mathcal{R}_1$  and  $\mathcal{R}_2$ . In this way four simultaneous equations are obtained for the four constants  $A_i^{(j)}(i, j = 1, 2)$ . In the marginal state, these equations must have a nontrivial solution. This defines the critical values of  $\Lambda$ :

$$[\Lambda^2(\cos\Theta_1\cos\Theta_2 - \sin\Theta_1\sin\Theta_2\cos\Phi) - 3]^2 = 0. \quad (Eq. 9)$$

By Eq. (8), this condition clearly cannot be satisfied if  $\Theta_1$ ,  $\Theta_2$  or  $\Phi$  is zero. The configuration shown in Figure 1, in which  $\Theta_1 = \Theta_2 = \frac{1}{2}\pi$  and  $\Phi = \frac{3}{4}\pi$  satisfies Eq. (9) for Rm<sub>c</sub> =  $5 \times 3^{1/2} \times 2^{3/4} \approx 14.56$ . If Eq. (9) is satisfied, it is also satisfied if the sense of rotation of both rotors is reversed but that, if only one of  $\omega_1$  and  $\omega_2$  is reversed, Eq. (9) is no longer obeyed.

#### Later developments

The shape of the rotors in Herzenberg's model is not significant, so long as they are axisymmetric (Gailitis, 1973). Also, their solid-body motion can be replaced by a continuously varying internal angular velocity (Gibson, 1969; Moffatt, 1978), so avoiding the unphysical "tearing" of the "fluid" at the surfaces of the rotors. What is significant for such "point vortices" is their angular momenta (Roberts, 1971; Gailitis, 1973), and multirotor models provide a crude representation of field creation by helical turbulence (Kropachev, 1966; Roberts, 1971).

There is a subtlety. In deriving Eq. (9), terms of order  $(a/R)^4$  have been discarded. If they were restored, the right-hand side of Eq. (9), though small, might be negative. In that case Eq. (9) would prove nothing, since a complex Rm<sub>c</sub> for a DC dynamo is meaningless. Herzenberg (1958) recognized this difficulty and evaded it in a way relevant to experimental simulations of his dynamo. Instead of assuming that the conductor fills all space, he supposed that the rotors are embedded in a large conducting sphere, surface S, surrounded by an insulator. The electric currents produced by the rotors are "reflected" back by S, so creating new terms on the right-hand side of Eq. (9). He established situations in which these terms are positive. His idea also raises an interesting possibility: perhaps a single rotor can act as a dynamo by re-enforcing the fields reflected by S? This was first suggested by Herzenberg and Lowes (1957); see their case C on p. 568. Kropachev (1966) proposed a specific model of this type. See also Gibson (1968b).

Gibson (1968a) attempted to evade the difficulty raised by the sign of the missing right-hand side of Eq. (9) by taking Herzenberg's analysis to higher order in a/R. Unfortunately the modified Eq. (9) that resulted was again a perfect square, and the difficulty remained. This invited the speculation that, if the analysis could be carried out to

*all* orders in a/R, a perfect square would result. Gibson (1968b) did, however, resolve the difficulty in a totally different way. He pointed out that it did not arise for a three-rotor system. He obtained Rm<sub>c</sub> for such a dynamo, again in the asymptotic case of large R<sub> $\omega$ </sub> and small a/R. See also Kropachev *et al.* (1977a, b); Moffatt (1978).

Gailitis (1973) argued that, if the missing right-hand side of Eq. (9) is positive, there should be two distinct marginal solutions with different Rm<sub>c</sub> but that, if it is negative, an AC dynamo would exist. This conclusion was re-enforced in the analytical work of Brandenburg *et al.* (1998).

Advances in computer capability eventually made it practical to calculate numerically the three-dimensional fields produced by two rotors in the general (nonasymptotic) cases in which a/R is O(1). The integrations of Brandenburg et al. (1998) were carried out for a cubical box, with periodic boundaries in x and y, and bounded in z by perfect electrical conductors. As the dimension L of the box was fairly large compared with a and R, the fields reflected from the z-boundaries, and those transmitted through the xy-walls of the box into the adjacent cells of the infinite two-dimensional array of Herzenberg dynamos, were not particularly significant. Brandenburg et al. (1998) found that Herzenberg's asymptotic theory gave remarkably accurate values of Rm<sub>c</sub> far outside its apparent range of validity, when the rotors nearly touch one another. One of their main achievements was the discovery of a new family of AC solutions. To be more specific, they considered the case  $\Theta_1 = \Theta_2 = \frac{1}{2}\pi$  in which Eq. (9) requires that  $\frac{1}{2}\pi < \Phi < \pi$ (or  $-\pi < \Phi < -\frac{1}{2}\pi$ ). But they obtained AC solutions when ;  $\Phi < \frac{1}{2}\pi$ . It now appears that the Herzenberg dynamo functions, either as a DC dynamo or as an AC dynamo, for nearly all orientations of  $\boldsymbol{\omega}_1$  and  $\boldsymbol{\omega}_2$ except  $\Theta_1 = \Theta_2 = 0$  and  $|\Phi| = 0, \frac{1}{2}\pi, \pi$ , provided Rm is large enough.

The Herzenberg dynamo provided the inspiration for the first demonstration of homogeneous dynamo action in the laboratory; see *Dynamo, Lowes-Wilkinson.*

# DYNAMO, LOWES-WILKINSON

Bullard and Gellman (1954) made the first attempt at numerical solution of a (very crude) mathematical kinematic model of the geomagnetic self-exciting dynamo (see *Dynamo, Bullard-Gellman*). But because of computing limitation, they had to resort to hand-waving arguments as to convergence of the solution. Also, because of misinterpretation of a paper by Cowling (1934), many people believed that such self-excitation was impossible in what was essentially a homogeneous conductor; in effect such people thought that there was an "anti-dynamo" theorem (see *Cowling's theorem*). Then in 1958 two papers, by Backus and by Herzenberg, each showed algebraically, for quite different systems of motion, that self-excitation was in fact possible. The motions were not at all Earth-like, but these "existence proofs" showed that there could be no such antidynamo theorem.

Herzenberg's approach (see *Dynamo, Herzenberg*) involved the interaction between two rotating solid spherical eddies, embedded in a larger solid sphere, the whole system being of uniform electrical conductivity. To first order the basic interaction was straightforward, being analogous to a two-stage amplifier with positive feedback. However, to prove that successive secondary perturbations converged to a finite result involved a lot of detailed algebra. Also, the paper considered only a steady-state solution, while we knew that the Earth's field reversed.

Because of previous cooperation on a laboratory model of induction in a single "eddy" (Herzenberg and Lowes, 1957), at Newcastle we decided to make a physical laboratory model of the Herzenberg mathematical model, both to confirm the existence of self-excitation and also to investigate its time behavior; Rikitake's (1958) coupleddynamo extension of Bullard's (1955) mathematical modeling of a lumped-constant self-exciting dynamo (see *Dynamo, disk*) had suggested that a Herzenberg dynamo could spontaneously reverse.

So in 1959 we started to design and build a model. For mechanical convenience we used rotating cylinders rather than spheres, and to improve the efficiency we cut Herzenberg's model in half; mercury was used in the narrow gap between the (half) cylinders and the stationary block to give electrical contact. To give self-excitation, a nondimensional parameter called the magnetic Reynolds number

**Figure D18** Schematic diagram of the feedback loop in the laboratory dynamo. The arrows  $\omega_1$  and  $\omega_2$  show the angular velocities, and the circles are the resultant induced magnetic fields.

(see *Geodynamo*) had to be large enough. For our model this number was  $\sigma\mu\omega a^2$ , where  $\sigma$  and  $\mu$  were the electrical conductivity and magnetic permeability of the material,  $\omega$  the angular velocity of the cylinders, and *a* their radius. The size was limited by material availability and the velocity by turbulent power dissipation in the mercury, so we had to use a material with a large value of  $\mu\sigma$ . We chose an alloy called Perminvar, which had a high, but fairly constant, initial permeability, and made the radius *a* 3.5 cm. The cylinders were rotated by electric motors.

Figure D18 shows schematically the intended situation. Cylinder 1 is rotating in the presence of an axial magnetic field (initially applied from outside); this gives radial induced voltage inside the cylinder, leading to current flowing out from the bottom of the cylinder and returning through the side, and hence a "toroidal" magnetic field around the axis. The geometry of the cylinders is chosen so that the induced field of cylinder 1 is along the axis of cylinder 2. Then the same process in cylinder 2 leads to an induced magnetic field which at cylinder 1 is parallel to the original applied field. So there is positive feedback, and if the speeds are large enough, the fed-back field is as large as the original applied field, which is then no longer needed; the system would then be self-exciting.

It turned out that with the original model, we could not go fast enough to reach self-excitation. However we were able to deduce what was going wrong—the spacing between the two cylinders was too small for our approximate calculation to be valid, and the induced fields were more complicated than we expected, giving less feedback. By (effectively) changing the shape of the boundary of the stationary block, we were able to produce the intended simpler induced fields and so achieve self-excitation (Lowes and Wilkinson, 1963). There was now a working self-exciting dynamo on the surface of the Earth, as well as one in its core!

But while the model was self-exciting, it was stable, and did not reverse; this was probably mainly due to the damping coming from the power dissipation in the mercury, which was much larger than the electromagnetic power dissipation. However, with a rather larger steel model, in which the relative geometry of the two cylinders could be varied, we did produce spontaneous reversals (Lowes and Wilkinson, 1967). The reversal waveforms depended on the magnetic properties of the steel and on how the model was powered, so were not directly applicable to the Earth, but the instability which led to the reversals was what would be expected in the Earth. Later investigations by Wilkinson and by D.J. Kerridge are reported by Wilkinson (1984).

## DYNAMO, MODEL-Z

Model-Z, first proposed by S.I. Braginsky in 1975, is a dynamical balance in which the poloidal magnetic field in the Earth's core is aligned predominantly along the z-axis (hence the name). Braginsky conjectured that it is through this alignment that the adjustment to Taylor's condition comes about. This article should therefore be read in conjunction with the one on *Taylor's condition* (q,v.)

#### **Basic equations**

We start with the induction equation

$$\frac{\partial \mathbf{B}}{\partial t} = \nabla^2 \mathbf{B} + \nabla \times (\alpha \mathbf{B}) + \nabla \times (\mathbf{U} \times \mathbf{B}), \qquad (\text{Eq. 1})$$

with the flow U given by

$$\mathbf{U} = \mathbf{U}_{\mathrm{T}} + \mathbf{U}_{\mathrm{M}} + U_{\mathrm{g}}(s)\hat{\mathbf{e}}_{\phi}.$$
 (Eq. 2)

The precise definitions of the thermal wind  $U_T$ , the magnetic wind  $U_M$ , and the geostrophic flow  $U_g$  are given in the article on Taylor's condition. See also *Dynamos, mean-field* for a discussion of the  $\alpha$ -effect in Eq. (1).

We next apply the toroidal-poloidal decomposition

$$\mathbf{B} = \mathbf{B}_{t} + \mathbf{B}_{p} = B\hat{\mathbf{e}}_{\phi} + \nabla \times (A\hat{\mathbf{e}}_{\phi})$$
(Eq. 3)

appropriate for axisymmetric models. The flow may similarly be expressed as  $U = U_t + U_p$ , but the only aspects of this decomposition

that we will actually need are that  $U_T$  and  $U_g$  both contribute to  $U_t$  only. The induction equation then becomes

$$\frac{\partial A}{\partial t} = D^2 A + \alpha B + \hat{\mathbf{e}}_{\phi} \cdot (\mathbf{U}_{p} \times \mathbf{B}_{p}), \qquad (\text{Eq. 4})$$

$$\frac{\partial B}{\partial t} = D^2 B + \hat{\mathbf{e}}_{\phi} \cdot \nabla \times (\mathbf{U}_{\mathsf{t}} \times \mathbf{B}_{\mathsf{p}} + \mathbf{U}_{\mathsf{p}} \times \mathbf{B}_{\mathsf{t}}), \tag{Eq. 5}$$

where  $D^2 = \nabla^2 - 1/s^2$ , and  $(z, s, \phi)$  are standard cylindrical coordinates. Note also that  $\alpha$  is included only in Eq. (4), but not in Eq. (5). Model-Z is thus an  $\alpha\omega$ -dynamo, with the poloidal field  $\nabla \times (A\hat{\mathbf{e}}_{\phi})$  regenerated from *B* by the  $\alpha$ -effect, but the toroidal field  $B\hat{\mathbf{e}}_{\phi}$  regenerated from *A* only by the  $\omega$ -effect, which enters Eq. (5) in the form of some prescribed thermal wind  $\mathbf{U}_{\mathrm{T}}$ .

From Eq. (11) in Taylor's condition, the geostrophic flow becomes

$$U_{\rm g}(s) = -E^{-1/2} \frac{(1-s^2)^{1/4}}{4\pi s} \frac{\rm d}{{\rm d}s} \left[s^2 T\right], \tag{Eq. 6}$$

where the Taylor integral

$$T = \int_{-z_{\rm T}}^{+z_{\rm T}} B \frac{\partial A}{\partial z} \,\mathrm{d}z,\tag{Eq. 7}$$

and  $z_{\rm T} = (1 - s^2)^{1/2}$ . Note also that by integrating over this particular range  $\pm z_{\rm T}$  we have implicitly neglected the inner core. See *inner core tangent cylinder* for a discussion of how the Taylor integral becomes considerably more complicated if one includes an inner core.

### **Braginsky's analysis**

We see then that unless  $T \leq O(E^{1/2})$ , the geostrophic flow will increase without bound as  $E \to 0$ . As discussed in *Taylor's condition*, there are a number of ways of achieving such a scaling. First, we could simply have  $\mathbf{B} \leq O(E^{1/4})$ , the so-called Ekman states. Next, we could have  $\mathbf{B} = O(1)$ , but with sufficient internal cancellation in the integral. This is the so-called Taylor state. Finally, we could have  $\mathbf{B} = O(1)$ , but with  $\partial A/\partial z \to 0$ . This is precisely Braginsky's model-Z, as  $\partial A/\partial z \to 0$  implies that the poloidal field lines become aligned with the *z*-axis. (We note though that  $\partial A/\partial z = 0$  does not satisfy the appropriate boundary conditions. There must therefore be a boundary layer in which this alignment breaks down.)

In fact, the difference between the Taylor state and model-Z is more profound than whether  $T \rightarrow 0$  comes about by having regions of positive and negative  $B\partial A/\partial z$  cancel in the integral, or by having  $\partial A/\partial z$ essentially zero everywhere. Braginsky argues that T tends to zero *more slowly* than  $O(E^{1/2})$ , so that  $U_g \rightarrow \infty$ . The fundamental distinction between a Taylor state and model-Z is therefore whether E enters in an essential way (model-Z, where  $\mathbf{B} = O(1)$  but  $U_g \rightarrow \infty$ ), or only as a perturbation (Taylor state, where  $\mathbf{B}$  and  $U_g$  are both independent of E at leading order). In other words, are viscous effects important or not?

Now, why might *T* tend to zero more slowly in model-*Z* than in a Taylor state? In a Taylor state, any *T* in excess of  $O(E^{1/2})$  immediately induces a series of *torsional oscillations* (*q.v.*), which eventually decay away again, taking the excess with them. However, as Braginsky points out, the efficiency with which torsional oscillations drive *T* toward zero depends on the extent to which the different cylindrical shells that constitute a torsional oscillation are coupled to one another. In his model, the *z*-aligned field lines do not thread adjacent cylindrical shells, so the coupling is very weak, so weak that *T* tends toward zero, but never quite reaches the  $O(E^{1/2})$  that it does if the coupling is strong. That is, having  $\partial A/\partial z \approx 0$  is the mechanism whereby *T* tends to zero, but is also the mechanism that prevents it from tending to zero as rapidly as  $O(E^{1/2})$ .

We can gain further useful insight into the rate at which *T* tends to zero by considering the energetics associated with the geostrophic flow. We begin by noting that, as part of  $U_t$ ,  $U_g$  affects only *B*, not *A*. Specifically, its contribution to Eq. (5) ends up as

$$\frac{\partial B}{\partial t} = -s \frac{\mathrm{d}}{\mathrm{d}s} \left( \frac{U_{\mathrm{g}}}{s} \right) \frac{\partial A}{\partial z}.$$
 (Eq. 8)

Now insert Eq. (6) for  $U_g$ , multiply by *B*, and integrate over the entire volume. The final energy balance one eventually obtains is

$$\frac{1}{2}\frac{\partial}{\partial t}\int B^2 \mathrm{d}V = -\pi E^{-1/2} \int_0^1 \frac{(1-s^2)^{1/4}}{s^3} \left[\frac{\mathrm{d}}{\mathrm{d}s}(s^2T)\right]^2 \mathrm{d}s,$$
(Eq. 9)

indicating that the geostrophic flow will necessarily act to reduce the energy, unless *T* is identically equal to zero. Beyond that, we can easily see from Eq. (9) that as long as *T* tends to zero at least as rapidly as  $O(E^{1/4})$ , the energy drain associated with the geostrophic flow will still be bounded—as it must be if the energy input via  $\alpha$  and  $\mathbf{U}_{\rm T}$  is independent of *E*—even though  $U_{\rm g}$  itself increases without bound as  $E \rightarrow 0$ .

In fact, in Braginsky's original analysis he has *T* tending to zero as  $E^{1/6}$ , even more slowly than  $E^{1/4}$ . This is energetically sustainable, as he also takes  $U_T$  to scale as  $E^{-1/6}$ , so an  $E^{-1/6}$  energy input via  $U_T$  then balances an  $E^{-1/6}$  energy drain via  $U_g$ . Taking one of the kinematically prescribed forcing terms to depend on *E*, and at leading order, is not really desirable though, as it eliminates any possibility of obtaining a solution that does not also depend on *E* at leading order. That is, by doing so one has eliminated *a priori* the possibility of obtaining a Taylor state. However, as the above analysis demonstrates, this is not an essential feature of model-*Z*; one can obtain solutions in which  $U_g$  scales as some negative power of *E* even if  $U_T$  (and  $\alpha$ ) are taken to be independent of *E*, so that the Taylor state is also accessible.

Finally then, which solution corresponds to the real Earth, Taylor state or model-Z? One weakness of model-Z is that it is a rather special case. That is, given that  $\partial A/\partial z \approx 0$ , one can understand how the other features follow, but why should the field adopt such a special configuration in the first place? And perhaps not surprisingly then, model-Z only arises for certain special choices of  $\alpha$ . Most fully three-dimensional numerical models, in which  $\alpha$  is not prescribed at all, also show no particular tendency for the poloidal field lines to align with the *z*-axis (although the Ekman numbers in these models are so large that one is not unambiguously tending toward a Taylor state either). Another drawback of model-Z is that there is no observational evidence (see *Core motions*) for the very large geostrophic flows that it predicts. Walker and Hollerbach (1999) suggest though that Io may have a model-Z dynamo, since there the background Jovian flux is aligned in *z*, which may prompt the internal field to adopt the same configuration.

## DYNAMO, PONOMARENKO

#### Definition of the model

Human-made dynamos are complex, multiconnected, asymmetric devices, but those operating in Nature have to function in geometrically-simple (usually almost spherical) bodies of electrically conducting fluid, such as Earth's core. During the early development of dynamo theory, it seemed possible that no motion within such a simple "homogeneous" system could maintain a magnetic field, a feeling reenforced by some antidynamo theorems (see Antidynamo and bounding theorems and Cowling's theorem). Whether homogeneous dynamos exist or not is an electrodynamic question, i.e., one that can be addressed without asking how the velocity V of the conductor is maintained and how a magnetic field **B** would affect it. It is necessary only to find a V that can sustain a nonzero B, and these are then called "kinematic dynamos", to distinguish them from "MHD dynamos" which satisfy the full equations of magnetohydrodynamics. (See Dynamos, kinematic and Magnetohydrodynamics.) The first kinematic dynamo models were created in 1958 (see Dynamo, Backus and Dynamo, Herzenberg). It was clear, especially from the Herzenberg model, that nonmirror-symmetric motions are potentially efficient generators of magnetic field; roughly speaking, the lack of mirror-symmetry provides a homogeneous system with a means of mimicking the asymmetry of human-made dynamos. This added credence to the earlier speculations of Parker (1955) that helical motions could regenerate magnetic field. Ponomarenko (1973) provided the simplest realization of this idea. See also Geodynamo, symmetry properties.

As dynamo theory evolved, it became increasingly focused on the MHD dynamo in which *V* and (nonzero) **B** are solutions of the magnetohydrodynamic equations, maintained by appropriate forces such as buoyancy (in the case of convective dynamos). Nevertheless, interest in the Ponomarenko model has been sustained. There are two reasons for this. First, the model provides the simplest illustration of how motions possessing nonzero helicity,  $V \cdot \nabla \times V$ , can sustain a magnetic field. Second, the model has been the key ingredient in laboratory dynamo experiments (see *Dynamos, experimental*).

Although the Ponomarenko model is one of the simplest homogeneous dynamos, it is not the simplest; a model due to Lortz (1968) can, without recourse to numerical or asymptotic methods, be shown to regenerate magnetic field. Although this model has been developed (see Gilbert, 2003, for references), it has not yet been as influential as the Ponomarenko model, possibly because it does not expose the role of helicity as clearly.

In Ponomarenko's model, the electrical conductor fills all space but motion is confined to the interior of a solid cylinder C, the exterior  $\hat{C}$ of which is a stationary conductor of the same magnetic diffusivity,  $\eta$ , the electrical contact across the interface S being perfect; see Figure D19. The velocity V of C is a "solid-body" motion, i.e., a motion that the cylinder can execute even if solid; in this respect the model resembles the Herzenberg dynamo in which the moving parts are spherical rotors. The Ponomarenko motion is a combination of a uniform velocity U along the axis Oz of the cylinder and a rotation

**Figure D19** The Ponomarenko dynamo. The cylinder C, radius *a*, moves as a solid body in a helical motion, a combination of a uniform velocity  $U = V_z$  along the axis Oz of C and a rotation about that axis with angular speed  $\Omega$ . The  $\infty$  sign indicates that the conductor with which C is in electrical contact fills the rest of space.

about that axis with uniform angular velocity  $\Omega$  so that, in cylindrical coordinates  $(s, \phi, z)$ , its components are

$$\mathbf{V} = \begin{cases} (0, \Omega s, U), & \text{if } s < a \\ 0, & \text{if } s > a \end{cases}$$
(Eq. 1)

where *a* is the radius of the cylinder. The motion in C is helical, the conductor at distance *s* from the axis describing a helix of pitch  $\Omega s/U$ . The pitch  $p = \Omega a/U$  on *S* serves to single out one model from the complete one-parameter family,  $-\infty , of Ponomarenko dynamos. For <math>p \neq 0$ , the motion Eq. (1) is nonmirror-symmetric, the right-handed screw motion of a model with p > 0 being mirrored by the left-handed model of the opposite *p*.

#### The theory of Ponomarenko's model; generalizations

The kinematic dynamo problem consists, for a specified motion such as Eq. (1), in solving the magnetic induction equation (see *Magnetohy-drodynamics*),

$$\frac{\partial \mathbf{B}}{\partial t} = \nabla \times (\mathbf{V} \times \mathbf{B}) + \eta \nabla^2 \mathbf{B}, \tag{Eq. 2}$$

in the conductor, which in the Ponomarenko model also includes  $\hat{C}$  (with  $\hat{V} \equiv 0$ ). Also,  $\nabla \cdot \mathbf{B} = 0$  everywhere. Across the discontinuity, S, the three components of the magnetic field and the two tangential components of the electric field,  $\mathbf{E} = -\mathbf{V} \times \mathbf{B} + \eta \nabla \times \mathbf{B}$ , must be continuous, but these conditions are not independent; if four of the five conditions are satisfied, so is the fifth.

A dynamo can legitimately be called a dynamo if two demands are met. The first of these is permanence: if a "seed field" is present initially, then **B** must persist for all time. The second is the "dynamo condition": there can be no external sources of magnetic field; the only electric currents flowing are those that are created by the motion itself. For the present model, this requires that  $\hat{\mathbf{B}} \to 0$  as  $s \to \infty$ .

The kinematic problem just defined governs  $\mathbf{B}$  through linear, homogeneous equations. Therefore,  $\mathbf{B}$  will either grow without limit

(the dynamo succeeds!), or tend to zero as  $t \to \infty$  (the dynamo fails), or become constant in amplitude (dynamo action is marginal). Which of these happens depends on whether the creation of field by the  $\nabla \times (\mathbf{V} \times \mathbf{B})$  term dominates the right-hand side of Eq. (2), or whether it is insufficient to compensate for the ohmic loss due to the  $\eta \nabla^2 \mathbf{B}$  term, or whether one term exactly offsets the other. The relative importance of the terms is quantified by a magnetic Reynolds number, such as

$$R_m = aU_{\max}/\eta$$
, where  $U_{\max} = \sqrt{\left[U^2 + (\Omega a)^2\right]}$ , (Eq. 3)

which is based on the maximum velocity,  $U_{\text{max}}$ , which occurs on the inner side of S. It is intuitively clear that the motion Eq. (1) cannot function as a dynamo unless  $R_m$  is sufficiently large, but (as the anti-dynamo theorems show) a large  $R_m$  does not guarantee dynamo action.

The kinematic dynamo defines a *linear stability problem*, of a type familiar in fluid mechanics. The "control parameter" is  $R_m$ , and the key questions are

*Question 1:* What is the critical value,  $R_{mc}$ , of  $R_m$ , that separates "instability" (i.e., dynamo action) from "linear stability" (no dynamo action)?

*Question 2:* What is the maximum growth rate of the magnetic field when  $R_m > R_{mc}$ 

A third question becomes pertinent when designing an experiment: *Question 3:* Which model of the Ponomarenko family most easily generates magnetic field, i.e., for which value of |p| is  $R_{mc}(p)$  smallest, and what is the corresponding value of  $R_{mc}$ ?

As in linear stability theory, these questions should be answered by solving the general initial value problem, i.e., by determining (perhaps by Laplace transform methods) how a general seed field, specified at time t = 0, evolves in time. Because the conductor fills all space, this is a complicated undertaking, but Ponomarenko (1973) concluded that the answers to the three questions can be found by analyzing "normal modes" of the form

$$\mathbf{B} = \mathbf{B}_0(s) \exp[i(m\phi + kz) + \lambda t].$$
 (Eq. 4)

Possible values of the complex growth rate,  $\lambda = \sigma + i\omega$ , are obtained, for given constant values of the wavenumbers *k* and *m* (*m* being an integer), by solving numerically a certain transcendental "dispersion relationship", obtained from Eq. (2) by Ponomarenko (1973). The mode Eq. (4) travels in the direction of  $\nabla(m\phi + kz)$  along the constant *s*—surfaces as a "wave" that grows, decays, or maintains a constant amplitude, depending on whether  $\sigma$  is positive, negative, or zero. In other words, the phase of the wave travels along helices of pitch ks/m.

For given *m*, *k*, and *p*, Ponomarenko's dispersion relation gives infinitely many  $R_m$  for which  $\sigma = 0$ . The smallest of these is shown in Figure D20 as a function of *k* for several values of |m| in the case p = 1.2. Each curve possesses a single minimum,  $R_m = R_{m\min}(m, p)$ , at one particular value,  $k_{\min}(m, p)$ , of *k*. These give (for the *m* and *p* concerned) the wavenumber *k* and the corresponding  $R_m$  for which the dynamo first functions when  $R_m$  is gradually increased from zero. Figure D21 shows  $R_{m\min}(m, p)$  as a function of *p* for m = 1 - 9. When  $R_{m,\min}$  is minimized over *m*, the *critical state*,  $R_m = R_{mc}(p)$ , and the corresponding wavenumbers  $m = m_c$  and  $k = k_c$  are obtained. Figure D21 shows that  $m_c = 1$  when |p| < 4, and probably  $m_c = 1$  for all *p*.

The general seed field contains a linear combination of every normal mode Eq. (4) and, if  $R_m < R_{mc}(p)$ , then  $\sigma < 0$  for all of them, so that they all disappear as  $t \to \infty$ . In the critical state  $R_m = R_{mc}(p)$ however, every  $\sigma$  is negative except for a single mode,  $(m, k) = (m_c, k_c)$ , for which  $\sigma = 0$ . This mode survives for all time at constant amplitude, and is oscillatory (since  $\omega_c \neq 0$ ). Finding this mode answers Question 1. If  $R_m > R_{mc}$ , then  $\sigma > 0$  in a range of k lying within the m = 1 "lobe" in Figure D20 and, as  $R_m$  is increased, modes of larger m become successively unstable too.

**Figure D20** The minimum magnetic Reynolds number  $R_m$  as a function of the axial wavenumber k for different values of the angular wavenumber m. For the case shown, p = 1.2. The minimum  $R_m$  on each constant-m curve is denoted by  $R_m \min(m,p)$ . (After Gailitis and Freiberg, 1976.)

**Figure D21** The minimum,  $R_{m \min}(m,p)$ , of the constant-*m* curves shown in Figure D20 as a function of *p* for m = 1 - 9. The minimum of  $R_{m \min}(m,p)$  over *m* gives the critical magnetic Reynolds number,  $R_{mc}(p)$ , for the model of the Ponomarenko family having that value of *p*. The minimum of  $R_{mc}$  over *p* defines the most easily excited member of the family (see Eqs. (5) and (6)). (After Gailitis and Freiberg, 1976.)

Having obtained  $R_{mc}(p)$ , Question 3 can be answered. As Figure D21 indicates,  $R_{mc}(p)$  has a single minimum in p. Numerical work shows that it is

$$R_{mc} = 17.7221176...,$$
 for  $p = \pm 1.31406737...$  (Eq. 5)

The corresponding wavenumbers and frequency are

$$m_{\rm c} = 1, \quad k_{\rm c}a = \pm 0.387532..., \quad a^2\omega_{\rm c}/\eta = \pm 0.410300....$$
(Eq. 6)

Question 2 has been thoroughly answered but only asymptotically, in the limit of  $R_m \to \infty$  (Ponomarenko, 1973; Roberts, 1987; Gilbert, 1988). Nevertheless, the results give insight into how the dynamo functions. The most unstable wave (corresponding to the largest  $\sigma$ for given *p*) is of small wavelength:  $m \gg 1$ ,  $ka \gg 1$ . The velocity and field helices are almost orthogonal so that  $m\omega + kU \approx 0$ . This means that the phase,  $m\phi + kz$ , of the wave is approximately constant on the helical "streamlines",  $\phi = \Omega sz/aU$ , of *V*. Compared with its value on *S*, the magnetic field becomes exponentially small within a distance of order 1/k from *S*. This highlights the fact that **B** is created by electric currents generated by the potential differences produced by the discontinuity in *V* at *S*.

The generation of **B** can be thought of as a two-step process: (i) the creation of the tangential components,  $B_{\phi}$  and  $B_z$ , from the radial component  $B_s$ , and (ii) the production of  $B_s$  from  $\mathbf{B}_{tang} = (0, B_{\phi}, B_z)$ . Because  $R_m \gg 1$ , Alfvén's theorem holds approximately (see *Alfvén's theorem and the frozen flux approximation*). The theorem helps in picturing step (i), the action of the differential shear across S. The shear stretches out the radial field  $B_s$  crossing S, so creating on and near S a strong field ( $\mathbf{B}_{tang}$ ) approximately in the direction of the helical motion of C. Since  $R_m$  is not infinite, Alfvén's theorem is not strictly enforced and this is significant for step (ii). The field lines of  $\mathbf{B}_{tang}$  are curved and tend to shorten as they diffuse relative to the conductor. As they shorten, they produce  $B_s$  so completing the regenerative process.

As  $R_m \to \infty$ , the maximum of  $\sigma$  tends to a positive value proportional to  $\Omega$  and, because it is independent of  $R_m$ , it is what is known as a *fast dynamo* (see Gilbert, 1988; Childress and Gilbert, 1995 and *Dynamos, fast*). Although a fast dynamo functions only because  $\eta$  is nonzero, the growth rate of magnetic field is, paradoxically, independent of  $\eta$ . The fact that the Ponomarenko dynamo is fast can be traced to the discontinuity in *V* at *S*. A real fluid is a continuum in which such "tearing motions" are impossible. When the discontinuity at *S* is replaced by a thin layer in which *V* varies rapidly but continuously with *s*, the dynamo becomes "slow";  $\sigma$  is proportional to  $R_m^{-1/3}\Omega$  and therefore tends to zero as  $R_m \to \infty$  (see Gilbert, 1988).

#### Generalizations

The Ponomarenko model has been generalized in several ways. Gailitis *et al.* (1989) studied several slow dynamos in which V in C is a continuous function of *s* that vanishes on *S*. The special case when V is spiral Couette flow was analyzed by Solovyev (1985a,b; 1987). Asymptotic properties of such "screw dynamos" were investigated by Ruzmaikin *et al.* (1988).

Gailitis and Freiberg (1980) generalized the Ponomarenko model by considering models in which C is surrounded by one or more cylindrical shells in which V is nonzero, but different from V in C. One of these provides a theoretical idealization of a successful laboratory experiment based on Ponomarenko's concept. The spatial extent of the electrical conductor in an experiment is necessarily limited in both s- and z-directions. Moreover, the flow along C must return to pumps before being reinjected into C. The efficiency of the dynamo can be improved (i.e.,  $R_{mc}$  can be reduced) by making the conducting fluid return in a sheath surrounding C. In modeling this, Eq. (1) is replaced by

$$\mathbf{V} = \begin{cases} (0, \Omega s, z), & \text{for } s < a; \\ (0, 0, -W), & \text{for } s > a, \end{cases}$$
(Eq. 7)

the region s > A being an electrical insulator. By taking  $W = a^2 U/(A^2 - a^2)$ , the return flow is equal and opposite to the flow

along *C*. Model Eq. (7) should also be limited in *z*, but mathematical difficulties arise if the conductor is confined to (say) |z| < L, with electrical insulators filling not only s > A but also |z| > L. It is hard to solve for the potential field  $\hat{\mathbf{B}}$  outside such a finite cylinder, but Gailitis and Freiberg devised an ingenious way of estimating  $R_m$ ; see also Gailitis (1990). Another way of limiting the spatial extent of the dynamo led to the models of Dudley and James (1989) which confine the helical motion to the interior of a spherical conductor.

Starting in the mid 1970s, the MHD liquid metals group at the Institute of Physics in Riga set themselves the task of building a laboratory dynamo based on Ponomarenko's model and idealized by Eq. (7) (see Gailitis *et al.*, 1987, 1989 and Gailitis 1996). The difficulty of reaching a magnetic Reynolds number of order 20 (see Eq. (5)) was severe and there were setbacks. Their goal was finally achieved by the turn of the century (see Gailitis *et al.*, 2000, 2001 and *Dynamos, experimental*).

# DYNAMO, SOLAR

#### Solar magnetic fields

The strong 1-3 kG magnetic fields of sunspots were discovered by Hale (1908) nearly a hundred years ago. The weaker magnetic fields, appearing all over the surface of the Sun, were discovered, and subsequently mapped and monitored, by Babcock and Babcock (1955) about 50 years ago. The cyclic behavior of the magnetic fields of the Sun, to which the 11-year sunspot cycle is closely tied, indicates a creation and annihilation of magnetic field on an 11-year basis, presumably by the inductive effects of the convective motions within the Sun. For the basic fact is that the Sun is entirely gaseous, and the gas is highly ionized and an excellent conductor of electricity. Even the thin partially ionized layer at the photosphere makes a fairly good conductor, given the 100-km thickness of the layer. Hence there can be no significant electric fields in the frame of reference of the moving gas, from which it follows that the magnetic fields are caught up in the swirling gases and carried bodily with them. The result is, somehow, the complicated cyclic magnetic behavior that we see (see Magnetic field of Sun).

The bodily transport of magnetic field  ${\bf B}$  is described by the magnetohydrodynamic (MHD) induction equation

$$\frac{\partial \mathbf{B}}{\partial t} = \nabla \times (\nu \times \mathbf{B}) \tag{Eq. 1}$$

in terms of the fluid velocity v (see *Alfvéns theorem and the frozen flux approximation*). In fact, the gas is not a perfect conductor but has some small resistivity. Hence, there is diffusion of the magnetic field relative to the fluid, which can be represented in simplest form by the addition of the term  $\eta \nabla^2 \mathbf{B}$  on the right-hand side of Eq. (1) (assuming a uniform resistive diffusion coefficient ( $\eta$ ). As we shall see, the diffusion is as essential for field production as the bodily transport of magnetic field.

The ongoing deformation of the solar magnetic field takes place largely out of sight, beneath the visible surface, so the first task is to look closely at the fields emerging through the surface that we may infer what is happening below. The outstanding magnetic features on the visible surface of the Sun are the large  $(2 \times 10^4 - 2 \times 10^5 \text{ km})$  bipolar magnetic regions, with approximate east-west orientation and field strengths of the general order of  $10^2$  Gauss in both the positive and negative ends of the bipole (Babcock and Babcock, 1955, see *Magnetic field of Sun*). It is inferred that each bipolar region arises from the upward bulge (a so-called  $\Omega$ -loop) in a large bundle of east-west (azimuthal) magnetic field lying somewhere below. A bipolar region may endure for months by continuing emergence of fresh  $\Omega$ -loops at the site (Gaizauskas, *et al.*, 1983), driven to the surface by the intrinsic buoyancy of the magnetic field. A magnetic field **B** provides a pressure **B**<sup>2</sup>/8 $\pi$  without weight, causing buoyancy and a general instability of horizontal fields to form  $\Omega$ -loops (Parker, 1955a).

Now, the first appearance of the bipolar regions is in the vicinity of  $35-40^{\circ}$  latitude. Following first appearance, there are soon many bipolar regions distributed around the Sun, forming a broadband of emerging  $\Omega$ -loops that migrates ( $1.5 \text{ ms}^{-1}$ ) toward the equator over the next 10 years or so. Note then that the bipolar regions have opposite orientation in the northern and southern hemispheres, and their numbers decline as the two bands of opposite orientation approach each other at the equator. The next wave of bipolar regions has opposite orientation to its predecessor and appears at latitudes of  $35-40^{\circ}$  at about the time the old bands are fading out at the equator. Thus, the complete magnetic cycle occupies 22 years.

An observational inventory of the magnetic flux emerging over a six month period in a particularly long lived bipolar magnetic region suggests that the subsurface azimuthal field contains a total magnetic flux of at least  $2 \times 10^{23}$  Maxwells in each hemisphere (Gaizauskas, *et al.*, 1983), assuming that the emerging magnetic fields were not recycled in some way and appeared more than once during that time. The fact is that  $2 \times 10^{23}$  Maxwells is a large quantity of magnetic flux, implying a mean azimuthal magnetic field of  $2 \times 10^{3}$  Gauss even if spread over  $20^{\circ}$  in latitude ( $2 \times 10^{10}$  cm) and  $0.5 \times 10^{10}$  cm in depth.

There are smaller bipolar regions called *ephemeral regions*  $(<2 \times 10^4 \text{ km})$ , appearing at all latitudes and varying but little with the 11-year magnetic cycle. The smaller among them show no tendency to align east and west. The place of the ephemeral regions in the overall magnetic picture is not clear.

In addition to the bipolar regions, there are weaker small-scale fields (with mean intensity of the order of 10 G) in the broad spaces between the bipolar regions. The polar regions, above latitudes of about 55°, exhibit large-scale weak (10 G) fields oriented inward at one pole and outward at the other so that the Sun has a net magnetic dipole moment. This is the principal manifestation of the poloidal field of the Sun. The polar fields reverse at about the time the azimuthal fields reach their peak strength (at latitudes of  $15-20^\circ$ ). Some observational analyses of the field reversal show the reversal to be a rotation of the dipole of one half-cycle around across the equator to the opposite orientation of the next half cycle.

Improved telescopic resolution in recent decades shows that all these fields, as well as the stronger fields of the large bipolar regions, are made up of many intense  $(10^3 \text{ Gauss})$  magnetic fibrils, i.e., isolated bundles of magnetic field, with diameters of the order of  $10^2 \text{ km}$ . The magnetic field in the wide space between the fibrils is too weak to be detected with existing magnetographs. The mean field in the region is determined by the spacing of the fibrils. In the weak field regions the individual fibrils emerge through the solar surface in the central updrafts of the large  $(10^4 \text{ km})$  convective cells—the supergranules—subsequently migrating into the weak downdrafts at the junctions of boundaries. The fibrils interact with each other, producing tiny flares. In the large bipolar regions the emerging  $\Omega$ -loops (that maintain the regions) are composed of fibrils when they first appear at the surface (Zwaan, 1985).

The observed coordinated cycles of the poloidal and azimuthal (toroidal) magnetic fields suggest that they are both the product of the global internal hydrodynamics of the Sun.

#### Theory

There have been attempts to explain how the azimuthal magnetic field might come about through torsional oscillations of the Sun interacting with a primordial dipole magnetic field rooted in the central core. Such a dipole would decay with a characteristic time of the order of  $10^{10}$  years, or by a factor of only about  $e^{0.5} \approx 1.6$  since the Sun was formed. There are two objections to the concept: The necessary torsional oscillations of the Sun would be readily observed, but have not been seen, and the dipole field observed at the visible surface is not rooted in the central core, because it reverses every 11 years, along with the azimuthal field.

This leaves only the concept of direct MHD dynamo creation and annihilation of the magnetic fields by the internal convection and nonuniform rotation of the Sun (see *Elsasser, W.; Dynamos, kinematic; Dynamos, mean field*). That is to say, the dynamo action evidently takes place in and around the convective zone of the Sun, comprising the outer 2/7 ( $2 \times 10^5$  km) of the solar radius ( $R = 7 \times 10^5$  km). The convective velocities increase upward through the convective zone, from essentially zero ( $1 \text{ ms}^{-1}$ ) at the base to  $1 \text{ kms}^{-1}$  at the visible surface (see Spruit, 1974). The characteristic scale, or mixing length, of this turbulent convection is believed to be comparable to the local pressure scale height of  $5 \times 10^4$  km at the bottom (where  $T \cong 2 \times 10^6$  K) and 200 km at the top (where  $T = 6 \times 10^3$  K).

Now recall that the magnetic field of Earth appears to be generated by the combined nonuniform rotation and the cyclonic convection in the spinning liquid metal core, referred to as an  $\alpha\omega$ -dynamo and representing the most efficient theoretical convective dynamo mode (see *Elsasser, W.; Geodynamo*). More complicated fluid motions, or, for instance, cyclonic convection alone, can be shown to provide a selfsustaining magnetic field, but they require higher speeds and greater energy input for the same field production (see Steenbeck and Krause, 1966). So consider the basic  $\alpha\omega$ -dynamo process for the origin of the magnetic fields of the Sun.

The surface of the Sun is observed to rotate nonuniformly, with a 25-day period at the equator and something in excess of 30 days at the poles. Years ago one was inclined, by theoretical considerations on conservation of angular momentum in rising and falling convective columns, to suppose that the rate of rotation depends primarily on distance from the spin axis of the Sun, presumably in the form that is observed at the surface. Fortunately helioseismology (see Helioseismology) has stepped in to provide a detailed map of the internal rotation, which turns out to be quite unlike the conjectured form. To put it simply, the angular velocity in the convective zone varies but little with depth below the surface, so at any given depth the angular velocity has much the same latitudinal profile as the visible surface. The radiative zone ( $0 < r < 5 \times 10^5$  km) enclosed by the convective zone rotates approximately rigidly with a period of about 28 days. It is evident then that there is a strong shear between the base of the nonuniformly rotating convective zone and the contiguous outer surface of the radiative zone, with the convective zone rotating faster than the radiative zone at low latitudes and slower at high latitudes. The thin shear layer between is called the *tachocline*. It should be appreciated that this remarkable internal rotation has not yet been explained by the theoretical hydrodynamics of the convection, which presumably drives the nonuniform rotation.

The dipole magnetic field of the Sun is caught up in the shearing, producing a strong azimuthal magnetic field at the tachocline—presumably the azimuthal magnetic field that spawns the bipolar magnetic regions observed at the surface. It remains then to understand how the dipole (poloidal) field is generated from the azimuthal (toroidal) field. There is no way to accomplish this within the confines of rotational symmetry about the spin axis of the Sun (see *Elsasser, W.*). Cowling's theorem (see *Cowling's theorem*) points out that no magnetic field with rotational symmetry can be sustained by the inductive effects of fluid motions. The same situation arises in the geodynamo, where the poloidal magnetic field must be generated somehow from the azimuthal field. Note then that the cyclonic convection, arising from the Coriolis force on the many individual convective cells, breaks rotational symmetry around the Sun, and, as it turns out, is the most effective mechanism for producing poloidal field.

The essential point is that cyclonic convection pokes up  $\Omega$ -shaped loops in the deep azimuthal magnetic field and rotates those  $\Omega$ -loops into meridional planes. Thus each rotated  $\Omega$ -loop represents a local magnetic circulation in the meridional plane. Merging many loops through diffusion obliterates the individual loops and leaves the net overall magnetic circulation intact. It is that net circulation of magnetic field in meridional planes in the Sun that is the observed poloidal field. Combining the cyclonic convection with the nonuniform rotation provides the  $\alpha\omega$ -dynamo process (Parker, 1955b, 1957, 1979).

The azimuthal vector potential  $\mathbf{A}$  provides a convenient description of the poloidal magnetic field, with each rotated  $\Omega$ -loop contributing a local clump of azimuthal  $\mathbf{A}$ . On average, then,

$$\frac{\partial \mathbf{A}}{\partial t} = \alpha \mathbf{B} \tag{Eq. 2}$$

where **B** is the azimuthal magnetic field and  $\alpha$  represents the mean effective rotational velocity of the  $\Omega$ -loops multiplied by their filling factor. Then, allowing for diffusion, the dynamo equation for the generation of the mean poloidal field becomes

$$\frac{\partial \mathbf{A}}{\partial t} - \eta (\nabla^2 - \frac{1}{\bar{\omega}^2}) \mathbf{A} = \alpha \mathbf{B}$$
 (Eq. 3)

where  $\eta$  is again the uniform resistive diffusion coefficient and  $\bar{\omega}$  represents distance from the spin axis of the Sun (Parker, 1955b, 1970; see *Dynamo, Backus; Dynamos, mean field*). Note that this simple formulation neglects the interaction of the cyclonic convection with the relatively weak poloidal field, which is easily included if desired (see Parker, 1979; Krause and Rädler, 1980; Choudhuri, 1990).

The production of azimuthal field **B** by shearing the poloidal field  $\nabla \times A$  follows from the induction equation

$$\frac{\partial \mathbf{B}}{\partial t} - \eta (\nabla^2 - \frac{1}{\bar{\omega}^2}) \mathbf{B} = \{ \nabla \times [\nu \times (\nabla \times \mathbf{A})] \}_{\phi}$$
(Eq. 4)

These two equations constitute the dynamo equations to lowest order. They have been derived from first principles in the idealization of intermittent cyclonic motions (Parker, 1955b, 1970, 1979; Backus, 1958) and in the quasilinear approximation (Steenbeck, Krause, and Rädler, 1966). The nature of the dynamo equations and their solutions has been investigated by many authors over the last 50 years (see Moffatt, 1978; Parker, 1979; Krause and Rädler, 1980, and references therein). As already noted, it has not yet been possible to reproduce the fluid motions in the Sun from the hydrodynamic equations, so the dynamo equations are explored by specifying the fluid velocity v-the kinematic dynamo problem (see Dynamos, kinematic). Perhaps one day the fluid dynamics can be brought into line and the  $\alpha\omega$ -dynamo equations solved simultaneously with the fluid equations, as has been accomplished for Earth (Glatzmaier and Roberts, 1996). Note, then, that the quasistationary magnetic field of Earth and the oscillatory field of the Sun arise from the same basic dynamo process, the difference in the fields caused by the different shapes of the dynamo regions and the different distribution of the nonuniform rotation and cyclonic convection within.

For the present brief article, the goal is to display the basic wave properties of the dynamo equations, for which it is sufficient to consider their solution in rectangular coordinates. Consider the simple case that the large-scale fluid motion  $v_y(z)$  is in the *y*-direction and a function only of *z*, in the form of the uniform shear  $G = dv_y/dz$ . The *y*-direction corresponds to the azimuthal direction, and  $\partial/\partial y = 0$ , representing rotational symmetry of the mean fields. It follows that the magnetic field **B** in that direction is given by

$$\frac{\partial \mathbf{B}}{\partial t} - \eta \left( \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial z^2} \right) \mathbf{B} = G \frac{\partial \mathbf{A}}{\partial x}, \qquad (\text{Eq. 5})$$

where the poloidal field components are

$$\mathbf{B}_{x} = -\frac{\partial \mathbf{A}}{\partial z}, \mathbf{B}_{z} = +\frac{\partial \mathbf{A}}{\partial x}$$
(Eq. 6)

in terms of the vector potential A in the y-direction. The equation for A is

$$\frac{\partial \mathbf{A}}{\partial t} - \eta \left( \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial z^2} \right) \mathbf{A} = \alpha \mathbf{B}.$$
 (Eq. 7)

With uniform  $\alpha$ ,  $\eta$ , and G, the plane wave solution

$$\mathbf{A} = C \, \exp(t/\tau + ik_x x + ik_z z), \tag{Eq. 8}$$

$$\mathbf{B} = D \, \exp(t/\tau + ik_x x + ik_z z),\tag{Eq. 9}$$

is appropriate, where C and D are constants (see Gubbins and Gibbons, 2002, for 3-D waves in a sphere). Then substituting into the dynamo Eqs. (5) and (7), the result is

$$\frac{D}{C} = \frac{1/\tau + \eta \left(k_x^2 + k_z^2\right)}{\alpha} = \frac{ik_x G}{1/\tau + \eta \left(k_x^2 + k_z^2\right)},$$
 (Eq. 10)

so that

$$\frac{1}{\tau} = -\eta \left( k_x^2 + k_z^2 \right) \pm (\alpha G k_x / 2)^{1/2} (1+i).$$
 (Eq. 11)

It is sufficient for present purposes of illustration to consider the idealized example of an infinitely long train of dynamo waves (real  $k_x$  and  $k_z$ ) with constant amplitude (Re  $1/\tau = 0$ , Im  $1/\tau = \omega$ ). Supposing  $\alpha G$  to be nonnegative, use the upper sign in Eq. (11). The amplitude remains constant, then, when the rate of generation  $(\alpha G k_x/2)^{1/2}$  is equal to the rate of dissipation  $\eta (k_x^2 + k_z^2)$ . The angular frequency of the wave is related to  $\alpha$  and G by

$$\omega = (\alpha G k_x/2)^{1/2} = \eta (k_x^2 + k_z^2), \qquad (Eq. 12)$$

and

$$\frac{1}{\tau} + \eta \left( k_x^2 + k_z^2 \right) = 2^{1/2} \omega \exp(i\pi/4).$$
 (Eq. 13)

It follows that

$$\alpha = 2\omega^2/Gk_x,\tag{Eq. 14}$$

and

$$\frac{D}{C} = \frac{k_x G}{2^{1/2} \omega} \exp(i\pi/4).$$
 (Eq. 15)

The ratio Q of the amplitude of the "azimuthal" field **B** to the vertical "poloidal" *z*-component  $B_z = ik_x \mathbf{A}$  is

$$Q = \frac{D}{ik_x C}$$
  
=  $\frac{G}{2^{1/2}\omega} \exp(-i\pi/4).$  (Eq. 16)

## Application to the Sun

Fitting this simple dynamo wave into the Sun, to represent the migratory bands of azimuthal magnetic field, requires that the vertical half wavelength  $\pi/k_z$  be set equal to something of the order of the characteristic thickness  $10^{10}$  cm of the convective zone, so that  $k_z \approx 3 \times 10^{-10}$  cm, with  $k_x \approx 10^{-10}$  cm to represent the  $3 \times 10^{10}$  cm horizontal half wavelength from the equator up to latitude  $35-40^{\circ}$ . The 22-year period of the solar magnetic cycle implies that  $\omega \approx 1 \times 10^{-8} \text{ s}^{-1}$ . It follows from Eq. (12) that the effective diffusion coefficient  $\eta$  must be approximately equal to  $1 \times 10^{11} \text{ cm}^2 \text{ s}^{-1}$ . Then if the shear *G* arises from a horizontal velocity difference *u* over a vertical height  $\pi/k_z$ , it follows that  $G = k_z u/\pi$ . As a rough estimate, put *u* equal to a twentieth of the 2.0 km s<sup>-1</sup> equatorial rotation velocity of the Sun, or  $u = 1 \times 10^4 \text{ cms}^{-1}$ , with the result that  $G \approx 1 \times 10^6 \text{ s}^{-1}$ . It follows from Eq. (14) that  $\alpha \approx 2 \text{ cm s}^{-1}$  (more precise models give  $\alpha \approx 4-10 \text{ cm s}^{-1}$ ).

Consider then the effective values of  $\eta$  and  $\alpha$  in the Sun. The diffusion coefficient  $\eta$  is conventionally attributed to turbulent diffusion in the vigorous convection, given by something of the order of 0.1 wh, where w is the characteristic convective velocity and h the associated mixing length, assumed to be comparable to the local pressure scale height. Thus a turbulent convective velocity of 1 km s<sup>-1</sup> and a scale height of  $10^2$  km at the visible surface yields  $\eta$  equal to the required  $10^{11}$  cm<sup>2</sup>s<sup>-1</sup>. Deeper in the convective zone the convective velocities are smaller (see Spruit, 1974), while the larger-scale height provides a comparable value for  $\eta$ . Turning to the convective rotational velocity a, note that in some ideal way the Coriolis force might produce a rotational velocity as large as  $h\Omega \sin \lambda$ , where  $\Omega$  is the angular velocity of the Sun, equal to  $3 \times 10^{-6} \text{ s}^{-1}$ , and  $\lambda$  is the latitude. With  $h = 3 \times 10^9$  cm (comparable to the pressure scale height in the lower convective zone) the result is the ideal rotational velocity  $\alpha = 10^4 \sin \lambda \text{ cms}^{-1}$ , far in excess of the required 2 cms<sup>-1</sup> estimate. In fact, with the positive and negative contributions to  $\alpha$  from the converging and diverging portions of a convective column, the net effect is certainly much smaller than the simple ideal  $h\Omega \sin \lambda$ .

Now one of the several remarkable features of the magnetic fields in the Sun is the large strength of the azimuthal magnetic field relative to the poloidal field—evidently more than a hundred times stronger. The magnitude of the ratio Q of the amplitudes follows from Eq. (16) as 70, which is on the small side. Several times larger would better fit the present interpretation of the observations of emerging magnetic flux. The total azimuthal flux  $\Phi$  is given by the integral of **B** over the rectangle with sides  $\pi/k_x$  and  $\pi/k_z$ , yielding

$$\Phi = \frac{\pi^2}{k_x k_z} \left(\frac{2}{\pi}\right)^2 \mathcal{Q} k_x C \tag{Eq. 17}$$

Putting the poloidal field amplitude  $k_x C$  equal to 10 G yields the result  $\Phi \approx 0.8 \times 10^{23}$  Maxwells. This is rather less than the 2  $\times 10^{23}$  Maxwells inferred from observations of magnetic flux emerging in a large magnetic bipolar region. Nonetheless, it is in the right range of magnitude, and we cannot expect better from the crude plane wave dynamo model.

## Conditions in the Sun

A proper theoretical treatment of the solar  $\alpha\omega$ -dynamo requires solving the dynamo equations in spherical geometry with appropriate distributions of *G*,  $\alpha$ , and  $\eta$  over the region, and then applying the relevant boundary conditions (see Gubbins and Gibbons, 2002). The wave numbers are complex in the general case, with the dynamo wave amplitude growing as the waves progress toward lower latitudes, while Re  $1/\tau = 0$ . For instance, in the special case of the geodynamo, with more or less static field strength,  $1/\tau = 0$ , the result is simply

$$k_x = \left(\frac{\alpha G}{\eta^2}\right)^{1/3} \exp(i\pi/6)$$

in the simple case that  $k_z = 0$ .

Consider then how G and  $\alpha$  are distributed in the Sun. The situation is relatively complicated, with the strongest shear G confined mostly to a thin tachocline at the bottom of the convective zone and reversing sign across middle latitudes. The estimation of the magnitude and sign of  $\alpha$  as a function of depth and latitude is an obscure process. As already noted, one would expect to find the Coriolis force enhancing the rate of rotation in the region of converging flow at the base of a rising convective column or cell, and retarding the rotation in the expanding rising column above. The effective mean  $\alpha$  is the algebraic sum of these two opposing effects. The value of  $\alpha$  is certainly a function of height, and only a small net residual  $\alpha$  is expected from the large magnitude already estimated from dimensional considerations (see general review by Ossendrijver, 2003 and references therein).

Perhaps the most puzzling parameter is the turbulent diffusion coefficient  $\eta$ , for which mixing length theory provides approximately the theoretically desired value, of the order of  $10^{11}$  cm<sup>2</sup>s<sup>-1</sup>. The essential point is that the magnetic field must diffuse over distances comparable to the dimensions of the convective zone in the characteristic five or ten years of the magnetic cycle. Now, the mixing length representation,  $\eta = 0.1$  wh, is based on analogy with the turbulent diffusion of a scalar field, e.g., smoke, where it works very well. One might expect that the mixing length representation would apply to the turbulent diffusion of a vector field in the limit of weak field, but there is no proper theory for this. The big problem is that the azimuthal magnetic field in the Sun is estimated to be  $2 \times 10^3$  Gauss or more, and that is, in fact, a rather strong field. It is comparable to the equipartition field, for which the tension  $\mathbf{B}^2/4\pi$  in the magnetic field is equal to the Reynolds stress  $\rho v^2$  in the convection, and it must be appreciated that the magnetic stresses rise rapidly as the convection deforms the magnetic field. So it is not clear how the convection can deform and mix the magnetic field to provide the essential turbulent diffusion. It can only be said that the observed behavior of the magnetic fields in the Sun suggests that there is a way, and that dimensional analysis-which is the essential feature of the application of mixing length theory-somehow leads us to the truth, however much physics we do not understand at the present time.

The puzzles do not stop there, however. For instance, the meridional circulation in the convective zone, poleward and of the order of 20 m  $s^{-1}$  at the visible surface, must play a role in the migration of the bands of magnetic field. It is not known how fast or where the equatorward return flow might be deep in the convective zone. The higher gas density suggests that the speed is substantially less than the speed of the poleward flow at the surface. As already noted, the bands of azimuthal magnetic field migrate toward the equator at about 1.5 ms<sup>-1</sup> deep in the convective zone. The mystery goes back to the fact that the overall hydrodynamics of the convective zone is not yet in hand. Nor is it obvious what improvements in the hydrodynamic theory and modeling are needed. So the investigations have turned to exploring the various plausible theoretical possibilities. Numerical models of the solar dynamo with meridional circulation and overshoot of the convection into the radiative zone below have been constructed to investigate the possible role of meridional circulation above and below the tachocline in the dynamo process (see Gubbins, et al., 2000). Nandy and Choudhuri (2002) explore the consequences of substantial latitudinal transport of azimuthal magnetic field in an equatorward flow below the tachocline.

A few words should be said about boundary conditions for the solar dynamo, essential for constructing quantitative theoretical models. The crucial questions concern the boundary conditions at the under side of the tachocline and at the visible surface. In the simplest picture the bottom surface of the dynamo is rigid and impenetrable. In fact there is overshoot of the convection into the radiative zone, together with the meridional circulation just mentioned. Then it has been suggested that the regions of *G* and  $\alpha$  may not over lap, and communicate only through diffusion  $\eta$  (Parker, 1993; Schmitt, 1993; Tobias, 1996). The idea would be that the cyclonic convection  $\alpha$  is important only above the base of the convective zone, while the principal shear *G* in the tachocline may lie entirely below that level. There is also the possibility that strong azimuthal magnetic field is stored in the convectively stable region beneath the convective zone (Moreno-Insertis, Schüssler, and Ferriz-Mas, 1992).

Boundary conditions at the upper surface of the dynamo, usually identified with the visible surface of the Sun, are even more complicated. It is sometimes assumed in theoretical models that the poloidal field of the dynamo fits smoothly to a vacuum potential field above the surface, with no restriction on the outward diffusion of azimuthal flux at the free surface. However, azimuthal magnetic flux can be lost through the visible surface only if there is some means for unloading the plasma from the magnetic field. Upward bulging  $\Omega$ -loops do not represent a loss of azimuthal flux by themselves. Only if there is magnetic reconnection between adjacent vertical legs of neighboring  $\Omega$ -loops around the Sun is there a net loss of flux. In that case the upper portions of the extended  $\Omega$ -loops are first unloaded when the plasma slides down the vertical legs of the  $\Omega$ -loops and then cut free of the Sun by the reconnection between neighboring  $\Omega$ -loops (Parker, 1984). It is not evident from observations that there is much reconnection occurring. In the absence of such universal reconnection the upper boundary is closed and the magnetic loss through the boundary is zero, enhancing the efficiency of the dynamo (Choudhuri, 1984). Finally, it should be noted that the escape through reconnection is not a linear process, so the poloidal field cannot be treated independently of the azimuthal field.

The effects and the causes of the fibril structure of the fields have been speculated on at length (see Schüssler, 1993; Choudhuri, 2003 and references therein). The intense fibril state of the magnetic field at the surface of the Sun, consisting of 100 km diameter magnetic filaments of  $1-2 \times 10^3$  G, suggests that the solar dynamo may actually be working with magnetic fibrils rather than the mean field continua for which the dynamo equations are presently formulated. In any case, the mean field treatment represented by the dynamo equations (see *Dynamos, mean field*) is presumed to provide only the large-scale features of the dynamo, but when we inquire into the nature of the diffusion  $\eta$  and the effective cyclonic velocity  $\alpha$ , we come face to face with the fibril microstructure, perhaps with rapid reconnection between nonparallel fibrils. Indeed, one wonders if the ephemeral active regions and the individual magnetic fibrils, found all over the surface of the Sun at all times, are related in some way to the subsurface process of turbulent diffusion, magnetic reconnection, and the fibril structure of the magnetic field.

The effects of turbulence may be presumed important, although little is known from formal theory about the detailed interactions of the turbulent convection and the magnetic fibrils. However, one believes that somewhere in hydrodynamics and MHDs, perhaps including effects of radiative transfer in the lower convective zone, and perhaps even extending down into the radiative zone, the generation of the active magnetic fields of the Sun have their rigorous explanation. Theory needs all the guidance from helioseismology and tomography that it can get, because there are too many semiplausible possibilities within the present inadequate understanding of so many complicated processes.

#### Long-term variation

It must be appreciated, in the development of the theory of the solar dynamo, that direct observations of solar magnetic activity over the last four centuries, combined with radiogenic studies of such nuclei as <sup>10</sup>Be and <sup>14</sup>C (produced in the terrestrial atmosphere by the cosmic rays that are modulated by the solar wind and the magnetic activity of the Sun) show that the Sun slips off into periods of 50–100 years of

greatly reduced activity, e.g., the well-known Maunder Minimum (A.D. 1645-1715), while at other times it exhibits 50-100 year periods of hyperactivity, e.g., the Medieval Maximum (12th to 13th centuries) (Eddy, 1976; Beer, et al., 1990). Sometimes these wide swings can be abrupt, making the transition in a decade or less. One can only conjecture (see Mininni, Gòmez, and Mindlin, 2001; Mininni and Gòmez, 2005 and references therein) on how the hydrodynamics within the Sun, and the consequent MHD dynamo effects, cause this to happen. Observations of other stars show similar variations in their magnetic state (Baliunas, et al., 1995), so there is nothing unique about the Sun, except that we are close enough to it to recognize the general form of the problem, even if not able to see below the surface to resolve the mystery. We must not overlook the important point, however, that the Sun shows activity variations over centuries and perhaps millennia, well beyond the range of contemporary research. Monitoring a large number of other stars-particularly solar-type stars-provides an effective means for viewing in a human lifetime the long-term possibilities for the Sun.

# DYNAMOS, EXPERIMENTAL

Dynamo experiments attempt to reproduce the mechanisms active in planetary dynamos on a laboratory scale. Most researchers would accept convecting liquid metal in a rotating spherical shell as a sensible model of the geodynamo. A straightforward experimental investigation of such a system is technically too demanding, so that driving mechanisms other than convection need to be used. Every experiment focuses on particular features of the dynamo effect, which makes it necessary to build many different experiments in order to obtain a complete picture of the dynamo process. A series of reviews (Busse, 2000; Tilgner, 2000; Gailitis *et al.*, 2002; Nataf, 2003) documents the progress that has been made in the field over the past couple of years.

Fluid flow can only generate a magnetic field if the generating mechanism overcomes ohmic dissipation. This condition translates into the requirement that the magnetic Reynolds number  $R_m$  must be large enough. This number is given by  $R_m = VL/\lambda$  for a liquid conductor with magnetic diffusivity  $\lambda$ , which fills a volume of extent L

and flows with the typical velocity V. If  $R_m$  exceeds a critical value, arbitrarily small magnetic fluctuations start to grow. The growth of the magnetic field is eventually stopped because magnetic fields and electric currents in the fluid combine to create the Lorentz force, which modifies the flow so as to saturate field growth. The value of the critical magnetic Reynolds number depends on the flow chosen, but is typically on the order of 10–100 in the experiments.

Lowes and Wilkinson in 1963, built an experiment with solid, elictrically conducting, ferromagnetic material in order to keep the magnetic diffusivity small. The motion of the conductor consisted in two cylinders rotating inside a solid block. This experiment was the first laboratory demonstration of a dynamo working in an essentially electrically homogeneous medium (see *Dynamo, Lowes-Wilkinson*).

All other experiments have opted for liquid sodium as working fluid. Among the liquid metals, which are liquid below 500°C, sodium has the lowest magnetic diffusivity. Nonetheless, if an  $R_m$  in excess of 10–100 is necessary for dynamo action and if one is willing to build an experiment of size L = 1 m, one still needs sodium flowing at velocities 1–10 ms<sup>-1</sup>. Under these conditions, the flow of sodium is fully turbulent. These velocities present a technical challenge even when the sodium is pumped and cannot reasonably be reached in convection-driven flows. For instance, extrapolation of other laboratory experiments predicts flow velocities around 0.1 ms<sup>-1</sup> if a thermal driving power of 100 kW is applied to a sphere of 1 m radius filled with sodium and spinning at 200 rpm (Nataf, 2003).

Sodium has the pleasant property that its kinematic viscosity at 120°C (the typical working temperature of the experiments) is close to the kinematic viscosity of water at room temperature. Every experiment can thus go through the following design procedures: (1) From analytical or numerical simulations of the induction equation, select a flow and a driving mechanism which are promising (i.e., values of  $R_m$  exceeding the critical  $R_m$  by a comfortable margin can be achieved with a reasonable driving power). (2) Build a model with water and check whether the selected driving mechanism (usually propellers or pumps) produces the intended flow. Because of turbulence, numerical computation can never tell for sure. (3) Build a sodium experiment. If it is not able to generate a self sustained magnetic field, investigate induction effects with externally applied magnetic fields. For instance, the decay time of the field after the external field has been switched off must go to infinity as  $R_m$  approaches the critical value. One can therefore obtain estimates of the critical  $R_m$  for the flow under investigation. (4) If necessary, and if the critical  $R_m$  estimated in step 3 seems accessible, build a bigger experiment and investigate the properties of the running dynamo.

There are at least two major questions we want these experiments to answer. First, at what magnetic Reynolds numbers does dynamo action set in? In particular, how, if at all, do small turbulent eddies affect the field generation, which mostly occurs at large scales? Second, what exactly determines the strength of the magnetic field at which it stops growing? The role of turbulent eddies is unknown in this context, too. In order to provide answers, experiments monitor the magnetic field as well as the power input into the flow. We have so far only very limited information about the velocity field in dynamo experiments, which reflects the difficulties of anemometry in liquid metals (Brito *et al.*, 2001). The problems of field saturation and of onset of dynamo action are peculiar to the dynamo effect and cannot be answered by MHD experiments with turbulent or rotating liquid metal flows in an externally applied magnetic field. For a recent review of this latter type of experiments relevant to geophysics, see Nataf (2003).

In the following, experiments are classified according to the stage of the design process they are in and are named after their geographic location.

Two different experiments have generated self-sustained magnetic fields. One is located in Riga, Latvia. It is inspired by the arguably simplest known kinematic dynamo (see *Dynamo, Ponomarenko*). The experiment consists of three coaxial pipes. A propeller forces a helical flow in the innermost pipe, the return flow occurs in the second

pipe, and the third pipe contains sodium at rest (see Figure D22a). The inner pipe has a length of 3 m and a diameter of 0.25 m. For this extreme aspect ratio, edge effects at the ends of the cylinder are of minor importance, and reasonable design calculations were possible with the computational capabilities of the time at which the design started (Gailitis and Freiberg, 1980). A first experiment in 1987 was unsuccessful (Gailitis, 1987). An improved configuration did produce a self-excited magnetic field in 1999 (Gailitis *et al.*, 2000; Gailitis *et al.*, 2001).

Another experiment in Karlsruhe, Germany, is based on theoretical models dating back to Roberts (1972) (see Dynamos, periodic) and Busse (1992). The flow in this experiment is divided into 52 cells arranged in an array (Figure D22b). Each cell contains a right-handed helical flow with alternating directions in adjacent cells. The sodium is guided by pipes and blades made out of stainless steel so that the mechanical structures do not electrically separate the cells. Three independent pumps are necessary to achieve the flow velocities of about  $4 \text{ ms}^{-1}$  required for dynamo action. As opposed to the Riga dynamo, the helical flow in a single cell of the Karlsruhe dynamo cannot sustain a magnetic field on its own. The Karlsruhe dynamo relies on a cooperative effect: The many small eddies generate a global (large-scale) magnetic field. In the terminology of mean field MHD, the Karlsruhe dynamo is an  $\alpha^2$ -dynamo (see *Dynamos, mean field*). Calculations of the onset of dynamo action are based either on a mean field approach (Rädler et al., 2002, 2003) or on direct numerical simulation (Tilgner, 1997, 2002). The flow qualitatively mimics convection in one hemisphere of a rotating planet with the rotation axis aligned with the axis of the eddies. In this context, it is a paradox that the Karlsruhe dynamo excites a field with a dipole moment perpendicular, rather than parallel, to the axis of the eddies. This paradox is dealt with in Tilgner (2004). The Karlsruhe experiment has been running since 1999 and details of the experimental observations are in Stieglitz and Müller (2001), Müller, Stieglitz and Busse (2004), and Stieglitz and Horanyi (2004).

The most important merits of the Riga and Karlsruhe experiments have been to demonstrate the feasibility of fluid dynamo experiments and to reveal a convincing agreement between experimental data and numerical simulations. This last point is not trivial because numerical simulations at present are unable to take into account all geometrical details of an experiment. They also have to ignore turbulence and numerous other real world complications. The dynamo effect appears to be robust enough so that all these features can be safely neglected.

The velocity field cannot change dramatically in response to the magnetic field in both the Riga and Karlsruhe dynamos because of mechanical structures guiding the flow. A series of experiments located in Cadarache (France), Madison (Wisconsin), and College Park (Maryland) are currently in stage 3 of the design process described above and will give more freedom to the fluid. They are based on theoretical work by Dudley and James (1989) and use cylindrical or spherical vessels stirred by one or two propellers (Figure D22c–e). Reports on induction effects in these flows have appeared (Peffley, Cawthorne and Lathrop, 2000; Bourgouin *et al.*, 2002; Pétrélis *et al.*, 2003). Turbulence is a more important ingredient in these experiments than in Riga or Karlsruhe because turbulence makes predictions of critical magnetic Reynolds numbers more difficult.

Should the experiments just described work as dynamos, there will still be room for exploration. Most importantly, one would like to

**Figure D22** Sketch of several dynamo experiments. (a) the Riga dynamo. The drawing is not to scale. At equal diameter, the pipes should be shown three times as long. (b) The Karlsruhe experiment. The arrows indicate flow directions within each cell. The entire vessel has a diameter of about 2 m and a height of approximately 1 m. (c) to (e) Different flows which can be realized in the experiments in Cadarache, Madison, and Maryland. (e) is the favored flow because it has the smallest critical magnetic Reynolds number according to numerical simulations. The experiment in Cadarache uses a cylindrical instead of a spherical container.

include the effects of rotation since the Coriolis force must play an important role in the equilibrium of forces in real planets. The group in Maryland is building an experiment with two concentric spheres rotating at different angular velocities in order to drive a nontrivial flow in the gap between the spheres. The outer sphere has a diameter of 3 m and magnetic Reynolds numbers of nearly 700 will be accessible. There are several other experiments in stage 2 coming from a variety of backgrounds, but they are all rotating. A configuration studied in New Mexico is motivated by astrophysics and intends to produce an aw-dynamo (Colgate et al., 2001) (see Dynamos, mean field). A group in Perm (Russia) wants to use a torus, rotate it about its axis so that the sodium inside the torus is in solid body rotation, and suddenly stop the torus from rotating. Because of inertia the sodium in the torus continues to rotate and has a nonzero velocity relative to the walls of the torus, so that obstacles placed on the wall can induce in the sodium a flow suitable for a dynamo effect (Dobler et al., 2003). The concept is appealing because of its simplicity but has the disadvantage to generate only a transient flow and not a stationary state.

The possibility exists that the geodynamo is driven by the precession of the rotation axis of the Earth rather than by convection. Following up on earlier experiments by Gans (1970) a group in Meudon (France) explores the feasibility of driving a laboratory dynamo by precession. The apparatus presently in use is a cylinder filled with water rotating about its axis and precessing about an axis perpendicular to the axis of the cylinder (Léorat *et al.*, 2003).

Existing dynamo experiments are not small-scale replica of the geodynamo but can nonetheless provide information directly useful for the analysis of geomagnetic data. For instance, Christensen and Tilgner (2004) extract a scaling from numerical simulations and dynamo experiments which constrains the value of the ohmic dissipation in the Earth's core. The experimental data proves crucial because it is for a magnetic Prandtl number (the ratio of viscosity and magnetic diffusivity) characteristic of liquid metals and presently inaccessible to numerical simulations. Experimental investigation of the dynamo effect is likely to become an increasingly important tool in the study of the geodynamo as more features such as rotation are added to the experiments.

### DYNAMOS, FAST

As explained in other chapters dynamo action occurs when the effects of advection (Faraday's law) are vigorous enough to overcome the effects of Ohmic diffusion. The ratio between these two effects is expressed by the *magnetic Reynolds number* 

$$R_m \equiv \mathcal{UL}/\eta$$

where  $\mathcal{U}$ ,  $\mathcal{L}$  are typical length and timescales, and  $\eta$  is the magnetic diffusivity. If we nondimensionalize the induction equation by scaling lengths with L and time with the turnover time  $\mathcal{L}/\mathcal{U}$  we get the following form (assuming  $\eta$  uniform):

$$\frac{\partial \mathbf{B}}{\partial t} = \nabla \times (\mathbf{u} \times \mathbf{B}) - R_m^{-1} \nabla \times \nabla \times \mathbf{B}$$

At the onset of dynamo action, when induction just balances diffusion,  $R_m$  is of order unity by definition. However in some astrophysical bodies (though probably not the Earth)  $R_m$  is very large, and the question then arises whether magnetic flux can grow at a rate  $\mathcal{O}(1)$  (that is on the turnover time) or whether in fact the growth rate is much smaller, depending on some negative power of  $R_m$  (the rate  $R_m^{-1}$  would imply growth on the Ohmic time  $\mathcal{L}^2/\eta$ ). If the first alternative holds, we say that the dynamo is *fast*, otherwise it is *slow*.

It might be expected to be obvious from Faraday's law (prohibiting any change in the flux linked with a perfect conductor) that all dynamos would be slow, since the growth rate at  $R_m = \infty$  would be zero. However if as  $R_m$  becomes very large the length scales of the magnetic field become small, then diffusion can never be neglected, even in the limit. Thus the question of the type of dynamo action is intimately bound up with the complexity of the field structure.

It can be important to know whether the dynamo is fast or not; for example the Ohmic time for the Sun is comparable with the age of the universe, whereas the large-scale solar dynamo evolves on scales of a few years. If the solar dynamo were not fast, then it would not be able to generate flux in the way that it does.

While it is probably not the case that the Earth is in a regime appropriate for fast dynamo action, there is no doubt that our understanding of dynamo action in general has been enhanced by the study of fast dynamos, which have proved a valuable interface between MHD and dynamical systems thory; see for example the monograph of Childress and Gilbert (1995).

#### Examples of slow dynamos

Here we give two rather different examples of slow dynamos. The first is an adaptation of the Faraday disk dynamo introduced by Moffatt (see Figure D23 and *Dynamo, disk*). Then there are simple equations that relate current in the wire *I*, the current round the disk *J*, the angular velocity  $\Omega$  and the fluxes of magnetic field through the wire and the disk  $\Phi_I$ ,  $\Phi_J$ . These are

$$\begin{split} \Phi_I &= LI + MJ, \quad \Phi_J = MI + L'J, \quad RI = \Omega \Phi_J - \frac{\mathrm{d} \Phi_J}{\mathrm{d} t}; \\ R'J &= -\frac{\mathrm{d} \Phi_J}{\mathrm{d} t} \end{split}$$

where *M* is the mutual inductance, and *L*, *L'* the self-inductances of the circuit, and  $LL' > M^2$ . We can seek solutions  $\propto e^{pt}$ , and find growth (dynamo action) if  $\omega M > R$ . The growth rate is

$$p_{+} = \left(\sqrt{(RL' + R'L)^{2} + 4R'(\Omega M - R)(LL' - M^{2})} - (RL' + R'L)\right)/2(LL' - M^{2}).$$

 $p_+ > 0$  for all  $\Omega > R/M$  but  $p \sim \sqrt{\Omega R'}$  as  $\Omega \to \infty$ . Identifying R' with  $\eta$  we can see that the growth rate scales as  $R_m^{-1/2}$ . This is not really surprising since by Faraday's law zero growth rate of the flux through the disk should be expected as  $\eta \to \infty$ .

A second slow dynamo is the so-called Roberts flow (Robert, 1970) (see also *Dynamos, periodic*). This is a simple steady cellular flow depending on only two space dimensions. The velocity takes the form

$$\mathbf{u}(x,y) = \nabla \times (\psi(x,y)\mathbf{e}_z) + \gamma \psi(x,y)\mathbf{e}_z; \quad \psi = \sin y + \cos x$$

Thus we can see that the helicity  $\langle \nabla \times \mathbf{u} \cdot \mathbf{u} \rangle = \gamma \langle \psi^2 \rangle$ . Solutions exist in the form  $\mathbf{B} = Re(\tilde{\mathbf{B}}(x, y, t)e^{ikz})$ . The optimum growth rate occurs at large k when  $R_m \gg 1$ , in fact  $(k \sim (R_m^{1/2} / \ln R_m))$ . These scales, though small, are long compared to the thin boundary layer scale  $R_m^{-1/2}$  for field near stagnation points. As  $R_m \to \infty$  the optimum growth rate  $\sim \mathcal{O}(\ln(\ln R_m) / \ln R_m)$ . This is *just* a slow dynamo! What these two rather different examples have in common is that the flows to not act to separate nearby points exponentially in time. That is, they are not stretching flows (in fact the Roberts flow does have exponential stretching at the stagnation points of  $\phi$ , but nowhere else).

**Figure D23** The segmented disk dynamo (Moffatt 1979). Radial strips prevent circumferential current except in the outer part of the disk.

## Two examples of fast dynamos

We now turn to two examples of fast dynamos. The first is the stretchtwist-fold (STF) flow of Zel'dovich, which in the absence of diffusion acts to double the magnetic energy by stretching. The diagram in Figure D24 shows how the field has to be moved at large  $R_m$ , when the field lines are almost frozen in. Two issues immediately arise. Firstly, the role of diffusion, however small, is not clear near the cross-over points of the field, where gradients may be high. Secondly, the flow field required is certainly not steady, or easily realizable in a finite domain. However, it is possible to manufacture realistic flows that have the required folding properties.

The second example is a development of the Roberts flow introduced by Galloway and Proctor (1992). The velocity field (the "GP-flow") now takes the form:  $\mathbf{u}(x,y,t) \propto \nabla \times (\psi(x,y,t)\mathbf{e}_z) +$  $\gamma \psi(x,y,t)\mathbf{e}_z; \ \psi = \sin(y + \epsilon \sin \omega t) + \cos(x + \epsilon \cos \omega t)$  and it can be seen that the Eulerian pattern of the Roberts flow is advected in a circle. However the Lagrangian pattern is completely different; while the

**Figure D24** The STF dynamo (after Fearn *et al.,* 1988). The initial loop of flux is made to lie on top of itself but with twice the original energy.

Roberts flow has no exponential separation of nearby points (except at corners) the GP-flow has large stretching in large regions of the domain. This can be seen by looking at the Liapunov exponents for the flow with  $\epsilon = \omega = 1$ : The dynamo behavior of this flow is quite different from that of the Roberts flow. For large  $R_m$ , the growth rate levels off at about 0.3, while the critical wavenumber converges to about 0.57. The magnetic field structure becomes very complicated in the limit of large  $R_m$ , as can be seen in the right hand panel of Figure D25. In fact diffusion remains important even in the limit, and while the smallest scales  $\sim R_m^{-1/2}$ , the overall width of the flux structures reaches a finite limit. The contrast between this behavior and that of the Roberts flow can be seen in Figure D26. The key to this complex behavior lies in a delicate balance between the stretching properties of the flow, which tend to increase the energy at a rate independent of diffusion, and the folding of flux elements back on themselves which is inevitable given that the velocity does not lead to unbounded excursions of fluid particles in general. If folding takes place so as to bring oppositely directed field lines close together, the resulting cancellation due to diffusion can result in a net decay of the field. This always happens when the field is two-dimensional. In three dimensions, however, with the right flow and the right scales across the folding direction the folding can be constructive, leading to net growth of the field even when diffusion is very small.

## Nonlinear development

The idea of a fast dynamo is essentially a linear one, related to the rate of growth of magnetic fields for a given velocity field u. If instead we regard the velocity as being produced by some given force field, subject to the action of Lorentz forces, then as the field grows to finite amplitude the flow field will be modified in such a way that the growth of the field ceases. How is this achieved? One possibility is that the vigor of the flow is decreased while its transport properties remain constant; that is, equilibration is achieved by a reduction of the effective  $R_m$ . However, a number of numerical simulations of nonlinear dynamos suggest that instead reduction in dynamo action is achieved by a change in the stretching properties of the flow, with little change in the kinetic energy or other Eulerian properties. When there is no significant field, the rate separation of fluid particles is unconstrained by their initial position. When there is a magnetic field present, and  $R_m$  is large on the dominant scales of the flow, then the fluid particles are closely linked to the field lines and so acquire a

**Figure D25** *Left panel*: Liapunov exponents for the GP-flow (courtesy of D.W. Hughes), found by integrating two nearby particle paths for a finite time and measuring the total stretching; dark shades indicate small stretching, lighter shades higher stretching. *Right panel*: intensity graph of the normal component of the dynamo field for this flow (courtesy of F. Cattaneo). Medium gray (red in online encyclopedy) denotes weak, and white strong, field regions. Both plots show a periodic domain in the (x,y) plane. Note the close correlation.

**Figure D26** Left panel: Growth rates for the Roberts flow as a function of *k* for various  $R_m = 1/\varepsilon$  (solid lines, numerical results, dotted lines, asymptotic theory); *right panel*: Growth rates as a function of *k* for the GP-flow.

history; unlimited stretching is impossible without inducing large Lorentz forces due to field line folding. When a stationary state is reached the stretching is considerably reduced. The final velocity field has less stretching than the linear flow, and is just such as to achieve a zero growth rate. The resulting dynamo is thus neither slow nor fast, just marginal!

#### Summary

By means of simple examples I have tried to demonstrate the distinction between fast and slow dynamos. From these it is clear that the limit of infinite  $R_m$  is not a simple one. Fast dynamos have become the object of intense study by mathematicians: the outstanding monograph describing this work, and much else concerning fast dynamos, is that of Childress and Gilbert (1995). In the context of the geodynamo, the limit of large  $R_m$  is not approached, and the advection (turnover) time and the diffusion time can be considered comparable, so that the limiting behavior discussed here is unlikely to be relevant. Nonetheless, an understanding of dynamos at large  $R_m$  has, as explained above, proved very fruitful in advancing our understanding of dynamos in general, including the geodynamo, and so an appreciation of the issues involved is very important.

## DYNAMOS, KINEMATIC

#### Introduction

In the Earth's fluid outer core, the motion of electrically conducting molten iron is responsible for the generation of the magnetic field. In general, this field reacts back onto the flow by the Lorentz force in a nonlinear fashion, introducing complex behavior into the system which is not well understood. Under the kinematic assumption, we study the simpler problem in which the fluid flow is prescribed (and typically time-independent), ignoring this back reaction. In this case, we are at liberty to analyse the time behavior of the magnetic field in isolation and test whether or not a given flow can act as a dynamo.

Such an analysis is a gross simplification, since the geodynamo is thought to be in the so-called strong-field regime where the flow is significantly affected by the magnetic field and will therefore differ from any fixed kinematic flow structure. Such effects are taken into account in fully dynamical models, however, these are so complex that the behavior of the system often defies simplistic interpretation (see *Geodynamo, numerical simulations*). Additionally, the parameter values at which these models operate are so far from geophysical estimates that it is by no means certain that the results can be extrapolated to the Earth. Bearing this in mind, the analyses of simple kinematic Earth-like models are important in the understanding of the dynamo process.

## The induction equation

The magnetic induction equation governs the time evolution of a magnetic field **B** under the influence of a moving conductor **u** (the outer core) in the reference frame of the mantle and magnetic diffusion (see *Magnetohydrodynamics*). It is written in nondimensional form below, the sole parameter being the magnetic Reynolds number  $R_m = \mathcal{UL}/n$  where  $\mathcal{U}$  is a typical value of the flow velocity,  $\mathcal{L}$  is the typical length scale taken to be the radius of the outer core and  $\eta = (\mu_0 \sigma)^{-1}$  is the (constant) magnetic diffusivity,  $\mu_0$  being the permeability of free space, and  $\sigma$  the electrical conductivity;

$$\frac{\partial \mathbf{B}}{\partial t} = R_m \nabla \times (\mathbf{u} \times \mathbf{B}) + \nabla^2 \mathbf{B}.$$
 (Eq. 1)

The value of  $R_m$  is the ratio of the effects of the flow to magnetic diffusion (associated with Ohmic dissipation of energy), and lies in

the geophysical range of 500–1000. Time has been scaled relative to the *a priori* magnetic diffusion timescale  $\mathcal{L}^2/n$ , which is typically 200000 years for the Earth. A straightforward analysis however shows that the true diffusive decay time for the Earth is more like 20000 years (see Moffatt, 1978). The exterior of the outer core is the mantle, well approximated by an electrical insulator (see *Mantle, electrical conductivity, mineralogy*). The inner core is often ignored for simplicity, but if included, is given the same conductivity as the outer core.

Kinematic dynamo theory is concerned with magnetic field solutions of Eq. (1) that grow in time given a flow structure **u**. It is by no means obvious that these exist, for in a sphere the dynamo mechanism, associated with electric currents, could easily short-circuit prohibiting any magnetic field to grow. Nevertheless, growing solutions have been found, as is outlined in the historical overview below. In general, the kinematic assumption is valid assuming firstly we choose a geophysically motivated flow, plausibly generated by rotating convection (see *Core convection*) and secondly that the Lorentz force is small, usually taken to mean that the initial and subsequent magnetic fields are also small.

The induction equation is typically solved in a spherical geometry using vector spherical harmonics (see *Harmonics, spherical*), in which the divergence-free magnetic field is expanded in toroidal-poloidal form (see Moffatt, 1978).

The outer core is commonly taken to be incompressible and so **u** may also be written in this way:

$$\mathbf{u} = \sum_{l,m} t_l^m + s_l^m = \sum_{l,m} \nabla \times [Y_l^m(\theta, \phi) t_l^m(r) \hat{\mathbf{r}}] + \nabla \times \nabla \times [Y_l^m(\theta, \phi) s_l^m(r) \hat{\mathbf{r}}]$$
(Eq. 2)

where *l* and *m* are the degree and order of the spherical harmonic  $Y_l^m(\theta, \phi)$  (in spherical polar coordinates), and  $\hat{\mathbf{r}}$  is the unit position vector. The toroidal and poloidal scalar functions  $t_l^m$  and  $s_l^m$  are given. The magnetic field is written in a similar fashion as  $\mathbf{B} = \sum_{l,m} \mathbf{T}_l^m + \mathbf{S}_l^m$  (always using upper case). The value m = 0 represents a vector independent of  $\phi$ , axisymmetric about the *z*-axis.

A typical flow comprises several harmonic components, for example,  $t_1^0$  representing differential rotation and  $s_2^0$  representing convection as shown in Figure D27, being nonslip at the boundary r = 1. Both of these components are important aspects of core convection.

#### An historical overview: after Cowling's theorem

Cowling's theorem (q.v.), published in 1933, caused a major setback in the early days of geodynamo theory. It proved that no axisymmetric field could be sustained by dynamo action and since the Earth's field is principally of this type, it was thought at the time that the geodynamo hypothesis was untenable. Indeed, it was not known whether a general antidynamo theorem (see Antidynamo and bounding theorems) might exist thus ruling out any kind of generative mechanism altogether. In 1947 Elsasser (see Elsasser, Walter M.) was the first to suggest that a complex mechanism might be taking place within the outer core, converting magnetic field between symmetries thus breaking the constraints of Cowling's theorem. He suggested that differential rotation could convert an axisymmetric dipole field, represented by the  $S_1^0$  vector harmonic, into  $T_2^0$  by what is now called the  $\omega$ -effect (see Dynamos, mean field).

The problem remained of how to close the loop, that is, how to change the newly created  $T_2^0$  field back into  $S_1^0$  so that the process might continue indefinitely. Of the two mechanisms he suggested, namely turbulence and tilted flows, the latter was pursued by Bullard (see *Bullard*, *Edward Crisp*) who argued qualitatively that a flow component  $s_2^{2c}$  (describing a tilted convection roll) might be sufficient to regenerate the axial dipole field. Figure D28 shows a schematic picture of this process. Solid arrows show the effect on the field of the  $t_1^0$  flow; dashed

**Figure D27** (a) Streamlines of an  $s_2^0$  flow in a meridian plane; (b) contours of  $u_{\phi}$  in a meridian plane of a  $t_1^0$  flow, giving rise to differential rotation, the flow differing from solid body rotation and is faster midstream than at the boundaries.

**Figure D28** The interactions between the lowest degree harmonics involving the axial dipole  $S_1^0$  that forms a closed loop. Solid arrows denote coupling by  $t_2^0$  motion; dashed by  $s_2^{2c}$ . If all links of this chain work sufficiently quickly then the axial dipole harmonic could be infinitely sustained by this process.

190

arrows show the effect of the flow component  $s_2^{2c}$ . Thus, an  $S_1^0$  field, if acted upon in this manner, might be sustained creating byproducts of  $T_2^0$ ,  $T_2^{sv}$ , and  $T_2^{2c}$  fields *en route*. The emphasis at this time was on finding a mechanism whereby the principally observed geophysical field component ( $S_1^0$ ) could be sustained; no attention was given to other field symmetries. Since this four component field is not axisymmetric, Cowling's theorem does not apply and the idea is plausible.

#### The Bullard and Gellman model

The first quantitative model of a self-sustaining process taking place inside the Earth's core was proposed by Takeuchi and Shimazu (1953). This work was closely followed by Bullard and Gellman (1954) (see *Dynamo, Bullard-Gellman*); both papers extended the suggestions of Elsasser and Bullard that if a flow was chosen carefully, through a sequence of interactions, the original field might be amplified and lead to a self-sustaining process.

The original procedure used to solve the induction equation was to seek steady fields, which after numerical discretisation, converts Eq. (1) into a generalized eigenvalue problem for  $R_m$ ; a steady solution was manifested by the existence of a real eigenvalue. The magnetic field was expanded in vector spherical harmonics and each unknown radial scalar function using a finite difference scheme. The velocity chosen was defined by

$$t_1^0(r) = \varepsilon r^2 (1-r)$$
  $s_2^{2c} = r^3 (1-r)^2$  (Eq. 3)

where  $\varepsilon$  is an adjustable parameter. No inner core was included in the flow pattern to make it as simple as possible. Real eigenvalues were found for  $R_m$ , which did not appear to be affected greatly by changing the numerical resolution, at least within the limited computer resources available at that time. Thus it had appeared that a working dynamo had been discovered: the combinations of the differential rotation  $t_1^0$  and the tilted convection roll  $s_2^{2c}$  was such that a (nonaxisymmetric) steady field could be maintained with an Earth-like  $S_1^0$  component. However, 13 years later, a repeat of the calculations (Gibson and Roberts, 1967) at higher resolution using vastly more powerful computers showed that the positive dynamo action found was spurious: the results were merely an artifact of the inadequate numerical method used and not of the underlying physics. The question of the possibility of dynamo action in a homogeneous conducting sphere was again reopened.

#### Other advances

In 1958 both Backus (see *Dynamo, Backus*) and Herzenberg (see *Dynamo, Herzenberg*) published analytic studies that strengthened the belief that dynamo action was possible. The problem with the induction effect is that for any length scale, successively smaller scales will be created by the fluid-field interactions. Numerically it is hoped that on increasing the resolution, the solution converges sufficiently quickly to be captured with the available computing resources. Both of these dynamos use diffusive effects to kill off the small-scale fields: the Backus dynamo by periods of stasis and the Herzenberg dynamo by spatial attenuation, both amenable in analytic treatment. Neither of these solutions would be a possible candidate for the Earth; however, this was evidence that no generalized antidynamo theorem existed.

The study of the dynamo problem in a sphere was also complimented by calculations in other geometries. An analytical solution of a working dynamo in a cylindrical helical flow was published in 1973 by Ponomarenko (see *Dynamo, Ponomarenko*). Roberts (1970) studied infinite spatially periodic dynamos, and found that almost all motions performed as working dynamos. This was real evidence that not only was it possible to find flows that worked as dynamos but that it was relatively easy to do so, finally laying to rest the fear of a generalised antidynamo theorem and gave dynamo theory centre stage for the origin of Earth's magnetic field.

#### Further work on spherical dynamos

In the 1970s and onward, much progress was made with spherical kinematic dynamos. Lilley (1970) studied the flow  $\mathbf{u} = t_1^0 + s_2^{2c} + s_2^{2s}$ and found ostensibly converged growing magnetic field solutions. Unfortunately, yet again, later workers discovered his results to be unconverged; this was to be the last of the spurious discoveries. The first converged solutions were presented by Gubbins (1972), Roberts (1972), and Pekeris et al. (1973). The method of solution had switched from seeking steady solutions (leading to a generalised eigenvalue problem for  $R_m$ ) to time-dependent eigenmode solutions. In this paradigm, the assumption that  $\mathbf{B} = \hat{\mathbf{B}} e^{\lambda t}$  is made thereby reducing the induction equation to an eigenvalue problem for the complex growth rate  $\lambda$ . The adjustable parameter  $R_m$  was varied and the lowest value giving  $\Re(\lambda) = 0$  sought. If such a value could be found (which was by no means certain) this was termed the critical magnetic Reynolds number  $(R_m^c)$ . It is entirely possible that  $\Im(\lambda) \neq 0$  in this critical state so that the dynamo would be oscillatory.

In the various flows studied, these workers found growing magnetic fields although not always of the correct symmetry for the Earth. Nonetheless, this was the first concrete evidence that the geodynamo could work, at least in a simplified case. It was also found that a greater flow complexity introduced by the choice of radial scalar functions favoured dynamo action, i.e., the critical value of  $R_m$  was smaller. This characteristic was also found in the study of the nonaxisymmetric flow of Kumar and Roberts (1975) with four components:

$$\mathbf{u} = t_1 + \varepsilon_1 \mathbf{s}_2 + \varepsilon_2 \mathbf{s}_2^{2c} + \varepsilon_3 \mathbf{s}_2^{2s} \tag{Eq. 4}$$

where the values of  $\varepsilon_1$ ,  $\varepsilon_2$ , and  $\varepsilon_3$  are adjustable. The  $t_1^0$  component again represented an azimuthal differential rotation, the  $s_2^0$  a meridional circulation, and the  $s_2^{2c}$  and  $s_2^{2s}$  terms tilted convection rolls. They found converged field solutions containing the axial dipole, and that the direction of the flow components (i.e., the sign of the values of  $\varepsilon_i$ ) was crucial in determining the symmetry of the growing magnetic field.

In later studies of the Kumar and Roberts flow (e.g., Sarson and Gubbins, 1996; Gubbins *et al.*, 2000) it was found that steady magnetic field solutions were favored with strong meridional circulation. The inclusion of a solid inner core introduced significant changes in the field solutions; the fact that different symmetries adapted in different ways led to the possibility that the inner core might play a role in field symmetry selection. Additionally, it was concluded that whether or not kinematic dynamo action exists depends critically on the exact choice of flow, an issue that makes it difficult to attribute a robust physical interpretation to such a dynamo mechanism. The influence of helicity (the spiralling nature of the flow) was found to be favourable to dynamo action, although was not essential.

Despite the correlation between increasing flow spatial complexity and dynamo efficiency, Dudley and James (1989) found growing magnetic field solutions in very simple axisymmetric convection roll flows, of  $t_1^0 s_2^0, t_2^0 s_2^0$ , and  $t_1^0 s_1^0$  type. The fact that a one cell convective flow  $t_1^0 s_1^0$  can support dynamo action dispelled beliefs that the flow had to be complex in nature, as previous results suggested.

An alternative methodology to solving the kinematic dynamo problem, instead of seeking eigenvalue solutions as has been popular in most of the previous literature, is to apply an energetic analysis (Livermore and Jackson, 2004). Under this paradigm, instead of only seeking exponentially indefinitely growing solutions, any magnetic field that grows is sought, including those that eventually decay. Crucially, they found that the dynamo action, although not necessarily indefinite, was robust under small changes in the flow, something that previous studies did not find. It is therefore much more straightforward to assign a physical mechanism to such a dynamo process, in this case attributable to magnetic field line stretching by upwelling convective flows, generating Earth-like  $S_1^0$  fields.

## The influence of an insulating boundary

Despite many authors finding spherical flows that operated as kinematic dynamos, it was well known that many other choices failed. This was in stark constrast to Roberts (1970) who had showed that almost all infinite spatially periodic flows show dynamo action. One cause has been attributed to the influence of the mantle, introducing electrically insulating boundary conditions on the magnetic field, these making no appearance in a periodic domain. The study of Bullard and Gubbins (1977) showed that the insulating boundary trapped currents near the edge of the flow region and catastrophically increased Ohmic dissipation, inhibiting dynamo action. They suggested that this might not be a problem if the flow near the CMB was quiescent, a topic later taken up by Hutchenson and Gubbins (1994). They found that the addition of a static outer conducting region on top of the fluid core promoted dynamo action: either the critical magnetic Reynolds number was lowered or growing magnetic fields were found when all had previously decayed. The trapped currents could now flow outside the core region facilitating dynamo action, geophysically motivated by the possibility of a stably stratified layer at the top of the outer core

## Motivating the choice of flow

Although one of the great strengths of kinematic theory is the ability to prescribe the flow, the lack of physical self-consistency is one of its great drawbacks. To partially mitigate this issue, Love and Gubbins (1996) studied the problem whereby the dynamo efficiency, defined in terms of the critical magnetic Reynolds number and the Ohmic dissipation produced by the growing field, was minimized over a choice of flow (in this case the the values of  $\varepsilon$  in the Kumar and Roberts flow). Such a method of choosing a flow has a strong basis on physical grounds because it might be energetically favored. They found dynamo action with much reduced Ohmic dissipation.

A partial solution to the full Navier-Stokes equations (see *Geodynamo*) is another way of choosing the flow. Sarson (2003) considered the geophysically relevant geostrophic approximation, balancing the Coriolis force, buoyancy, and pressure. He derived a fully consistent flow although the driving temperature profile was not geophysically plausible, and found growing field solutions of dipole symmetry in line with the studies of the Kumar and Roberts flow.

#### Summary

Kinematic dynamo theory has proven very successful in helping scientists understand the complex process of magnetic field generation inside the Earth. Conclusive evidence in the 1970s that the geodynamo could function is of particular historical importance and paved the way for many of the subsequent advances in geodynamo theory. In addition, some links have been made between the generated fields and various flow properties and the presence of a thin stably stratified conducting layer on top of the outer core. Kinematic reversal mechanisms have also been proposed (see *Reversals, theory*).

The main outstanding problem of kinematic dynamos is their sensitivity to the exact choice of flow chosen, making it difficult to attribute physical processes in such cases. Nevertheless, complex dynamical models are still often understood by simple kinematic arguments and this will undoubtedly remain the case for the foreseeable future.

#### DYNAMOS, MEAN-FIELD

#### DYNAMOS, MEAN-FIELD

#### Introduction

The mean-field concept was introduced into the dynamo theory of the magnetic fields of the Earth, the Sun, and other cosmic objects in the sixties of the last century. As was known or at least considered as very probable at that time, magnetic fields as well as the motions inside the electrically conducting interiors of these objects show rather complex geometrical structures and time behaviors. In addition antidynamo theorems suggested that dynamo action requires a certain complexity of magnetic field and motion (see *Antidynamo theorems* or *Cowling's theorem*). No solution of the dynamo equations has been found until this time, which could be interpreted as an approximate picture of the situation in the Earth or any cosmic body.

The central idea of the mean-field concept is to define mean magnetic fields, mean velocity fields etc., which reflect essential features of the original fields but show simpler, that is more smooth, geometrical structures and time behaviors, and to derive equations for them, which are easily treatable, in particular numerically solvable with the available tools. Of course, these equations must contain terms accounting for the deviations of the original fields from the mean fields, in which these deviations, however, enter only in the form of averaged quantities.

On the basis of this concept indeed dynamo models for the Earth, the Sun, and many other cosmic objects including galaxies have been developed. A remarkable step in this direction was done by Braginsky in 1964, who considered the Earth and proposed the theory of the "nearly symmetric dynamo" (Braginsky, 1964a,b) (see *Dynamo, Braginsky* and *Dynamo, model Z*). Independent from this, a general mean-field electrodynamics was established by Steenbeck *et al.* in 1966, and it was used to develop a general mean-field dynamo theory, applicable to all objects mentioned (Steenbeck *et al.*, 1966; Krause *et al.*, 1980). The rigorous mathematical formulation of the mean-field theory also covers Parker's ideas on dynamo action described already in 1955 (Parker, 1955, 1957).

A crucial point in mean-field electrodynamics and mean-field dynamo theory is a mean electromotive force resulting from the deviations of motion and magnetic field from mean motion and mean magnetic field. The occurrence of a specific type of this electromotive force, with a component in the direction of the mean magnetic field, is called " $\alpha$ -effect". The mean-field dynamo theory revealed basic dynamo mechanisms working with the  $\alpha$ -effect or with related effects. In this way it created a system of ideas which is now of importance in all dynamo theory, also beyond the mean-field theory.

As far as the geodynamo is concerned, a series of direct numerical simulations on very powerful computers has been carried out since the end of the last century (see *Geodynamo, numerical simulations*). The mean-field dynamo models, which, although in some respect problematic, were important for designing the more advanced models investigated in this way, are now no longer of primary interest. Nevertheless, the mean-field concept is still a useful tool for the interpretation of the numerical results and for understanding the basic dynamo mechanisms. In view of the solar and other cosmical dynamos, however, the mean-field approach is till now the only adequate way of describing and investigating them.

In this article a brief outline is given of the main ideas of mean-field electrodynamics and the dynamo theory based on it as well as a few specific applications to the geodynamo. See also more detailed presentations (e.g., Moffatt, 1978; Krause *et al.*, 1980; Zeldovich *et al.*, 1983; Rädler, 1995, 2000).

#### Mean-field electrodynamics

#### **Basic** equations

The standard dynamo theory assumes that the electromagnetic field in an electrically conducting moving fluid is governed by the Maxwell equations and Ohm's law in the form

$$\nabla \times \boldsymbol{E} = -\partial_t \boldsymbol{B}, \quad \nabla \times \boldsymbol{B} = \mu \boldsymbol{j}, \quad \nabla \cdot \boldsymbol{B} = 0$$
 (Eq. 1)

$$\boldsymbol{j} = \boldsymbol{\sigma}(\boldsymbol{E} + \boldsymbol{u} \times \boldsymbol{B}). \tag{Eq. 2}$$

As usual, E is the electric field and B the magnetic flux density, simply called magnetic field in the following, j is the electric current density, u the velocity of the fluid motion,  $\mu$  the magnetic permeability of the fluid, assumed to be equal to that of free space, and  $\sigma$  the electric conductivity of the fluid. These equations together with proper initial and boundary conditions determine B, E, and j if u is given. They can be reduced to the induction equation for B alone. For the sake of simplicity it is assumed here that  $\sigma$  does not vary in space. Then it follows that

$$\eta \nabla^2 \boldsymbol{B} + \nabla \times (\boldsymbol{u} \times \boldsymbol{B}) - \partial_t \boldsymbol{B} = 0, \quad \nabla \cdot \boldsymbol{B} = 0, \quad \text{(Eq. 3)}$$

where  $\eta$  is the magnetic diffusivity defined by  $\eta = 1/\mu\sigma$ . If **B** is known from these equations for a given **u**, then both **E** and **j** can be determined without further integrations.

#### Definition of mean fields

Let us focus our attention on situations in which the fluid motion possesses components showing spatial scales that are small compared to the scales of fluid body considered. Typical examples of that are turbulent or convective motions. Then, of course, the electromagnetic field has to show small scales in that sense, too.

In view of the definition of mean fields we consider first a scalar field F. We define the corresponding mean field  $\overline{F}$  as an average of F obtained with an averaging procedure which, as a rule, smoothes its variations in space and time. Adopting the terminology of turbulence theory the difference  $F' = F - \overline{F}$  is called "fluctuation." To extend the definition to a vector field F we refer to a coordinate system with unit vectors  $e^{(i)}$  and write, using the summation convention,  $F = e^{(i)}F_i$ . Then we define the mean-field  $\overline{F}$  by  $\overline{F} = e^{(i)}\overline{F_i}$ .

Various choices of the averaging procedure may be admitted. The only requirement is that Reynolds' averaging rules apply exactly or at least as an approximation. They read

$$\overline{F} + \overline{G} = \overline{F} + \overline{G} \tag{Eq. 4}$$

$$\overline{\partial F/\partial x} = \partial \overline{F}/\partial x, \quad \overline{\partial F/\partial t} = \partial \overline{F}/\partial t$$
 (Eq. 5)

$$\overline{\overline{F}} = \overline{F}$$
 or, what is in this context the same,  $\overline{F'} = 0$  (Eq. 6)

$$\overline{\overline{F}G} = \overline{F}\,\overline{G},\tag{Eq. 7}$$

where *F* as well as *G* are arbitrary fields, and *x* stands for any space coordinate. Clearly Eq. (6) is a special case of Eq. (7). An important consequence of Eqs. (4) and (7) is  $\overline{FG} = \overline{FG} + \overline{F'G'}$ .

As can easily be seen below, mean vector fields defined on the basis of a Cartesian coordinate system are well different from those defined, e.g., with respect to a cylindrical or a spherical coordinate system.

Giving now a few examples of averages we distinguish between "local" averages, for which  $\overline{F}$  in a given point depends only on the values of F in this point or a small neighborhood of it, and "nonlocal" averages.

#### (i) Local averages

1

;

(ia) *Statistical or ensemble averages*. In this case we suppose that there is an infinity of copies of the object considered. The individual copies are labeled by a parameter, say p. In that sense any quantity F

to be averaged depends, in addition to the space and time variables, x and t, on this parameter p. The average  $\overline{F}(x, t)$  is then defined by averaging F over all p. Averages of this kind clearly ensure the validity of all four rules Eqs. (4)–(7). There is, however, a serious difficulty to relate these averages to observable quantities.

(ib) Space averages. A general form of a space average is given by

$$\overline{F}(\mathbf{x},t) = \int_{\infty} F(\mathbf{x} + \boldsymbol{\xi}, t) g(\boldsymbol{\xi}) \, \mathrm{d}^{3} \boldsymbol{\zeta}, \quad \int_{\infty} g(\boldsymbol{\xi}) \, \mathrm{d}^{3} \boldsymbol{\zeta} = 1. \quad (\mathrm{Eq. 8})$$

Here  $g(\xi)$  is a normalized weight function which is different from zero only in some region around  $\xi = 0$ . The integrations, formally over all  $\xi$ -space, are in fact over this region only. With such averages the two rules Eqs. (4) and (5) apply exactly but in general Eqs. (6) and (7) are violated. The latter two can be justified as an approximation if there is a gap in the spectrum of the length scales of *F*, and all large scales are much larger, and all small ones much smaller than the characteristic length of the averaging region. A situation of that kind is sometimes named a "two-scale situation".

(ic) *Time averages*. Similar to space averages, we may define time averages by

$$\overline{F}(\mathbf{x},t) = \int_{\infty} F(\mathbf{x},t+\tau) g(\tau) \, \mathrm{d}\tau, \quad \int_{\infty} g(\tau) \, \mathrm{d}\tau = 1, \qquad \text{(Eq. 9)}$$

with some normalized weight function  $g(\tau)$  different from zero in some neighborhood of  $\tau = 0$ . The comments made under (ib) apply analogously.

## (ii) Nonlocal averages

(iia) Azimuthal average. There are, however, particular space averages to which all averaging rules apply. Consider, for example, a case in which the variation of F in space is properly described by spherical coordinates  $r, \theta, \varphi$ , and put

$$\overline{F}(r,\theta,t) = \frac{1}{2\pi} \int_0^{2\pi} F(r,\theta,\varphi,t) \,\mathrm{d}\varphi.$$
(Eq. 10)

This kind of average is used in particular in Braginsky's theory of the nearly symmetric dynamo. Of course, all mean-fields are by definition axisymmetric. All four rules Eqs. (4)–(7) apply exactly.

(iib) Averages based on filtering of spectra. We may, for example, represent F in its dependence on space coordinates by a Fourier integral and define  $\overline{F}$  by another integral of this type which covers only the large-scale part of the Fourier spectrum beyond some averaging scale. For averages defined in this way the three rules Eqs. (4)–(6) apply exactly, and with a sufficiently large gap in the spectrum and a proper choice of the averaging scale the remaining rule Eq. (7) can again be justified as an approximation. The azimuthal average defined by Eq. (10) can also be interpreted as one based on filtering a Fourier spectrum with respect to  $\varphi$ . Another interesting possibility consists, e.g., in filtering the multipole spectrum of vector fields so that the mean fields are just dipole fields, or dipole and quadrupole fields, etc.

## Basic mean-field equations

Returning to the Eqs. (1), (2), and (3), we understand now B, E, j, and u as superpositions of mean and fluctuating parts. Applying the averaging procedure to Eqs. (1) and (2) we obtain

$$\nabla \times \overline{E} = -\partial_t \overline{B}, \quad \nabla \times \overline{B} = \mu \overline{j}, \quad \nabla \cdot \overline{B} = 0$$
 (Eq. 11)

$$\boldsymbol{j} = \sigma(\boldsymbol{\overline{E}} + \boldsymbol{\overline{u}} \times \boldsymbol{\overline{B}} + \boldsymbol{\varepsilon}). \tag{Eq. 12}$$

From these equations, or taking the average of Eq. 
$$(3)$$
, we further obtain

$$\eta \nabla^2 \overline{\mathbf{B}} + \nabla \times (\overline{\mathbf{u}} \times \overline{\mathbf{B}} + \mathbf{\mathcal{E}}) - \partial_t \overline{\mathbf{B}} = 0, \quad \nabla \cdot \overline{\mathbf{B}} = 0.$$
 (Eq. 13)

 $\mathcal{E}$  is the mean electromotive force due to the fluctuations of motion and magnetic field,

$$\boldsymbol{\mathcal{E}} = \overline{\boldsymbol{u}' \times \boldsymbol{B}'}.$$
 (Eq. 14)

These equations together with proper initial and boundary conditions determine  $\overline{B}$  if  $\overline{u}$  and  $\mathcal{E}$  are given, and so also  $\overline{E}$  and  $\overline{j}$ .

The crucial point in the elaboration of mean-field electrodynamics is the determination of the mean electromotive force  $\mathcal{E}$  for given  $\overline{u}$ , u', and  $\overline{B}$ . Using Eqs. (3) and (13), an equation for the magnetic fluctuations B' can be derived. It allows us to conclude that B' can be considered as a functional of  $\overline{u}$ , u', and  $\overline{B}$ , which is linear in  $\overline{B}$ . Thus,  $\mathcal{E}$  must show the same dependence on these fields. For the sake of simplicity we restrict our attention to the case in which the magnetic fluctuations B' are due to the interaction of the velocity fluctuations u' with the mean magnetic field  $\overline{B}$  only, that is, decay to zero if  $\overline{B}$  is zero. In other words, the possibility of a magnetohydrodynamic turbulence with zero  $\overline{B}$  is ignored. Apart from some initial time, which is not considered here,  $\mathcal{E}$  is then not only linear but also homogeneous in  $\overline{B}$ , that is, has to vanish if  $\overline{B}$  does so. For the sake of simplicity we restrict our attention first to mean fields defined by local averages. Then it can be easily concluded that  $\mathcal{E}$  allows the representation

$$\mathcal{E}_{i}(\boldsymbol{x},t) = \int_{0}^{\infty} \int_{\infty} K_{ij}(\boldsymbol{x},t;\boldsymbol{\xi},\tau) \overline{B}_{j}(\boldsymbol{x}+\boldsymbol{\xi},t-\tau) \, \mathrm{d}^{3} \boldsymbol{\zeta} \, \mathrm{d}\tau, \quad (\mathrm{Eq. 15})$$

with some kernel  $K_{ij}$  determined by  $\overline{u}$  and u'. Here, and in what follows, indices like *i* and *j* refer to a Cartesian coordinate system and the summation convention is adopted.

Let us accept the further assumption that  $\mathcal{E}$  in a given point in space and time depends only on the values of u, u', and  $\overline{B}$  in some neighborhood of this point. This can easily be justified in the case of turbulent fluid motions but applies for most of the other situations of interest, too. Let us assume further that the variations of  $\overline{B}$  in space and time are weak enough so that its behavior in the relevant neighborhood of the considered point is to a good approximation determined by  $\overline{B}$ and its first spatial derivatives at this point. This implies that  $\mathcal{E}$  can be represented in the form

$$\mathcal{E}_i = a_{ij}\overline{B}_j + b_{ijk}\partial\overline{B}_j/\partial x_k, \qquad (\text{Eq. 16})$$

where the tensors  $a_{ij}$  and  $b_{ijk}$  are mean quantities which are determined by  $\overline{u}$  and u' but do not depend on  $\overline{B}$ . It remains of course to be checked in all applications that higher spatial derivatives or the time derivatives of  $\overline{B}$  are indeed negligible. Incidentally, as a consequence of  $\nabla \cdot \overline{B} = 0$ , three elements of  $b_{ijk}$  can be arbitrarily fixed.

In the case of a nonlocal, e.g., the azimuthal average in Eqs. (15) and (16) occur primarily in slightly different forms. We may, however, justify Eq. (16) as well.

Let us consider the simple (somewhat academic) example in which the mean motion is zero,  $\overline{u} = 0$ , and the fluctuations of the velocity field, u', correspond to a homogeneous isotropic turbulence. In this case, no preferred points in space and no preferred directions can be found in the u' field. In other words, all mean quantities depending on u' are invariant under arbitrary translations of the u' field and under arbitrary rotations of this field about arbitrary axes. Simple symmetry considerations allow us then to conclude that  $a_{ij}$  and  $b_{ijk}$  are isotropic tensors and are independent on position. That is,  $a_{ij} = \alpha \delta_{ij}$  and  $b_{ijk} = \beta \epsilon_{ijk}$ , where the coefficients  $\alpha$  and  $\beta$  are independent of position and determined by u' only, and  $\delta_{ij}$  and  $\epsilon_{ijk}$  are the Kronecker and the Levi-Civita tensors. This result allows us to write Eq. (16) in the form 7)

$$\boldsymbol{\mathcal{E}} = \alpha \overline{\boldsymbol{B}} - \beta \nabla \times \overline{\boldsymbol{B}}.$$
 (Eq. 1)

Together with Eqs. (11) and (12) this yields

$$\bar{\boldsymbol{j}} = \sigma_{\rm m}(\overline{\boldsymbol{E}} + \alpha \overline{\boldsymbol{B}}), \quad \sigma_{\rm m} = \frac{\sigma}{1 + \beta/\eta}.$$
 (Eq. 18)

That is, in Ohm's law for the mean fields occurs a mean-field conductivity  $\sigma_m$ , which (if  $\beta \neq 0$ ) differs from the molecular conductivity  $\sigma$ . In addition, there is (if  $\alpha \neq 0$ ) an electromotive force parallel (or antiparallel) to  $\overline{B}$ . This is remarkable as in the original form (Eq. (2)) of Ohm's law the magnetic field enters only via the term  $u \times B$ , which has no component in the direction of B. The occurrence of a mean electromotive force with a component in the direction of the mean magnetic field  $\overline{B}$  is called " $\alpha$ -effect."

The  $\alpha$ -effect makes a dynamo possible. As can be easily followed up, Eq. (13) for  $\overline{B}$  with  $\overline{u} = 0$  and  $\mathcal{E}$  specified according to Eq. (17) possesses growing solutions for proper choices of  $\eta$ ,  $\alpha$ , and  $\beta$ .

Under realistic circumstances an isotropic turbulence is also reflectionally symmetric ("mirror-symmetric") in the sense that there is no preference of left-handed over right-handed helical motions or vice versa. More precisely, all mean quantities are invariant under reflections of the u' field, e.g., at the origin of the coordinate system, that is, under exchanging u'(x,t) with -u'(-x,t). Symmetry considerations show then  $\alpha = 0$ . Although in a sense unrealistic, the simple example under discussion reveals the fundamental connection between the violation of reflectional symmetry of the turbulence and the  $\alpha$ -effect. The turbulence on a rotating body is neither homogeneous nor isotropic. Apart from the fact that reflectional symmetry in the above sense is anyway not compatible with inhomogeneity or anisotropy, it is in particular disturbed by the influence of the Coriolis force. Inhomogeneity and the violation of reflectional symmetry due to the Coriolis force lead again to an  $\alpha$ -effect similar to that discussed here and, as a consequence, to dynamo action.

Leaving this simple example and returning to arbitrary  $\overline{u}$  and the representation of  $\mathcal{E}$  in the form (Eq. (16)) we give an alternative representation of  $\mathcal{E}$ . The tensor  $a_{ij}$  may be split into a symmetric and an antisymmetric part, and the latter can be expressed by a vector. Likewise the gradient tensor  $\partial \overline{B}_j / \partial x_k$  can be represented by its symmetric part and a vector, which proves to be proportional to  $\nabla \times \overline{B}$ . Considering these possibilities we may write

$$\boldsymbol{\mathcal{E}} = -\boldsymbol{\alpha} \circ \boldsymbol{\overline{B}} - \boldsymbol{\gamma} \times \boldsymbol{\overline{B}} - \boldsymbol{\beta} \circ (\nabla \times \boldsymbol{\overline{B}}) - \boldsymbol{\delta} \times (\nabla \times \boldsymbol{\overline{B}}) - \boldsymbol{\kappa} \circ (\nabla \boldsymbol{\overline{B}})^{(s)}$$
(Eq. 19)

Here  $\boldsymbol{\alpha}$  and  $\boldsymbol{\beta}$  are symmetric second-rank tensors,  $\boldsymbol{\gamma}$  and  $\boldsymbol{\delta}$  vectors, and  $\boldsymbol{\kappa}$  is a third-rank tensor, all being determined by  $\boldsymbol{\overline{u}}$  and  $\boldsymbol{u}'$ . Further  $(\nabla \boldsymbol{\overline{B}})^{(s)}_{ij}$  is the symmetric part of the gradient tensor of  $\boldsymbol{\overline{B}}$ , that is,  $(\nabla \boldsymbol{\overline{B}})^{(s)}_{ij} = (1/2)(\partial \boldsymbol{\overline{B}}_i/\partial x_i + \partial \boldsymbol{\overline{B}}_j/\partial x_i)$ . Of course,  $\boldsymbol{\kappa}$  may be assumed to be symmetric in the indices connecting it with  $(\nabla \boldsymbol{\overline{B}})^{(s)}$ , and because  $\nabla \cdot \boldsymbol{\overline{B}} = 0$  three of its elements can be fixed arbitrarily.

Inserting  $\mathcal{E}$  according to Eq. (19) into Ohm's law Eq. (12), we may write the latter in the form

$$\overline{j} = \boldsymbol{\sigma}_{\mathrm{m}} \circ (\overline{\boldsymbol{E}} - \boldsymbol{\alpha} \circ \overline{\boldsymbol{B}} + (\overline{\boldsymbol{u}} - \boldsymbol{\gamma}) \times \overline{\boldsymbol{B}} - \boldsymbol{\delta} \times (\nabla \times \overline{\boldsymbol{B}}) - \boldsymbol{\kappa} \circ (\nabla \overline{\boldsymbol{B}})^{(s)})$$
(Eq. 20)

Here,  $\sigma_{\rm m}$  is a conductivity tensor incorporating the  $\beta$  term of Eq. (19) and being symmetric. Again, the mean electric current is no longer determined by the molecular conductivity, and the relation between mean current and mean electric field plus mean electromotive force is in general anisotropic. The  $\alpha$  term defines some generalization of the  $\alpha$ -effect discussed above, that is, an anisotropic  $\alpha$ -effect. The  $\gamma$  term corresponds to a transport of mean magnetic flux like that by a mean motion, which occurs however even in the absence of any mean motion. Clearly  $\overline{u} - \gamma$  is the effective velocity for the transport of mean flux. The  $\delta$  term

describes an induction effect, which was first found in the special case in which  $\boldsymbol{\delta}$  was proportional to an angular velocity  $\boldsymbol{\Omega}$  and has been called " $\boldsymbol{\Omega} \times \boldsymbol{j}$ -effect". The  $\boldsymbol{\kappa}$  term is less easy to interpret. Analogous to the notation  $\alpha$ -effect, we speak of " $\beta$ -effect", " $\delta$ -effect" etc. when referring to the induction effects described by the terms with  $\boldsymbol{\beta}$ ,  $\boldsymbol{\delta}$  etc. in Eqs. (19) or (20). By the way, we arrive at an alternative form of Ohm's law if we interpret  $\boldsymbol{\sigma}_{m}$  as tensor incorporating both the  $\boldsymbol{\beta}$  and  $\boldsymbol{\delta}$  terms and cancel the last ones otherwise. Then, however,  $\boldsymbol{\sigma}_{m}$  is no longer symmetric.

It is important to know the dependence of the quantities  $\alpha, \beta, \gamma, \delta$ , and  $\kappa$  on the fluid motion, that is, on  $\overline{u}$  and u'. Unfortunately there is no simple way to derive general results of that kind. A series of extended calculations have been carried out using specific approximations. Often the "second-order correlation approximation", also called the "first-order smoothing approximation", has been adopted, which, roughly speaking, can be justified only for u' not too large.

Assume for the sake of simplicity that  $\overline{u} = 0$  and u' represents a turbulence with a characteristic velocity  $u'_c$ , a correlation length  $\lambda_c$ , and a correlation time  $\tau_c$ . Define then the magnetic Reynolds number  $R_m = u'_c \lambda_c / \eta$ , the Strouhal number  $S = u'_c \tau_c / \lambda_c$ , and the quantity  $q = \lambda_c^2 / \eta \tau_c$ , Clearly q is the ratio of the characteristic time  $\lambda_c^2 / \eta$  for electromagnetic processes in a region with the length scale  $\lambda_c$  to the time  $\tau_c$ . In the high-conductivity limit, defined by  $q \gg 1$ , a sufficient condition for the applicability of the second-order correlation approximation reads  $S \ll 1$ . In the low-conductivity limit,  $q \gg 1$ , the corresponding sufficient condition is  $R_m \ll 1$ .

As an example we give here results for  $\alpha$  and  $\beta$  for the simple case in which u' corresponds to a homogeneous isotropic turbulence. In the high-conductivity limit,  $q \gg 1$ , this approximation yields

$$\alpha = -\frac{1}{3} \int_0^\infty \overline{\boldsymbol{u}'(\boldsymbol{x},t) \cdot (\nabla \times \boldsymbol{u}'(\boldsymbol{x},t-\tau))} \, \mathrm{d}\tau,$$
  
$$\beta = \frac{1}{3} \int_0^\infty \overline{\boldsymbol{u}'(\boldsymbol{x},t) \cdot \boldsymbol{u}'(\boldsymbol{x},t-\tau)} \, \mathrm{d}\tau,$$
 (Eq. 21)

or

$$\alpha = -\frac{1}{3}\overline{\boldsymbol{u}' \cdot (\nabla \times \boldsymbol{u}')}\tau_{\rm c}^{(\alpha)}, \quad \beta = \frac{1}{3}\overline{\boldsymbol{u}'}^2\tau_{\rm c}^{(\beta)}.$$
 (Eq. 22)

Here  $\tau_c^{(\alpha)}$  and  $\tau_c^{(\beta)}$  are primarily defined by equating the corresponding right-hand sides of Eqs. (21) and (22). It seems reasonable to assume that they do not differ markedly from  $\tau_c$ . For the low-conductivity limit,  $q \ll 1$ , it follows that

$$\alpha = -\frac{1}{12\pi\eta} \int_{\infty} \overline{\boldsymbol{u}'(\boldsymbol{x},t) \cdot (\nabla \times \boldsymbol{u}'(\boldsymbol{x}+\boldsymbol{\xi},t))} \, \frac{\mathrm{d}^{3}\xi}{\xi},$$
$$\beta = \frac{1}{12\pi\eta} \int_{\infty} \overline{\boldsymbol{u}'_{\xi}(\boldsymbol{x},t)\boldsymbol{u}'_{\xi}(\boldsymbol{x}+\boldsymbol{\xi},t))} \frac{\mathrm{d}^{3}\xi}{\xi}, \qquad (\mathrm{Eq.}\ 23)$$

where  $u'_{\xi} = (\boldsymbol{u}' \cdot \boldsymbol{\xi})/\xi$ . Interestingly enough, if  $\boldsymbol{u}'$  is represented in the form  $\boldsymbol{u}' = \nabla \times \boldsymbol{a}' + \nabla \phi'$  by a vector potential  $\boldsymbol{a}'$  and a scalar potential  $\phi'$  this can be rewritten into

$$\alpha = -\frac{1}{3\eta} \overline{\boldsymbol{a}' \cdot (\nabla \times \boldsymbol{a}')}, \quad \beta = \frac{1}{3\eta} (\overline{\boldsymbol{a}'^2} - \overline{\phi'^2}). \tag{Eq. 24}$$

With a reasonable assumption on  $\overline{u'_{\xi}(\mathbf{x},t)u'_{\xi}(\mathbf{x}+\boldsymbol{\xi},t)}$  it follows that  $\beta/\eta = (1/9)R_m^2$ . In the high-conductivity limit it is the mean helicity  $\overline{u' \cdot (\nabla \times u')}$ , in the low-conductivity limit the related quantity  $\overline{a' \cdot (\nabla \times a')}$ , which are crucial for the  $\alpha$ -effect. Both indicate the existence of helical features in the flow pattern and vanish for mirror-symmetric turbulence.

#### The kinematic dynamo problem

Let us consider the dynamo problem for a finite simply connected fluid body surrounded by electrically isolating matter (see also Dynamos, kinematic). Assume that the electromagnetic fields B and Esatisfy the Eqs. (1) and (2) inside this body and the same equations with  $\sigma = 0$  and therefore  $\mathbf{j} = 0$  in all outer space, further that **B** and the tangential components of E are continuous across the boundary, and finally that B and E vanish at infinity. All this can be reduced to the statement that the magnetic field B satisfies the Eq. (3) inside the body, continues as a potential field in outer space, and vanishes at infinity. The last-mentioned equations and requirements define an initial value problem for B. We speak of a dynamo if this problem for B with a given u possesses, for proper initial conditions, solutions which do not decay in the course of time, that is,  $B \neq 0$  as  $t \rightarrow \infty$ . Sometimes the notation "homogeneous dynamo" is used for dynamos as envisaged here in order to stress that they work, in contrast to technical dynamos, in bodies consisting throughout of electrically conducting matter, that is, not containing any electrically insulating parts.

It is well-known that dynamos cannot work with specific geometries of magnetic field or motion. In particular, Cowling's theorem excludes dynamos with magnetic fields *B* that are symmetric about an axis (see *Cowling's theorem*).

Simple examples of dynamos are those with spatially periodic flows of an infinitely extended fluid as proposed by Roberts already in 1970 (Roberts, 1970, 1972) (see also *Dynamos, periodic*). Assume, for example, that the fluid velocity  $\boldsymbol{u}$  is in a Cartesian coordinate system (x, y, z) given by  $\boldsymbol{u} = u_{\perp} \boldsymbol{a} \boldsymbol{e} \times \nabla \chi(x, y) + u_{\parallel} \boldsymbol{e} \chi(x, y)$  with  $\chi = \sin(\pi x/a) \sin(\pi y/a)$ , where  $\boldsymbol{e}$  is the unit vector in z direction and a is some length. This flow possesses helical features. It allows under some condition nondecaying magnetic fields  $\boldsymbol{B}$  varying like  $\boldsymbol{u}$  periodically in x and y and in addition with a period length, say l, in z. With magnetic Reynolds numbers defined by  $R_{m\perp} = u_{\perp} a/\eta$  and  $R_{m\parallel} = u_{\parallel} a/\eta$ , this condition reads  $R_{m\perp}R_{m\parallel}\phi(R_{m\perp}) \ge 8\pi a/l$ , where  $\phi$  is equal to unity in the limit  $R_{m\perp} \rightarrow 0$  and decays monotonically to zero with growing  $R_{m\perp}$ .

A useful tool in the investigation of dynamo models is the representation of vector fields like **B** or **u** as sums of poloidal and toroidal parts. If a field, say **F**, is symmetric about a given axis the poloidal part  $F^{P}$  and the toroidal one  $F^{T}$  are defined such that  $F^{P}$  lies completely in the meridional planes containing this axis and  $F^{T}$  is everywhere perpendicular to them. This definition can be extended in various ways to the general case, in which **F** is no longer necessarily axisymmetric. One possibility, which fits best to the situation with spherical objects, is to require that  $F^{P}$  and  $F^{T}$  allow the representations  $F^{P} = rU + \nabla V$ and  $F^{T} = r \times \nabla W$  with **r** being the radius vector and U, V, and W scalar functions of position. This is indeed a unique definition and generalizes the specific one given for the axisymmetric case (see, e.g., Krause *et al.*, 1980; Rädler, 2000). Then  $F^{P}$  is a specific three-dimensional field but  $F^{T}$  lies completely in spherical surfaces r = const.

## The kinematic dynamo problem at the mean-field level

Let us again assume that the fluid motion and so the electromagnetic fields, too, show small-scale parts in the sense explained above. Then it seems reasonable to take the average of all equations applying to fluid body and outer space mentioned in the above formulation of the dynamo problem. This means in particular that the mean magnetic field  $\overline{B}$  has to satisfy the Eq. (13) inside the fluid body, to continue as a potential field in outer space and to vanish at infinity. We speak of a "mean-field dynamo" if the problem for  $\overline{B}$  posed in this way has nondecaying solutions,  $\overline{B} \neq 0$  as  $t \to \infty$ . However, the notion "mean-field dynamo" has to be used with care. It does not refer to a real physical object but to a particular model of such an object only, which delivers a simplified picture of the real object. The existence

It is important to note that mean magnetic fields  $\overline{B}$  are not subject to Cowling's theorem. The proofs of this theorem cannot be repeated if Ohm's law Eq. (2) is replaced with its mean-field version Eq. (12). A possible exception is cases with  $\mathcal{E} \cdot \overline{B} = 0$ . Mean-field dynamos may thus well be axisymmetric. The deviation of B from axisymmetry, which is necessary for a dynamo, need not occur in  $\overline{B}$ . It is sufficient to have it in B'.

A simple illustration of a mean-field dynamo can be given on the basis of the spatially periodic dynamo mentioned above. When defining mean-fields by averaging over all values of x and y, we may derive an equation for  $\overline{B}$ , which implies an anisotropic  $\alpha$ -effect and allows growing solutions. This has been widely discussed in the context of the Karlsruhe dynamo experiment (see below).

#### Traditional mean-field dynamo models

Many mean-field dynamo models have been developed for various objects like the Earth and the planets, the Sun and several types of stars, or for galaxies. In almost all cases simple symmetries were assumed with respect to the shape of the conducting bodies, to the distributions of the electric conductivity and to the fluid motions.

Let us first formulate general assumptions of that kind. It is always supposed that a rotation axis and an equatorial plane perpendicular to it are defined. We assume that the shape of the fluid body and the distribution of the electric conductivity, or of the magnetic diffusivity, are

- symmetric about the rotation axis,
- symmetric about the equatorial plane,
- steady.

In addition we assume that all averaged quantities depending on the velocity field u, that is  $\overline{u} + u'$ , are invariant under

- rotations of *u* about the rotation axis,
- reflections of *u* about the equatorial plane,
- time shifts in *u*.

As the simplest consequence of these last assumptions, we note that the mean velocity  $\overline{u}$  is symmetric about both rotation axis and equatorial plane and steady. Another simple consequence is, e.g., that the mean helicity  $\overline{u' \cdot (\nabla \times u')}$  of the fluctuating motions as well as the related quantity  $\overline{a' \cdot (\nabla \times a')}$  mentioned above, which are of interest for the  $\alpha$ -effect, are symmetric about the rotation axis and steady but antisymmetric about the equatorial plane.

The assumptions introduced together with the Eq. (3) governing the magnetic field B also allow us far-reaching conclusions concerning the mean magnetic field  $\overline{B}$ .

- Firstly, if a field  $\overline{B}$  satisfies the relevant equations and conditions formulated above, the field  $\overline{B}^{\text{refl}}$ , which is generated by reflecting  $\overline{B}$  at the equatorial plane, satisfies them, too. The same applies to their sum or their difference, which are symmetric or antisymmetric, respectively, about the equatorial plane.
- Secondly, any field  $\overline{B}$  can be decomposed into its Fourier modes  $\Re(\hat{B}^{(m)} \exp(im\varphi))$  with respect to the azimuthal coordinate  $\varphi$ , where the  $\hat{B}^{(m)}$ , with nonnegative integer *m*, are complex vector fields symmetric about the rotation axis. Each individual Fourier mode of that kind again satisfies the relevant equations and conditions.
- Thirdly, the fields  $\overline{B}$  vary with time like  $\Re(\hat{B} \exp(pt))$  where  $\hat{B}$  is some complex vector field and p a complex constant, or are superpositions of such fields.

Taking these three findings together, we see that it is sufficient to look for solutions of the relevant equations and conditions having the form

$$\overline{\boldsymbol{B}} = \Re \Big( \widehat{\boldsymbol{B}}^{(m)} \exp(im\varphi + (\lambda + i\omega)t) \Big).$$
 (Eq. 25)

All further solutions can be gained by superposition of them. Now  $\hat{B}^{(m)}$  means a complex vector field being either antisymmetric or symmetric about the equatorial plane, symmetric about the rotation axis and steady; *m* is a nonnegative integer, and  $\lambda$  and  $\omega$  are real constants. We denote the solutions of the form Eq. (25) by A or S according to their antisymmetry or symmetry about the equatorial plane, and add the parameter *m* to characterize the symmetry with respect to the rotation axis. Examples of field patterns of A*m* and S*m* modes are given in Figure D29. The field of a dipole aligned with the rotation axis is of A0 type, that of an quadrupole symmetric about this axis is of S0 type. The field of a dipole perpendicular to this axis is of S1 type. Of course, dynamo-generated magnetic fields of the form Eq. (25) in general do not correspond to single multipoles but to superpositions of several multipoles with the same symmetry properties.

Clearly  $\lambda$  is the growth rate of the solution considered. A mean-field dynamo requires  $\lambda \ge 0$ . If  $\omega = 0$ , the solution varies monotonously with time; if  $\omega \ne 0$ , oscillatory. Axisymmetric modes, m = 0, with  $\omega \ne 0$  are intrinsically oscillatory. A nonaxisymmetric mode,  $m \ne 0$ , with  $\omega \ne 0$  has the form of a wave traveling in azimuthal direction. Its field configuration rotates rigidly with the angular velocity  $-\omega/m$  and is, of course, steady in a corotating frame of reference.

The axisymmetry of the mean velocity  $\overline{\boldsymbol{u}}$  allows us to split it into an axisymmetric circulation in meridional planes,  $\overline{\boldsymbol{u}}^{circ}$ , and an axisymmetric rotation,  $\overline{\boldsymbol{u}}^{rot}$ . The latter has in general the form of a differential rotation, that is  $\overline{\boldsymbol{u}}^{rot} = \omega \hat{\boldsymbol{\omega}} \times \boldsymbol{r}$ , where  $\omega$  is the angular velocity, which is axisymmetric and symmetric about the equatorial plane,  $\hat{\boldsymbol{\omega}}$  is the unit vector in axial direction and  $\boldsymbol{r}$  again the radius vector.

So far, no assumptions about the structure of  $\mathcal{E}$  have been used explicitly. Now we rely again on the assumption that  $\mathcal{E}$  in a given point depends on  $\overline{B}$  and its first spatial derivatives in this point only, and so on relation Eq. (19). Of course the assumptions made above about the symmetries of the distribution of the magnetic diffusivity and of the motion have consequences for the quantities  $\alpha, \beta, \gamma, \delta$ , and  $\kappa$ .

In order to formulate these consequences properly we introduce in addition to the unit vector  $\hat{\boldsymbol{\omega}}$  in axial direction another vector,  $\hat{\boldsymbol{g}}$ , describing another preferred direction in the fluctuating velocity

**Figure D29** Schematic representation of poloidal magnetic field lines of A0, S0, A1 and S1 modes in meridional planes of spherical bodies. In the case of A0 and S0 modes the patterns agree for all such planes. In the case of the A1 and S1 modes those planes have been chosen which are not crossed by field lines.

field. We may identify  $\hat{g}$ , e.g., with the unit vector in the direction opposite to the gravitational force but put it equal to zero where no such a direction can be defined. Whereas  $\hat{\omega}$  is independent of position,  $\hat{g}$  may vary in space but is symmetric about the rotation axis and the equatorial plane. We write

$$\begin{aligned} \alpha_{ij} &= \alpha_1(\hat{\boldsymbol{\omega}} \cdot \hat{\boldsymbol{g}}) \delta_{ij} + \alpha_2(\hat{\boldsymbol{\omega}} \cdot \hat{\boldsymbol{g}}) \hat{g}_i \hat{g}_j + \alpha_3(\hat{\boldsymbol{\omega}} \cdot \hat{\boldsymbol{g}}) \hat{\omega}_i \hat{\omega}_j \\ &+ \alpha_4(\hat{\omega}_i \hat{g}_j + \hat{\omega}_j \hat{g}_i) + \alpha_5(\hat{\boldsymbol{\omega}} \cdot \hat{\boldsymbol{g}}) (\hat{g}_i \hat{\lambda}_j + \hat{g}_j \hat{\lambda}_i) + \alpha_6(\hat{\omega}_i \hat{\lambda}_j + \hat{\omega}_j \hat{\lambda}_i) \\ (\text{Eq. 26}) \end{aligned}$$

$$\begin{aligned} \beta_{ij} &= \beta_1 \delta_{ij} + \beta_2 \hat{g}_i \hat{g}_j + \beta_3 \hat{\omega}_i \hat{\omega}_j + \beta_4 (\hat{\boldsymbol{\omega}} \cdot \hat{\boldsymbol{g}}) (\hat{\omega}_i \hat{g}_j + \hat{\omega}_j \hat{g}_i) \\ &+ \beta_5 (\hat{g}_i \hat{\lambda}_j + \hat{g}_j \hat{\lambda}_i) + \beta_6 (\hat{\boldsymbol{\omega}} \cdot \hat{\boldsymbol{g}}) (\hat{\omega}_i \hat{\lambda}_j + \hat{\omega}_j \hat{\lambda}_i) \end{aligned} \tag{Eq. 27}$$

$$\gamma_i = \gamma_1 \hat{g}_i + \gamma_2 (\hat{\boldsymbol{\omega}} \cdot \hat{\boldsymbol{g}}) \hat{\omega}_i + \gamma_3 \hat{\lambda}_i$$
 (Eq. 28)

$$\delta_i = \delta_1(\hat{\boldsymbol{\omega}} \cdot \hat{\boldsymbol{g}})\hat{g}_i + \delta_2\hat{\omega}_i + \delta_3(\hat{\boldsymbol{\omega}} \cdot \hat{\boldsymbol{g}})\hat{\lambda}_i \tag{Eq. 29}$$

where  $\hat{\lambda} = \hat{\omega} \times \hat{g}$ . As for  $\kappa$  we note that  $\kappa \circ (\nabla \overline{B})^{(s)}$  can be represented as a sum of the four contributions  $\beta^g \circ V^g, \beta^\omega \circ V^\omega, \delta^g \times V^g$ , and  $\delta^\omega \times V^\omega$  with  $\beta^g, \beta^\omega, \delta^g$ , and  $\delta^\omega$  analogous to  $\alpha, \beta, \gamma$ , and  $\delta$ , respectively, where  $V^g = (\nabla \overline{B})^{(s)} \circ \hat{g}$  and  $V^\omega = (\nabla \overline{B})^{(s)} \circ \hat{\omega}$ . Again, three elements of the tensors resulting from  $\kappa$  may be fixed arbitrarily. The assumptions introduced above just require that the coefficients  $\alpha_1, \alpha_2, \ldots \delta_3$  as well as  $\beta_1^g, \beta_2^g, \ldots \delta_3^\omega$  are symmetric about the rotation axis and the equatorial plane and are steady.

Comparing  $\mathcal{E}$  as obtained for homogeneous isotropic turbulence and given in Eq. (17) with our results Eq. (19) and Eqs. (26) to (29) we see that the contribution  $\alpha \overline{B}$  there, describing the isotropic  $\alpha$ -effect, corresponds to  $-\alpha_1(\hat{\omega} \cdot \hat{\mathbf{g}})\overline{B}$  here, which is however accompanied by other contributions causing an anisotropy of the  $\alpha$ -effect. We will use the notation  $\alpha$  in the following also in the sense of  $\alpha = -\alpha_1(\hat{\omega} \cdot \hat{\mathbf{g}})$ . Clearly  $\alpha$  is then, in contrast to  $\alpha_1$ , antisymmetric about the equatorial plane.

#### Basic dynamo mechanisms

In all dynamo models investigated so far, in which poloidal and toroidal parts of the magnetic field can be defined, dynamo action occurs due to an interplay between these parts. This applies to dynamos in the original sense as well as to mean-field dynamos. So the various mean-field dynamo mechanisms can be characterized by the induction processes, which are dominant in the generation of the poloidal field from the toroidal one and vice versa.

In the following discussion always rotating bodies are considered. In the case of a rigid-body rotation we use a corotating frame of reference in which  $\bar{\boldsymbol{u}}^{\rm rot} = 0$ . Nevertheless the rotation occurs in  $\boldsymbol{\mathcal{E}}$  via the Coriolis force. It is in particular important for the  $\alpha$ -effect. In general we also refer to a somehow fixed rotating frame of reference, in which  $\bar{\boldsymbol{u}}^{\rm rot} = \omega \hat{\boldsymbol{\omega}} \times \boldsymbol{r}$  with an angular velocity  $\omega$  depending on position. Clearly  $\omega$  depends on the choice of the frame whereas  $\nabla \omega$  is independent of it.

#### (i) The $\alpha^2$ and $\alpha\omega$ mechanisms

The  $\alpha$ -effect is capable of generating both a poloidal field from a toroidal one and also a toroidal field from a poloidal one. This is the basis of the " $\alpha^2$  mechanism". Figure D30 demonstrates it for a spherical body and axisymmetric magnetic fields of dipole and quadrupole type, that is, A0 and S0 modes. For the sake of simplicity no other contribution to the electromotive force  $\mathcal{E}$  is considered than  $\alpha \overline{B}$  with  $\alpha > 0$  in the northern and  $\alpha < 0$  in the southern hemisphere. As can be readily followed up in the figure, the  $\alpha$ -effect with the toroidal field leads to toroidal currents which just support the poloidal field. Likewise the  $\alpha$ -effect with the poloidal field results in poloidal currents, which in turn support the toroidal field. In this way, a sufficiently strong  $\alpha$ -effect is able to maintain magnetic fields with the configurations envisaged,

**Figure D30** Axisymmetric poloidal and toroidal magnetic field configurations of dipole and quadrupole type as can be maintained by an  $\alpha^2$  mechanism ( $\partial \omega / \partial r = 0$ ) or an  $\alpha \omega$  mechanism.

**Figure D31** The effect of differential rotation on an axisymmetric poloidal magnetic field. It is assumed that the surface of the fluid body is at rest and the inner parts rotate in the indicated way. A field line given initially by the dotted line in a meridional plane occurs later in the form of the solid line. The magnetic field that results from the action of differential rotation on an axisymmetric poloidal field can be understood as an superposition of the original poloidal field and an additional axisymmetric toroidal field.

or make them grow. If the signs of  $\alpha$  are inverted the orientation of either the poloidal or the toroidal fields have to be inverted, too. As a rule, the axisymmetric magnetic fields generated by the  $\alpha^2$  mechanism are nonoscillatory. The  $\alpha^2$  mechanism may work with nonaxisymmetric magnetic fields as well, that is, may support also A1, S1, A2, S2, ... modes. In all cases the poloidal and the toroidal parts of the fields are of the same order of magnitude.

The  $\alpha^2$  mechanism can be modified by differential rotation, that is, by a gradient of  $\omega$ . As illustrated by Figure D31 a differential rotation generates an axisymmetric toroidal magnetic field from a given axisymmetric poloidal one. The ratio of the magnitude of the toroidal to that of the poloidal field can be arbitrarily high if only the rotational shear is sufficiently strong. So the differential rotation modifies the generation of the toroidal field by the  $\alpha$ -effect. A very strong differential rotation can even dominate the generation of this field. In this case we speak of an " $\alpha\omega$  mechanism". It depends on details of the  $\alpha$ -effect and the rotational shear whether this mechanism supports preferably an A0 or an S0 mode, and whether this mode is oscillatory or non-oscillatory. The toroidal field is always much stronger than the poloidal one. With nonaxisymmetric fields the effect of differential rotation is more complex. Their structure is changed in such a way that they are subject to dissipation more heavily, and the ratio of the magnitudes of toroidal and poloidal field is therefore bounded. That is why the  $\alpha\omega$  mechanism is not effective with non-axisymmetric magnetic fields, that is, with Am or Sm modes with  $m \ge 1$ .

In general, of course, both  $\alpha$ -effect and differential rotation take part in the generation of the toroidal field. This case is sometimes labelled as " $\alpha^2 \omega$  mechanism", the case of a negligible influence of the  $\alpha$ -effect on the generation of the toroidal field as "pure  $\alpha \omega$  mechanism."

Since the end of the 1960s a large number of spherical and other dynamo models working with these mechanisms have been studied, taking into account various contributions to the mean electromotive force  $\mathcal{E}$  and various forms of the mean velocity  $\overline{u}$ , and considering both axisymmetric and nonaxisymmetric magnetic fields. The results have been summarized at several places (e.g., Krause *et al.* 1980; Rädler 1980, 1986, 1995, 2000). We note here only a few facts which are of particular interest for the geodynamo.

In simple models with  $\alpha^2$  mechanism the excitation conditions for A0, S0, A1, and S1 modes are in general close together, whereas the A2, S2, A3, S3, ... modes are less easily excitable. As already mentioned, the axisymmetric modes, A0 and S0, are in almost all cases non-oscillatory. The nonaxisymmetric ones show, depending on the specific form of the  $\alpha$ -effect, either eastward or westward migrations. With a fairly isotropic  $\alpha$ -effect in general one of the axisymmetric modes is slightly preferred over all others. Anisotropies of the  $\alpha$ -effect, also the presence of the  $\gamma$ -effect, lead to preferences of the A1 or S1 mode over all others. In particular the anisotropy of the  $\alpha$ -effect due to rapid rotation of the fluid body acts in this sense. That is, under realistic conditions the  $\alpha^2$  mechanism may well favor non-axisymmetric magnetic field structures. Incidentally, the isotropic  $\alpha$ -effect together with a weak differential rotation may also lead to a preference of A1 or S1 modes.

As explained above, a pure  $\alpha\omega$  mechanism supports only A0 or S0 modes. Which of them is preferably excited, and whether or not it is oscillatory, proved to depend indeed on the distribution of  $\alpha$ -effect and rotational shear. For the pure  $\alpha\omega$  mechanism, anisotropies of the  $\alpha$ -effect play a minor part. In the transition region between the  $\alpha^2$  mechanism and the pure  $\alpha\omega$  mechanism, that is, with the  $\alpha^2\omega$  mechanism, the situation is even more complex.

#### (ii) Mechanisms without $\alpha$ -effect

In addition to the  $\alpha$ -effect dynamo mechanisms explained so far, other mechanisms due to induction effects covered by the electromotive force  $\mathcal{E}$  in combination with differential rotation proved to be possible.

The contribution  $-\boldsymbol{\beta} \circ (\nabla \times \overline{\boldsymbol{\beta}})$  with an anisotropic tensor  $\boldsymbol{\beta}$  produces in general also poloidal magnetic fields from toroidal ones and vice versa. Under the reasonable assumption that the mean-field conductivity tensor  $\boldsymbol{\sigma}_m$ , which is determined by  $\boldsymbol{\beta}$ , is positive definite, however, a dynamo due to this contribution alone can be excluded. Remarkably enough, a particular contribution to  $\boldsymbol{\beta}$ , that is, the one with  $\beta_5$  in Eq. (27), together with differential rotation allows the generation of axisymmetric magnetic fields of both A0 and S0 types. That contribution to  $\boldsymbol{\beta}$  occurs due to the Coriolis force.

Likewise the contribution  $-\delta \times (\nabla \times \overline{B})$  implies couplings between poloidal and toroidal magnetic fields. Simple energy arguments show that this induction effect alone is not capable of dynamo action. However, the combination of that contribution with a differential rotation may again work as a dynamo for axisymmetric magnetic fields, that is, for such of A0 and S0 types. In the first investigations of dynamos of that kind a specific  $\delta$  was considered, given simply by the  $\delta_2$  term in Eq. (29). As explained above the induction effect defined by this specific  $\delta$  is called " $\Omega \times j$ -effect". Therefore the corresponding dynamo is sometimes labeled as " $\Omega \times j$  dynamo."

Incidentally, also the contribution  $-\kappa \circ (\nabla \overline{B})^{(s)}$  describes induction effects, which together with differential rotation might lead to dynamo action, or modify the dynamo mechanisms discussed before.

A few studies of these dynamo mechanisms without  $\alpha$ -effect have been carried out in spherical models (see, e.g., Krause *et al.*, 1980; Rädler, 1986, 1995, 2000).

## Mean-field magnetohydrodynamics and dynamically consistent dynamo models

## Mean-field magnetohydrodynamics

The mean-field concept, so far applied to the basic electrodynamic equations, can be extended to the equations of fluid dynamics, too. In the case of incompressible fluids these are the momentum balance, that is the Navier-Stokes equation, with the Lorentz force involved, and the mass balance, that is the continuity equation. In a rotating frame of reference they read

$$\begin{split} \varrho(\partial_t \boldsymbol{u} + (\boldsymbol{u} \cdot \nabla)\boldsymbol{u}) &= -\nabla p + \varrho v \nabla^2 \boldsymbol{u} - 2\varrho \boldsymbol{\Omega} \times \boldsymbol{u} \\ &+ (1/\mu) (\nabla \times \boldsymbol{B}) \times \boldsymbol{B} + \boldsymbol{F}, \quad \nabla \cdot \boldsymbol{u} = \boldsymbol{0}, \end{split}$$
(Eq. 30)

where  $\rho$  is the mass density of the fluid, *p* the hydrodynamic pressure, *v* the kinematic viscosity,  $\Omega$  the angular velocity describing the Coriolis force, and *F* some external force. For compressible fluids, apart from slight changes in these equations, the equation of state and in general also a thermodynamic equation, e.g. the heat conduction equation, have to be added.

Subjecting also the equations of fluid dynamics to averaging we arrive at mean-field magnetohydrodynamics. As we have seen above, in mean-field electrodynamics the basic equations for the mean-fields agree formally with those for the original fields with the exception that an additional mean electromotive force  $\mathcal{E}$  occurs,  $\mathcal{E} = \overline{u' \times B'}$ . In the case of an incompressible homogeneous fluid, to which attention is restricted in the following, this applies analogously to all mean-field magnetohydrodynamics. Starting from Eq. (30) we find

$$\begin{split} \varrho(\partial_t \overline{\boldsymbol{u}} + (\overline{\boldsymbol{u}} \cdot \nabla)\overline{\boldsymbol{u}}) &= -\nabla \overline{p} + \varrho v \nabla^2 \overline{\boldsymbol{u}} - 2\varrho \boldsymbol{\Omega} \times \overline{\boldsymbol{u}} \\ &+ (1/\mu) (\nabla \times \overline{\boldsymbol{B}}) \times \overline{\boldsymbol{B}} + \overline{\boldsymbol{F}} + \boldsymbol{\mathcal{F}}, \quad \nabla \cdot \overline{\boldsymbol{u}} = 0, \end{split}$$
(Eq. 31)

with a mean ponderomotoric force  $\mathcal{F}$  given by

$$\boldsymbol{\mathcal{F}} = -\varrho \overline{(\boldsymbol{u}' \cdot \nabla)\boldsymbol{u}'} + (1/\mu) \left( \overline{(\boldsymbol{B}' \cdot \nabla)\boldsymbol{B}'} - (1/2)\nabla \overline{\boldsymbol{B}'}^2 \right). \quad (\text{Eq. 32})$$

An alternative representation of  $\mathcal{F}$  is  $\mathcal{F}_i = \partial(V_{ij} + M_{ij})/\partial x_j$ , where  $V_{ij} = -\rho \overline{u'_i u'_j}$  is the Reynolds stress tensor and  $M_{ij} = (1/\mu)(\overline{B'_i B'_j} - (1/2)\overline{B'^2} \delta_{ij})$  the average of the Maxwell stress tensor formed with the magnetic fluctuations.

In mean-field magnetohydrodynamics the two quantities  $\mathcal{E}$  and  $\mathcal{F}$  play a central role. The fluctuating motion, u', is no longer considered as given but assumptions about its causes, e.g. instabilities, are made. It seems reasonable to evade detailed investigations on these causes by assuming a fluctuating force, say F', that drives these motions. Then u' and also B' are determined by this force and by  $\overline{u}$  and  $\overline{B}$ . So, as a matter of principle,  $\mathcal{E}$  and  $\mathcal{F}$  can be calculated for a given force F' as functionals of  $\overline{u}$  and  $\overline{B}$ . Eqs. (13) and (31), completed by relations connecting  $\mathcal{E}$  and  $\mathcal{F}$  with  $\overline{u}$  and  $\overline{B}$ , govern the behavior of  $\overline{u}$  and  $\overline{B}$ .

For sufficiently weak variations of  $\overline{B}$  in space and time  $\mathcal{E}$  can again be represented in the form of Eq. (16) or of Eq. (19). But the quantities  $a_{ij}$ ,  $b_{ijk}$  or  $\alpha$ ,  $\beta$ ,... are then no longer independent of  $\overline{B}$ . As a consequence of the action of the Lorentz force on the fluctuating motion, apart from an indirect influence via the mean motion, their tensorial structures and the magnitudes of the tensor elements depend on  $\overline{B}$ and its derivatives. For example, the  $\alpha$ -effect is in general reduced. This fact is called " $\alpha$ -quenching". Likewise corresponding influences on  $\beta$ , or  $\sigma$ , are sometimes labeled as " $\beta$ -quenching", etc.

We refer also to more comprehensive representations of mean-field magnetohydrodynamics (e.g., Rädler, 2000) and more specific results concerning  $\mathcal{E}$  or  $\mathcal{F}$  (e.g., Rüdiger *et al.*, 1993; Blackman, 2002; Blackman *et al.*, 2002).

## Dynamically consistent mean-field dynamo models

When proceeding from a kinematic dynamo model to a dynamically consistent one the electrodynamic Eqs. (1) and (2), or (3), applying inside the fluid body, have to be completed by the momentum balance and the mass balance as given by Eq. (30). These equations, together with proper conditions concerning the continuation of the electromagnetic field in outer space and with boundary conditions for the hydrodynamic quantities, pose a new, more complex initial value problem, which defines in particular B and u if F is given. The problem is nonlinear in both B and u. Whereas in the corresponding kinematic dynamo problem, which is linear in B, the magnitude of B remains undetermined, now the magnitudes of both B and u are fixed.

At the mean-field level the full dynamo problem has to be formulated on the basis of the mean-field Eqs. (13) and (31) and relations connecting  $\mathcal{E}$  and  $\mathcal{F}$  with  $\overline{B}$  and  $\overline{u}$ . A first step toward dynamically consistent mean-field dynamo models in that sense are models which consider as in the kinematic case the electrodynamic mean-field equations only but introduce there a dependence of quantities like  $\alpha$  or  $\beta$  on  $\overline{B}$ , that is,  $\alpha$  or  $\beta$  quenching. As a rule,  $\alpha$ -quenching limits the growth of the magnetic field. On this level several studies on the stability of dynamo-generated magnetic field configurations have been carried out (e.g., Rädler *et al.*, 1990). Using indeed the full set of electrodynamic and fluiddynamic equations, in several examples the coupled evolution of the mean magnetic field and the mean motions have been studied (e.g., Hollerbach, 1991).

#### Mean-field models of the geodynamo

#### Simple mean-field models

As mentioned above, the great breakthrough in our understanding of the geodynamo came with Braginsky's theory of the nearly symmetric dynamo and the findings of mean-field electrodynamics. The first mean-field dynamo model which was discussed in view of the Earth, an  $\alpha^2$  model, has been proposed by Steenbeck and Krause in 1969 (Steenbeck et al., 1969). A series of similar models were investigated and discussed later on. Whereas the mentioned first mean-field model and some of the following ones considered only axisymmetric magnetic fields, also nonaxisymmetric ones were included in later models (Rädler, 1975; Rüdiger, 1980; Rüdiger et al., 1994). In this way some understanding could be developed not only for the small deviations of the Earth's magnetic field from axisymmetry and for their drifts, but also for the much larger deviations of the magnetic fields of some planets from axisymmetry, in particular of Uranus and Neptune (Rüdiger et al., 1994). The tendency of differential rotation to reduce nonaxisymmetric parts of magnetic fields led to the suggestion that it is not too strong in the interiors of the objects mentioned. A strong differential rotation, however, could be an explanation for the high degree of axisymmetry of the Saturnian magnetic field.

#### On the applicability of the mean-field concept

For the crude models of the geodynamo and of planetary dynamos addressed so far more or less plausible assumptions were made on the validity of the results of mean-field electrodynamics to the Earth's and planetary interiors. For a more detailed elaboration of such models the applicability of the mean-field concept to these dynamo problems has to be checked carefully.

First of all, a proper averaging procedure has to be adopted which ensures at least the approximate validity of Reynolds' rules. As mentioned above, statistical averages satisfy Reynolds' rules exactly but their relation to measurable quantities is unclear. A spatial average in the sense of Eq. (8) is very problematic. There is no indication of a clear gap in the spectrum of length scales of the motions in the outer core of the Earth, which are relevant for the geodynamo process. That is, there is hardly a possibility to ensure the validity of Reynolds' rules. With the time average in the sense of Eq. (9) the situation is similar. It allows us only to study the long-term behavior of the magnetic field, that is, the behavior on time scales, which are very long compared with the characteristic time scales of motions in the liquid core. Otherwise the validity of Reynolds' rules is unsure. For several purposes the azimuthal average defined by Eq. (10) can be used, which satisfies these rules exactly. In this case, however, the mean fields are by definition axisymmetric. The investigation of any nonaxisymmetric structures in the geomagnetic field is excluded from the very beginning. In addition the averages are in general not really smooth with respect to the remaining space coordinates and to time. If the fluid motion is of a stochastic nature, the mean electromotive force  $\mathcal{E}$  and the mean magnetic field  $\overline{B}$  show certain stochastic features too. This applies the more the smaller the number of elements of motion, that is, of eddies or cells, along an averaging circle is. (This aspect is more important for the Earth rather than, e.g., the Sun.) Fairly smooth mean fields would occur only after an additional averaging with respect to the remaining space coordinates or time. The combination of azimuthal averaging with this additional averaging would define a new average, which, of course, can satisfy Reynolds' rules again only approximately.

Already these considerations show that the mean-field concept, although very useful in several respects, is far from being an ideal tool for studying the geodynamo or planetary dynamos. In addition, it remains to be checked whether the standard assumptions of mean-field electrodynamics, in particular the dependence of  $\mathcal{E}$  on  $\overline{\mathcal{B}}$  and its first derivatives only, indeed apply in a given model, or have to be replaced by more general assumptions.

## The mean-field concept and direct numerical simulations

As already mentioned the mean-field concept was helpful in designing models for direct numerical simulations of the geodynamo process (see Geodynamo, numerical simulations). In such models parameters like the Ekman number  $E = v/\Omega R^2$  or the magnetic Prandtl number  $P_{\rm m} = v/\eta$  play an important role; v and  $\eta$  are again kinematic viscosity and magnetic diffusivity,  $\Omega$  the angular velocity of rotation and R the radius of the core. With realistic molecular values of v and  $\eta$  the parameters E and  $P_{\rm m}$  are extremely small, typically  $E = 10^{-16}$  and  $P_{\rm m} = 10^{-6}$ . Such values do not allow to solve the numerical problem with the available computing power. One way out is to understand the underlying equations as mean-field equations based on a "low-level averaging," that is, on averaging over small lengths or short times, and to replace v and  $\eta$  by the corresponding mean-field quantities. In this way the requirements concerning the computing power are reduced. The direct numerical simulations done so far rest on a specific mean-field concept with "low-level averaging" in the above sense (Roberts et al., 2000; Kono et al., 2002).

At the same time the mean-field concept, now again understood in the usual sense, is a valuable tool for the interpretation of the results of direct numerical simulations. Adopt, e.g., azimuthal averaging. The coefficients which determine the mean electromotive force  $\mathcal{E}$ , that is  $\alpha, \beta, \gamma \dots$ , and the mean velocity  $\overline{u}$  can be extracted from the numerical results (Schrinner *et al.*, 2005, 2006). They depend, of course, on the remaining space coordinates and on time (and should perhaps be smoothed in space or time). In this way a mean-field model corresponding to that used for the direct numerical simulation can be constructed. It can tell us, which processes are dominant in the dynamo, whether the dynamo is of  $\alpha^2$  or of  $\alpha\omega$  type, to what extent other dynamo mechanisms are important, etc. (Possibly future investigations of this kind will also give some insight in the processes relevant for reversals of the magnetic field.)

#### Secular variation and reversals

As explained above, when using the azimuthal average and assuming fluid motions of stochastical nature, the electromotive force  $\mathcal{E}$  and so the  $\alpha, \beta, \gamma, \ldots$ , the mean velocity  $\overline{u}$  as well as the mean magnetic field  $\overline{B}$  show stochastical features, too. On this basis a simple model

of the geodynamo has been constructed by Hoyng, Ossendrijver and Schmitt, which is of interest in view of its time behavior (Hoyng *et al.*, 2001; Schmitt *et al.*, 2001; Hoyng *et al.*, 2002). In this model no other induction effect than the  $\alpha$ -effect, with a stochastically varying  $\alpha$ , is taken into account. The geodynamo occurs then as a bistable oscillator, in which the amplitude of the fundamental nonoscillatory dipolar dynamo mode performs a random walk in a bistable potential. The potential wells represent the normal and reversed polarity states, and the potential hill between the states is due to supercritical excitation. A random transition across the central potential hill corresponds to a reversal. Many features of the secular variation and reversal statistics can be modeled in this way.

### Laboratory experiments on dynamos

In 1999 the first two experimental devices aimed at realizing homogeneous dynamos have run successfully, one in Riga, Latvia, and the other in Karlsruhe, Germany (see Dynamos, experimental). In the Riga device a dynamo of Ponomarenko type has been realized (Gailitis et al., 2000, 2001). The Karlsruhe device was designed to simulate in a rough way the dynamo process in the Earth's core (Busse, 1975, 1992; Müller et al., 2000; Stieglitz et al., 2001, 2002). The flow pattern was chosen with a view to the convection rolls assumed in the outer core of the Earth (Busse, 1970). It is in fact some modification of a pattern periodic with respect to two Cartesian coordinates, whose capability of dynamo action has been demonstrated by Roberts already in 1970 (Roberts, 1970, 1972). This flow pattern suggests a meanfield formulation of the corresponding dynamo problem. Indeed, a mean-field theory of the Karlsruhe experiment has been developed, the central element of which is an anisotropic  $\alpha$ -effect. Its predictions concerning the excitation condition of the dynamo and the geometrical structure of the generated magnetic fields as well as the behavior of the dynamo in the nonlinear regime have been well confirmed by the measured data (Rädler et al., 1998, 2002a,b,c).

## DYNAMOS, PERIODIC

A periodic dynamo sustains a magnetic field by fluid flow that repeats periodically either in space or time. Consider spatially periodic dynamos first. Their flows are best described in terms of a lattice. A simple, two-dimensional flow that repeats in both y and z coordinates in shown on the left in Figure D32. The flow consists of rolls confined to rectangular cells. The roll structure by itself does not generate a magnetic field (Busse, 1973); dynamo action does result, however, with the addition of a shear flow in the x-direction. This flow was investigated by G.O. Roberts in his PhD thesis of 1969, with supervisor H.K. Moffatt. He showed that most periodic flows are capable of generating magnetic fields. This came at a time when very few examples of homogeneous dynamo action was known, and was an important step forward toward our present view that almost any sufficiently complicated and vigorous flow will generate magnetic fields. Of more lasting consequence, probably, was the use of the mathematical techniques that allowed G.O. Roberts to prove dynamo action.

Dynamo action only occurs for sufficiently large magnetic Reynolds number,  $R_m = \mu_0 lV\sigma$  (see *Geodynamo, dimensional analysis and timescales*), where *l* is the length scale, *V* a measure of the velocity magnitude,  $\sigma$  the electrical conductivity, and  $\mu_0$  the permeability. By their very definition, periodic flows are infinite in extent. The only length scale is therefore the repeat wavelength of the lattice, *l*. Since dynamo action depends only on  $R_m$ , only the product  $l\sigma$  is relevant. This allowed Roberts (1972a) to claim dynamo action at almost all values of the conductivity: reduced conductivity can be compensated for by simply increasing the length scale of the flow.

**Figure D32** Two simple periodic motions that generate magnetic fields. *Left:*  $v = (\cos y - \cos z, \sin z, \sin y)$ ; signs +/- indicate sign of *x*-component. The streamlines are all right-handed helices, the flow is maximally helical. *Right:*  $v = (2 \cos y \cos z, \sin z, \sin y)$ . The shear flow in the *x*-direction is now maximal at the corners of the cells. This flow has zero net helicity; the streamlines are closed.

Spatially periodic dynamos operate in two steps. Starting from a magnetic field whose length scale is much greater than the period of the flow's lattice,  $B_0$ , the flow induces a magnetic field B', with the same length scale as the lattice, *l*. Action of the same flow on B' reinforces the original field by induction. At first it seems surprising that small-scale flow can produce a large-scale field from B'; it arises from each roll twisting the field into the same direction in each lattice cell. Mathematically, the induction arises from  $v \times B$ , and the average  $v' \times B'$  contributes to a large-scale field. The simple trigonometric formula  $\cos^2 kx = 0.5(1 + \cos 2kx)$  shows that products of small-scale quantities produce large-scale quantities (the 0.5) as well as small-scale ones (the 0.5 cos 2kx). Here  $k = 2\pi/l$  may be thought of as the wavenumber for the flow.

The mathematical theory for periodic dynamos was initiated by Childress (1969) and developed further by Roberts (1972a). It involves the solution of differential equations with periodic coefficients. Floquet's theorem is central to the treatment of these equations; it states that the solution is a periodic function, with the same period as the coefficients, in this case the period of the flow, multiplied by an exponential factor exp iqx. For a 3-dimensional solution the factor is  $\exp i\mathbf{j} \cdot \mathbf{x}$ . The Floquet parameter, q, is a wavenumber (j is a wavevector) that must be found by solving the equations, just as an eigenvalue must be found by solving the characteristic equation of a matrix. It defines a second length scale,  $L = 2\pi/q$ . In three dimensions the theory is analogous to that of Bloch waves for electrons in solids (Gubbins, 1974). The periodic part of the solution may be expanded in an appropriate Fourier series, which converts the differential equation to a set of algebraic equations. These algebraic equations are then solved for the Fourier coefficients, which provides the complete solution.

The induction term  $v \times B$  involves the product of two periodic functions, which transforms into a sum involving all the Fourier coefficients for **B**. This sum is greatly simplified when there is a large disparity of length scales L and l. The general solution is developed as an expansion in the small parameter  $\varepsilon = l/L$  (Roberts, 1972a). Further simplification is obtained when the magnetic Reynolds number is small, when each Fourier coefficient is related only to the one corresponding Fourier coefficient in the expansion for the velocity. This is equivalent to the "first order smoothing" or FOST approximation in turbulent dynamo theory (Krause and Rädler, 1980).  $R_m$  is based on the small length scale l and is called the *microscale* magnetic Reynolds number. For dynamo action the magnetic Reynolds number must be sufficiently large (see *Antidynamo and bounding "theorems"*). In this case the relevant magnetic Reynolds number is not the microscale  $R_m$  but one based on the long length scale,  $R_m^L = \mu_0 \sigma VL$ . This condition is satisfied provided l/L is sufficiently small.

In his first paper, Roberts (1972a) presents the general theory in three dimensions, including periodicity in time as well as space, and concludes that *in a precisely defined sense, almost all steady spatially periodic motions of a homogeneous conducting fluid will give dynamo action*.... The "almost all" here is used in the mathematical sense, that the set of motions that fail to give dynamo action is not empty but has zero measure. Unfortunately, as often seems to be the case in dynamo theory, the set contains many of the simple flows that one thinks of first, such as flow on the right in Figure D32 (see *Antidynamo and bounding theorems*).

In his second paper, Roberts (1972b) concentrates on flows with two-dimensional periodicity (not to be confused with 2D flows) and gives four important illustrative motions. The first is given on the left of Figure D32. The equation governing the mean field contains instead of the velocity the mean helicity, or first Fourier coefficient of  $\alpha = \mathbf{v} \cdot \nabla \times \mathbf{v}$ . The mean field equation is analogous with that derived in *mean field dynamo theory* (*q.v.*). The mean field itself is a spiral  $\mathbf{B} = B_0(0, \cos jx, \sin jx)$ . The helical streamlines of the flow twist and push or pull the field lines in adjacent cells in such a way as to reinforce the mean fields at different heights *x*. Helicity is essential to the process, but what sustains the mean field is the mean helicity averaged over a lattice cell, not the point values of the helicity itself.

The remaining three illustrative flows chosen by Roberts (1972b) all fail as dynamos to first order in the expansion in l/L. These flows have zero mean helicity. One of these is sketched on the right in Figure D32. The shear flow along x is now at a maximum at the corners of the lattice cells rather than in the center. Roberts (1972b) was able to demonstrate numerically that all three flows do give dynamo action. Helicity is sometimes thought to be essential for dynamo action, but Roberts' example shows that this is not the case.

The theory of periodic dynamos is quite similar to that of turbulent dynamo action: it involves small- and large-scale fields, uses approximations that take advantage of the disparity of length scales and weak small-scale fields (FOST), and involves an average over the smallscales. It was developed independently from, but somewhat later than, the turbulence theory of Steenbeck *et al.* (1966). It has the advantage of mathematical rigor because the averaging process is well defined. In periodic dynamo theory the average is taken over the specified lattice cell of the flow, whereas turbulence theory requires an average over an ill-defined volume or measure of an ensemble of realizations of the flow.

Apart from providing an early demonstration of the near-universality of dynamo action, the theory of periodic dynamos provided the basis for two important extensions: application to motions in a sphere, and dynamo action by motions driven by thermal convection.

Childress (1970) considered a flow in a sphere by wrapping many cells of the flow in Eq. (1) around the  $\phi$ -axis. The streamlines are helices wrapped around the axis of the coordinate system. He showed that dynamo action occurred with the same mechanism as for the cartesian flow provided the sphere contained a sufficiently large number of cells, when the boundary conditions at the sphere's surface had little effect. Numerical examples of dynamo action by similar flows were demonstrated by Roberts (1969), Gubbins (1972, 1973), and Dudley and James (1989). These solutions are particularly easy to compute because the flow is axisymmetric and the magnetic field has modes proportional to  $\exp im\phi$ . Cowling's theorem rules out dynamos with m = 0 but solutions are possible with m = 1 and higher. The numerical problem becomes essentially two-dimensional. Gubbins (1972) was able to investigate the effect of a small number of cells within the sphere, and finally obtained a solution with just one cell in each hemisphere (Bullard and Gubbins, 1972).

Convection in a plane layer, under certain conditions, takes the form of periodically repeating rolls. The theory of periodic dynamos can therefore be used to explore generation of magnetic field by convection. Busse (1973) analyzed dynamo action of Bénard convection between two perfectly conducting parallel plates at infinite Prandtl number. Dynamo action is not possible for simple rolls, and Busse had to introduce a shear flow to mimic G.O. Roberts' periodic flow. He obtained dynamo action and was able to determine the final equilibrium value of the generated field. Meanwhile Childress and Soward (1972) examined dynamo action by Bénard convection with rotation.

Busse (1975) finally developed a model of the geodynamo by considering a set of rolls aligned with the rotation axis in a spherical annulus. The flow relies on the same dynamo properties of the G.O. Roberts example in Figure D32. The flow along the rolls, required to provide helicity for efficient dynamo action, was effected by the sloping spherical boundary at the ends of the rolls. This dynamo model was the earliest attempt to represent the Earth's dynamo with full dynamics, and it succeeded in generating a predominantly-axial dipole field. It is a "weak field dynamo" (see *Equilibration of magnetic field*) in the sense that the generated magnetic field has little effect on the basic form of the flow. This, and the small-scales implied by the low viscosity in the core, make it difficult to reconcile with the Earth's heat flux and other observables. Numerical models of the geodynamo have developed from Busse's original ideas.

The same mathematical approach can be applied to fluid motions that are periodic in time. Roberts (1972a) considered motions periodic in time as well as space. In some circumstances, oscillatory flows can be more effective in generating magnetic field than similar stationary flows (Willis and Gubbins, 2004). In 1971 Higgins and Kennedy (see *Higgins-Kennedy paradox*) raised the possibility that the core might be subadiabatic, in which case convection could not occur. The only allowed radial motions, essential for dynamo action, would be in the form of waves with frequency dominated by the degree of temperature stratification. Just as the theory of spatially periodic dynamos utilized expansions in the ratio of length scales, so the theory of temporally periodic dynamos employed a ratio of timescales. Bullard and Gubbins (1971) showed that dynamo action is less efficient when the flow oscillates with periods short compared with the magnetic

decay time. They used a disk dynamo model in which the disks oscillated rather than rotated, but the same general result applies to fluid dynamos. Higgins and Kennedy's stratification required motions with very short periods indeed, a few hours to days and would therefore be very inefficient in generating magnetic field: the core must therefore convect somehow. Current views include the scenario in which part of the core is stratified, with the deeper part convecting (see *Geodynamo, energy sources*).

In summary, the early papers on periodic dynamos provided essential confirmation that the dynamo theory was viable and, because dynamo action seemed almost universal for this particular class of flows, providing confidence that realistic geodynamo models could be found. Perhaps the most lasting legacy is the mathematical technique used for the kinematic studies in an infinite medium, which could be extended to apply to dynamical models, spherical geometry, and periodicity in time.

## DYNAMOS, PLANETARY AND SATELLITE

Large magnetic fields in planets and their satellites are thought to arise from dynamo generation, the same process responsible for Earth's magnetic field. A wealth of recent data, mainly from the Galilean satellites of Jupiter and the planet Mars, together with major improvements in our theoretical modeling effort of the dynamo process, have allowed a significant increase in our understanding. However, it is still not possible to state with confidence why only some planets and large satellites have dynamos. A major issue is whether convection can be sustained in a region of adequate electrical conductivity. This depends on the composition and evolution of planets. Even if convection is present, there are criteria that must be satisfied for a dynamo. These have both purely dynamical and energetic aspects. This article concerns all the observed fields, but with emphasis on those that appear to require a dynamo process.

These dynamos arise from thermal or compositional convection in fluid regions of large radial extent in which the electrical conductivity exceeds some value that may be only a few percent that of a typical metal. A significant Coriolis effect on the fluid motions is needed, but all planets rotate sufficiently fast. Although other sources of fluid motion can in principle be relevant, it is thought likely that convection is the dominant source. The maintenance and persistence of convection appears to be easy in gas giants and ice-rich giants, but is not assured in terrestrial planets because of the quite high electrical (and hence thermal) conductivity of iron-rich cores, which allows for a large core heat flow by conduction alone. High electrical conductivity may be unfavorable for a dynamo because it implies high thermal conductivity. If a dynamo operates, the expected field amplitude is plausibly  $\sim (2\rho\Omega/\sigma)^{1/2}$  tesla where  $\rho$  is the fluid density,  $\Omega$  is the planetary rotation rate, and  $\sigma$  is the conductivity (SI units). However, dynamo theory may admit solutions with smaller fields. Earth, Ganymede, Jupiter, Saturn, Uranus, and Neptune appear to have fields that are at least roughly consistent with the expectations of dynamo theory. Mercury may also have a dynamo although its field seems anomalously small. Mars has large remanent magnetism from an ancient dynamo, and the Moon might also require an ancient dynamo. Venus is devoid of a detectable global field but may have had a dynamo in the past. The presence or absence of a dynamo in a terrestrial body (including Ganymede) appears to depend mainly on the thermal histories and energy sources of these bodies, especially the convective state of the silicate mantle and the existence and history of a growing inner solid core. Induced fields observed in Europa and Callisto indicate the strong likelihood of water oceans in these bodies.

#### The significance of these magnetic fields

There are four reasons to be interested in these fields:

1. When a planet or satellite has a large global field, it provides us with insight into the state of matter and the dynamics deep down. There is currently no other way to do this.

- 2. When a planet has remanent magnetism of near surface rocks, it may tell us about the past behavior of the global field (see *Geomagnetic reversals*) and geological activity. Plate tectonics was deduced primarily from paleomagnetism. The history of the field may also affect climate (by modulating atmospheric escape) and the evolution of life.
- 3. When a body has an induced field, its magnitude and phase tells us about the body's conductivity structure.
- 4. Dynamo field generation is a nonlinear chaotic process whose dynamics are of interest in their own right (as a fundamental and very difficult problem in complex systems).

## **Observations**

Magnetic fields, unlike electric fields, do not come from monopoles but from an electrical current, or from the fundamental magnetic moments of elementary particles. In everyday experience, substantial fields arise either from *permanent magnets* where the magnetism arises at the microscopic level and is a thermodynamic property of the material, or through macroscopic currents in electrical conductors (e.g., as in a Helmholtz coil). Permanent magnetism is a satisfactory explanation for modest amounts of observed magnetism in solid bodies (e.g., Moon, Mars, and maybe even Mercury), but it requires low temperature (outer regions only of a planet) and it requires an adequate abundance of the minerals that exhibit permanent magnetization (e.g., magnetite, metallic iron). Typically, crustal magnetism has a coherence length small compared to the planet radius, so no large global field arises. On Earth, permanent magnetization accounts for typically 0.1% or less of the observed field. Localized fields of up to Earth's global field ( $\sim 10^{-4}$  T) are possible from permanently magnetized materials; this happens rarely on Earth but may be common in the southern hemisphere of Mars. On Earth, we have a much stronger argument for something else: The field is dynamic (time varying on all timescales from years to billions of years.) This field is generated in Earth's conducting core by a process known as a dynamo and involves very large-scale electrical currents. A similar process operates in many large cosmic bodies including the Sun.

By Faraday's law, a planetary body can also have an "internal" field that is induced by a time-variable external field. These eddy currents and associated fields can be identified by their distinctive time variability, phase, and amplitude. On Earth, these are called *magnetotelluric* currents and fields. They are also observed for the Moon, Europa, and Callisto.

Except for the special case of Jupiter, which is a synchrotron source of radio waves, we learn about planetary magnetic fields by the direct detection of the field (the magnetosphere) from a flyby or orbiter spacecraft. Orbital data are preferred (even for Earth), provided you can measure or get below the effects of an ionosphere. The observations, with likely interpretations, are given below in Table D1. For the large satellites embedded in giant planet magnetospheres, the quoted values have the external field subtracted.

#### The nature of planets and satellites

Planets and satellites are conveniently categorized according to their primary constituents. Distinguishing between planets and their satellites is artificial, at least for questions pertaining to their evolution and magnetic fields, since satellites are subject to the same planetary processes if they are sufficiently large (>1000 km radius, roughly). *Terrestrial planets* (Mercury, Venus, Earth, Moon, Mars, and Io) consist primarily of materials that condense at high temperatures: oxides and silicates of iron and magnesium, together with metallic iron. The high density and lower melting point of iron alloys relative to silicates generally lead us to expect that these bodies form metallic iron-rich cores. These cores are generally at least partially liquid, even after 4.5 billion years of cooling, because at least one of the core-forming constituents (sulfur) lowers the

Planet or Satellite	Observed Surface Field (in tesla, approximate)	Comments and Interpretation		
Mercury	$2 \times 10^{-7}$	Not well characterized or understood		
Venus	$<10^{-8}$ (global); no useful constraint on local fields	No dynamo. Small remanence might exist (but not yet detected).		
Earth	$5 \times 10^{-5}$	Core dynamo		
Moon	Patchy; no global fields	Impact generated? Ancient dynamo?		
Mars	Patchy but locally strong; no global field	Ancient dynamo, Remanent magnetic lineations and patches.		
Jupiter	$4.2 \times 10^{-4}$	Dynamo (extends to near-surface)		
Io <sup>a</sup>	$< 10^{-6}$ ?	Complex (deeply embedded in Jovian field.)		
Europa <sup>a</sup>	$10^{-7}$	Induction response (Salty water ocean)		
Ganymede <sup>a</sup>	$2  imes 10^{-6}$	Dynamo likely		
Callisto <sup>a</sup>	$4 \times 10^{-9}$	Induction response (Salty water ocean)		
Saturn	$2 \times 10^{-5}$	Dynamo		
Titan <sup>b</sup>	$< 10^{-7}$	No evidence for Ganymede-like dynamo		
Uranus	$2 \times 10^{-5}$	Dynamo		
Neptune	$2 \times 10^{-5}$	Dynamo		

Table D1 Observed magnetic fields (see also Russell, 1993 and Connerney, 1993)

<sup>a</sup>All the Galilean satellites are embedded in Jupiter's field and this poses difficulties for determining the fields associated with the satellites, except in the case of Ganymede which has its own magnetosphere. Listed fields for the Galilean satellites are based on downward continuations of the field measured at the spacecraft altitude. In the case of Io there is a major difficulty in this process because the external field from Jupiter is so large. As a consequence, Io's intrinsic field is highly uncertain and even the upper bound is somewhat uncertain.

<sup>b</sup>Titan spends much of its time in the magnetosphere of Saturn. The nearly spin-axisymmetric character of Saturn's magnetic field makes the detection of an induction response more difficult. As of mid-2006, there is no evidence of an induction response in the several flybys of Titan by the Cassini spacecraft.

freezing point of the iron alloy below the operating (convecting) temperature of the overlying mantle. If the sulfur content is small then the fluid region of a core may be thin. *Gas giants* (Jupiter and Saturn) have hydrogen as their major constituent. They may possess "Earthlike" central cores but this may have little bearing on understanding their magnetic fields. *Ice giants* (Uranus and Neptune) contain a hydrogen-rich envelope but their composition is rich in H<sub>2</sub>O, CH<sub>4</sub>, and NH<sub>3</sub> throughout much of the volume, extending out to perhaps ~80% of their radii. *Large icy satellites and solid icy planets* (Ganymede, Callisto, Titan, Triton, Pluto; also Europa as a special case) contain both ice (predominantly H<sub>2</sub>O) and rock. They may be differentiated into an Earthlike structure (silicate rock and possibly an iron-rich core), overlain with varying amounts of primarily water ice, or (as in the case of Callisto) the ice and rock may be partly mixed. Europa is a special case because the water-rich layer is relatively small and may be mostly liquid.

Planets differ from small masses of the same material because of the action of gravity and the difficulty of eliminating heat on billion year timescales. Gravity causes pressure, which can modify the thermodynamic and phase equilibrium behavior of the constituents. This is why bodies rich in materials that are poor conductors at low pressures (e.g., hydrogen, water) may nonetheless have high conductivity at depth. The difficulty of eliminating the heat of formation and subsequent radioactive heat generation leads to unavoidably large internal temperatures, frequently sufficient to guarantee fluidity of a deep conducting region, and often sufficient to guarantee sustained convection.

## The geometry of large fields

External to the planet and the large currents responsible for most of the field, the magnetic field **B** can be written as the gradient of a scalar potential that satisfies Laplace's equation. We can identify general solutions to Laplace's equation in terms  $\propto Y_{lm}r^{-(l+1)}$  where  $Y_{lm}$  is a spherical harmonic, r is the distance from the center of the planet l = 1 is the dipole, l = 2 is the quadrupole and so on. Terms with m = 0 represent spin-axisymmetric components (if we choose the pole of coordinates to be the geographically defined pole of planet rotation), so (for example) l = 1 and  $m = \pm 1$  represents the tilt of the dipole and the longitude of that tilted dipole. Planetary fields are sometimes described as "tilted, offset dipoles" but this is misleading at best.

There is no fundamental significance to a dipole: A current distribution of finite extent will typically produce many additional harmonics. It is nonetheless true that many bodies have fields that are predominantly dipolar, in the sense that the quadrupolar component is significantly smaller than the dipole component, even when evaluated at the core radius. For *Earth, Jupiter, and Saturn* (and probably *Ganymede*, maybe also *Mercury*), the field is predominantly dipolar. The tilt of the dipole relative to the rotation axis is of order 10 degrees for Jupiter and Earth and near-zero for Saturn. For *Uranus and Neptune*, the field is about equally dipole and quadrupole and the tilt of the dipole is 40–60 degrees. Evidently, Uranus and Neptune represent a different class of dynamos.

## Large magnetic fields require energy sources

Ohm's law, Ampere's law, and Faraday's law of induction lead to what is often called the *dynamo equation*:

$$\partial \mathbf{B} / \partial t = \lambda \nabla^2 \mathbf{B} + \nabla \mathbf{x} (\mathbf{v} \times \mathbf{B})$$
(Eq. 1)

where  $\mathbf{B}$  is the magnetic field,  $\mathbf{v}$  is the fluid motion (relative to a rotating frame of reference) and  $\lambda \equiv 1/\mu_0 \sigma$  is known as the *magnetic diffusivity* ( $\mu_0$  is the permeability of free space,  $4\pi$  imes  $10^{-7}$  NA<sup>-2</sup> (newtons/ (Ampere)<sup>2</sup>) and  $\sigma$  is the electrical conductivity in S m<sup>-1</sup> (siemens/ meter), and assumed constant). If there is no fluid motion then the field will undergo free ("diffusive") decay on a timescale  $\tau \sim L^2/\pi^2 \lambda \sim (3000$ year).  $(L/1000 \text{ km})^2 \cdot (1 \text{ m}^2 \cdot \text{sec}^{-1} \lambda^{-1})$  where L is some characteristic length scale of the field, no more than the radius of the electrically conducting region (the core). In terrestrial planets, the electrical conductivity corresponds to liquid metallic iron, modified by alloying with other elements (e.g., sulfur). This corresponds to  $\sigma \sim 5 \times 10^6$  $^1$  and  $\lambda \sim 2 \text{ m}^2 \text{ s}^{-1}$  . In gas giants, shock wave experiments suggest  $\mathrm{S}~\mathrm{m}^$ that hydrogen attains the lowest conductivities appropriate to metals  $(\sigma \sim 2 \times 10^5 \text{ Sm}^{-1}, \lambda \sim 20 \text{ to } 50 \text{ m}^2 \text{s}^{-1})$  at pressure  $P \sim 1.5$  Mbar and  $T \sim$  a few thousand degrees. This corresponds to the conditions at 0.8 of Jupiter's radius or 0.5 of Saturn's radius. Shock wave experiments suggest that an "ice" mixture (dominated by water) will reach conductivities of  $\sigma \sim 1 \times 10^5$  S m<sup>-1</sup> ( $\lambda \sim 100$  m<sup>2</sup> s<sup>-1</sup>), conditions met in Uranus and Neptune at around 0.7 of their radii.

In all cases, the free decay time is much less than the age of the solar system. For example, in Earth's core, this timescale is 10,000 years or so. The fact that free decay times are geologically short means that if a planet has a large field *now* then it must have a means of generating the field *now*; it cannot rely on some primordial field or preexisting field.

#### The dynamo mechanism

The essence of a dynamo lies in electromagnetic induction: The creation of emf and associated currents and field through the motion of conducting fluid across magnetic field lines (Moffatt, 1978; Parker, 1979). Dimensional analysis of the induction equation immediately suggests that the importance of this is characterized by the *magnetic Reynolds number*  $R_m \equiv v L/\lambda$  where v is a characteristic fluid velocity and L is a characteristic length scale of the motions or field (e.g., the core radius). Numerical and analytical work suggest that a dynamo will exist if the fluid motions have certain desired features and the magnetic Reynolds number  $R_m$  exceeds about 10 or 100. It seems likely that fluid motions of the desired character arise naturally in a convecting fluid (irrespective of the source of fluid buoyancy), provided the Coriolis force has a large effect on the flow, i.e.,  $v/\Omega L < 1$  where  $\Omega$ is the planetary rotation rate. Taking into account both criteria, a necessary but not sufficient criterion for a dynamo is that the free decay time of the field be very much larger than the rotation period. This is easily satisfied for any plausible fluid motion of interest, even for slowly rotating planets such as Venus, where the rotation period is at least four orders of magnitude less than the field decay time.

We do not have quantitatively precise sufficient conditions for the existence of a planetary dynamo. Some of the issues can be appreciated by considering the simple case of a generic planet in which the heat flow in the proposed dynamo region arises primarily from cooling, and no phase changes (e.g., freezing or gravitational differentiation) take place. (In terrestrial planets, the dominant source of *surface* heat flow is radioactive decay, but the radioactive elements are not predominantly in the core. In giant planets, cooling from a primordial hot state probably dominates at all levels, though gravitational differentiation may also contribute significantly.) In this approximation, and assuming that the core cools everywhere at the about the same rate, we have

$$F_{\text{total}}(r) = -\rho_{\text{c}}C_{p}r(\mathrm{d}T_{\text{c}}/\mathrm{d}t)/3 \tag{Eq. 2}$$

where  $F_{\text{total}}(r)$  is the total heat flow at radius r,  $\rho_c$  is the mean core density,  $C_p$  is the specific heat,  $T_c$  is the mean core temperature, and t is time. In fluid cores, the viscosity is so small that it plays a negligible role in the criterion for convection (totally unlike the case for convection in solid silicate mantles). To an excellent approximation, the condition for convection is that the heat flow must exceed that which can be carried by conduction along an adiabat:

$$F_{\text{total}} > F_{\text{cond, ad}} \equiv k \alpha T g(r) / C_p \Leftrightarrow \text{thermal convection} \quad (\text{Eq. 3})$$

where k is the thermal conductivity,  $\alpha$  is the coefficient of thermal expansion, and g(r) is the gravitational acceleration at radius r. If the heat flow were less than this value then the core would be stably stratified (vertically displaced fluid elements would tend to oscillate). We can approximate g(r) by  $4\pi G\rho_c r/3$  where G is the gravitational constant. Notice that both  $F_{\text{total}}$  and  $F_{\text{cond,ad}}$  are linear in r in this approximation, so the comparison of their magnitudes will be the same independent of planet size and location in the core. From this, we obtain a critical cooling rate that must be exceeded for convection. It is typically about 100 KGa<sup>-1</sup> for parameters appropriate to Earth's core and may be as large as 300 or 400 KGa<sup>-1</sup> for smaller (but Earth-like) cores. e.g., Ganymede, because  $\alpha$  is larger at low pressures. It is substantially lower for giant gas or ice planets, where the conductivity is lower. For Earth's core, a cooling rate like 100 KGa<sup>-1</sup> corresponds to a heat flow at the top of the core of around 20 mWm<sup>-2</sup>.

From condensed matter physics, we also have the Wiedemann-Franz "law" that

$$k/\sigma T \equiv L \approx 2 \times 10^{-8} \text{ W} \cdot \text{Ohm K}^{-2}$$
 (Eq. 4)

where L is called the Lorenz number. This applies to a metal in which the electrons dominate both the heat and charge transport. Combined with Eq. (3) this implies an *upper* bound to the electrical conductivity in order that thermal convection takes place. For nominal parameter choices, this upper bound is roughly the actual value of the electrical conductivity in Earth's core. This makes the important point that high electrical conductivity may prevent a dynamo! See Figure D33.

Even if convection is possible, it must be sufficiently vigorous. Two possible estimates for convective velocity might be considered. One comes from mixing length theory:

$$V_{ml} \sim 0.3 (lF_{\rm conv}/\rho H_T)^{1/3}$$
 (Eq. 5)

where  $V_{ml}$  is the predicted velocity, *l* is the "mixing length" (plausibly the size of the core),  $F_{conv} = F_{total} - F_{cond.ad}$ , and  $H_T \equiv C_p/\alpha g$  is the temperature scale height, not enormously larger than the core radius except in the limit of small bodies. An alternative estimate, plausibly more relevant if a dynamo is operating, assumes that buoyancy, Coriolis and Lorentz forces are comparable in the fluid flow. In this regime, sometimes referred to as the MAC regime,

Core size

conductivity

**Figure D33** Dependence of dynamo operating region on planet size and electrical conductivity. This schematic diagram focuses on two of the many parameters that determine whether a thermal convection dynamo exists in a planet. At sufficiently low conductivity, there is a size dependent cut-off based on the need to exceed a critical magnetic Reynolds number. As explained in the text, there is also an approximately size-independent criterion for the existence of convection, since if the conductivity is too high then the heat can be carried by conduction. Specific values are omitted from the plot because they depend on many (often poorly known) parameters. However, it is likely that terrestrial planets lie near the right hand dynamo boundary, ice giants lie near the left hand boundary and gas giants are comfortably removed from either boundary. A more complicated but conceptually similar diagram will apply if there is compositional convection.

(Eq. 6)

$$V_{\rm MAC} \sim (F_{\rm conv}/\rho\Omega H_T)^{1/2}$$

and this is typically an order of magnitude or so smaller than  $V_{ml}$ . Note that slow rotation is favorable (i.e., increases convective velocity). The acronym MAC stands for magnetic Archimedean Coriolis and refers to a system where the dynamics of the magnetic field (the Lorentz force), the Archimedean force due to buoyancy, and the dynamic effect of rotation (the Coriolis force) are all important for the flow. It should be stressed that the particular form adopted in Eq. (6) is not the only possible way of introducing the effect of rotation, and that there are alternatives in which the dependence on rotation is weaker (though generally the power law is still a negative one, implying less vigorous convection for faster rotation, provided the heat flow is kept constant).

In the dynamo regime, the expected field magnitude *inside the* region of field generation is plausibly given by Elsasser number  $\Lambda \equiv \sigma B^2/2\rho\Omega$  of order unity, which implies  $B \sim (2\rho\Omega/\sigma)^{1/2}$  T where  $\rho$  is the fluid density. As Table D2 shows, this may be roughly satisfied, especially if one allows that the field inside the dynamo region may be larger than at the top of the dynamo region by a factor of a few. There are enough uncertainties that one cannot state with confidence that dynamos operate near an Elsasser number of unity. There appears to be a clear exception for Uranus and Neptune, although downward extrapolation of their fields is difficult because they are not predominantly dipolar.

The cooling rates of giant gas and ice planets can be estimated and predict heat flows that are large compared to conductive transport, and close to the "nominal" values tabulated. However, the situation is far from clear in terrestrial planets, where our understanding of cooling rates is dictated by our (imperfect) understanding of mantle rheologies and heat production. It is possible that the actual heat flow does not exceed the conductive heat flow. This can happen in a convecting fluid provided that there is also compositional buoyancy.

If the core is cooling and the central temperature drops below the liquidus for the core alloy, then an inner core will nucleate. In Earth, we know from seismic evidence that the core is  $\sim 10\%$  less dense than pure iron and many suggestions have been offered for the identity of the light elements that are mixed with the iron. As the inner core freezes, it is likely that some or all of these light elements are excluded from the crystal structure. The introduction of light elements into the lowermost core fluid will tend to promote convection and cause mixing throughout all or most of the outer core, provided the cooling is sufficiently fast. Latent heat release at the inner core-outer core boundary will also contribute to the likelihood of convection. However, inner core growth permits outer core convection even when the heat flow through the core-mantle boundary is less (perhaps much less) than the heat carried by conduction along an adiabat. In this regime, the temperature gradient is very slightly less steep than adiabatic and the compositional convection carries heat downwards. The total heat flux is still outwards, of course, since the heat carried by conduction is large. This state is possible because the buoyancy release associated with the compositional change exceeds the work done against the unfavorable thermal stratification.

It is possible but not certain that terrestrial planets require inner core growth in order to sustain a dynamo at the present epoch. It does *not* follow that there is a one-to-one correspondence between presence of an inner core and presence of a dynamo. One can have an inner core without a dynamo (conceivably present Mars if the cooling of the core is insufficiently rapid). One can also imagine a dynamo without a growing inner core (conceivably early Earth or other bodies early in their history) if the core were then cooling much more rapidly than now. Partial freeze-out of light material from the core is also a possible dynamo driving mechanism.

### Induction fields

The requirement for a significant induction field is much less restrictive than for a dynamo. The conductivity can be much smaller and it does not have to be in differential motion (e.g., it can be a solid). For an external field that varies as  $\exp[i\omega t]$ , and a thin, conducting shell of thickness *d* and radius *R*, there will be a large induction response if the electromagnetic skin depth  $(\lambda/\omega)^{1/2} < (Rd)^{1/2}$ . For example, a layer of low-pressure salty water (such as Earth's oceans, with  $\lambda \sim 10^6$  m<sup>2</sup> s<sup>-1</sup>) will satisfy this for a thickness of order 10 km and  $\omega \sim 2 \times 10^{-4}$  (corresponding to the frequency of Jupiter's tilted dipole field as it sweeps by Europa). A plausible estimate for  $R_m$  in such an ocean is  $10^{-3}$  so there is no significant *internal* induction effect. The observed fields of Europa, Callisto are consistent with an externally induced induction field, and the most likely conductor is salty water.

### Summary for each planet

*Mercury* is likely to have a liquid outer core and some models predict that this core could continue to convect and perhaps sustain a dynamo. Mercury is nonetheless an enigma because the observed field is over an order of magnitude smaller than the field strength predicted for  $\Lambda \sim 1$ . There are at least four possibilities: permanent magnetism, an exotic nondynamo explanation such as thermoelectric currents, a dynamo that produces much larger internal (e.g., toroidal) fields than the observed external fields (as recent models suggest), or a dynamo that for some reason fails to reach the expected field amplitude Stanley *et al.* (2005). Future missions may test the alternatives through assessment of the harmonic structure of the field. The MESSENGER mission to Mercury was launched in 2004 and should collect data at the end of the decade.

*Venus* is likely to have a liquid outer core (with or without an inner core) but has no dynamo at present. The predicted dynamo field is over two orders of magnitude larger than the observational upper bound. Slow rotation may be good for dynamos, so if Venus were like Earth in all respects except for its rotation then it would have no difficulty exceeding this upper bound. The most probable interpretation is that the liquid core of Venus does not convect. This could arise because there is no inner core or because the core is currently not cooling. The absence of an inner core is plausible if the inside of Venus

Tab	e D2	Operating	conditions	for rep	presentative	dynamos
-----	------	-----------	------------	---------	--------------	---------

	Earth	Ganymede	Jupiter	Uranus

$\Lambda$ , Elsasser number at top of dynamo	0.3	0.3	0.3	$\sim 0.01?$

is hotter than the corresponding pressure level of Earth. This can arise because Earth has plate tectonics, which eliminates heat more efficiently than a stagnant lid form of mantle convection. Alternatively (or in addition), Venus' core may not be cooling at present because it is undergoing a transition in convective style following a resurfacing event  $\sim$ 700 Ma ago.

*Earth* remains imperfectly understood, a humbling reminder of the dangers of claiming an understanding of other planets. Growth of the inner core is thought essential for sustaining convection and sufficient energy to run the dynamo field. Doubts have been expressed about whether Earth's field can be sustained for its known history (at least 3.5 Ga) if the inner core has existed for only of order a couple of billion years or less. An additional energy source may be needed. One possibility is a modest amount of potassium in the core (since potassium has a radioactive isotope, <sup>40</sup>K Nimmo *et al.* (2004). Another possibility is that cooling rates of the lower mantle have been underestimated for earlier epochs.

*Moon* probably has a core that is at least partially liquid. It has patches of strong crustal magnetization that may have been acquired following impacts and compression of conducting plasma at the antipode. It is not known whether the preimpact field was necessarily a global field of the kind that only a dynamo produces. Even if it is a dynamo, it may (uniquely among planets in our solar system) have arisen through mechanical stirring of the inner core. This can arise because of the failure of the core to follow the nutation of the mantle (which currently has a period of 18.6 years). Rapid cooling of a boundary layer immediately above the core-mantle boundary might also conceivably maintain a dynamo for some time.

*Mars* had an ancient dynamo, probably in the period prior to 4.0 Ga. Connerney *et al.* (2004). There are three possibilities for why this dynamo existed and then died Stevenson (2001): (i) Core cooling decreased to the point where conductive heat loss dominated (but no inner core formed). This is the most well developed hypothesis. (ii) Mars underwent a change in convective style, from an efficient mode (e.g., plate tectonics) to the currently observed stagnant lid mode. This would cause the mantle and core to stop cooling and turn off core convection and the dynamo. This model would work irrespective of whether Mars has an inner core. (iii) The core of Mars froze sufficiently so that the remaining fluid region was too thin to sustain a dynamo.

*Jupiter* may have dynamo generation out to levels where hydrogen is only a semiconductor, perhaps 80% to 85% of the planet radius. This is compatible with the magnitude and harmonic structure of the field Bagenal *et al.* (2004).

*Io* exhibits no convincing evidence of a dynamo and no simple inductive response. Although Io has a metallic core, it might not be undergoing much long-term cooling if the mantle is heated steadily by tides.

*Europa* has a clear signature of an induction field and no evidence of a permanent dipole. The induction field can be explained by a water ocean of similar conductivity to Earth's oceans, provided this ocean has a thickness exceeding  $\sim 10$  km. No other plausible source of the required conductivity has been suggested.

*Ganymede* has a clear signature of a permanent dipole. A permanent magnetism explanation is conceivable but unlikely, and the most reasonable interpretation is a dynamo in the metallic core. A liquid Fe-S core is expected in Ganymede. Nonetheless, this dynamo is surprising, partly because of Ganymede's size but mainly because of the difficulty in sustaining convection in such a small body. The presence of large amounts of sulfur and large <sup>40</sup> K mantle heating may help. There may also be a much smaller induction signal from a water ocean.

*Callisto* has a clear induction signal; explained by a salty water ocean that underlies the ice I layer, around 150 to 200 km in depth. This ocean is expected because of radioactive heating alone.

Saturn may have a dynamo very similar to that of Jupiter, but more deep-seated (the reason for the smaller surface field). It may be

overlain by a region that greatly reduces the nonspin axisymmetric components, perhaps explaining the small observed dipole tilt.

*Titan* has an observed upper bound to the field that is less than the field expected for a Ganymede-like dynamo. It may have a water ocean and thus produce an induction signal, potentially detectable by Cassini. However, this will more difficult to detect because Saturn lacks a significant dipole tilt, so the time variable part of Saturn's field is much smaller than that for Jupiter.

*Uranus* and *Neptune* are very similar in structure and in field strength and geometries. Their very different obliquities are evidently irrelevant to understanding their fields. Although it seems likely that high-pressure water can provide the desired conductivity for a dynamo, it is marginal and the observed field strength seems smaller than expected (see Table D2). This raises the question of whether these planets are actually generating their fields deeper down. Quadrupolar dynamos are permitted by dynamo theory, and the dynamo activity might be limited to a thin shell Stanley and Bloxham (2004).

*Triton and Pluto* might possibly have water-ammonia oceans and might therefore be capable of induction signals, to the extent that they are subjected to small, time varying external magnetic fields.

*Extrasolar giant planets* can be expected to be convective at depth, and to have the conductivities sufficient for dynamo action.

## EARTH STRUCTURE, MAJOR DIVISIONS

Although the Earth is a complex body with pervasive three-dimensional structure in its solid portions, the dominant variation in properties is with depth. The figure of the Earth is close to an oblate spheroid with a flattening of 0.003356. The radius to the pole is 6357 km and the equatorial radius is 6378 km; for most purposes, a spherical model of the Earth with a mean radius of 6371 km is adequate. Thus, reference models for internal structure can be used in which the physical properties depend on radius. Three-dimensional variations can then be described by deviations from a suitable reference model.

The main divisions of Earth structure are illustrated in Figure E1. Beneath the thin crustal shell lies the silicate mantle which extends to a depth of 2890 km. The mantle is separated from the metallic core by a major change of seismic properties that has a profound effect on global seismic wave propagation (see *Seismic phases*). The outer core behaves as a fluid at seismic frequencies and does not allow the passage of shear waves, while the inner core appears to be solid. Thus only seismic compressional waves (P) can traverse the outer core.

Much of the evidence for the nature of internal structure comes from the analysis of seismograms and the patterns of propagation of seismic waves.

The existence of a discontinuity at the base of the crust was found by Mohorovičić in the analysis of the Kupatal earthquake of 1909, based on only a limited number of records from permanent seismic stations. Knowledge of crustal structure from seismic methods has developed substantially through the use of controlled sources, e.g., explosions. Indeed, most of the information on the oceanic crust comes from such work. The continental crust varies in thickness from around 20 km in rift zones to 70 km under the Tibetan Plateau. Typical values are close to 35 km. The oceanic crust is thinner with basalt pile about 7 km thick whose structure changes somewhat with the age of the oceanic crust.

The lithosphere continues from the crust into the mantle and also shows significant differences between the oceanic and continental regimes. The entire oceanic lithosphere is generated by the spreading process at mid-ocean ridges and the increase in thickness with age to at least 85 Ma is consistent with thermal cooling. Precambrian shield components of continents have a very thick but lower density lithosphere extending to 200 km (or possibly more in some places). The lithosphere beneath Phanerozoic regions tends to be thinner, about 120 km, with considerable complications in the neighborhood of active tectonic belts. Beneath the lithosphere lies the asthenosphere that is typically characterized by a decrease in shear wavespeed, increased attenuation and electrical conductivity, and inferred lower viscosity. The transition from lithosphere to asthenosphere appears to be generally sharp in oceanic regions, but probably is more gradational under the continents.

The mantle shows considerable variation in seismic properties with depth, with strong gradients in seismic wavespeed in the top 800 km. The presence of distinct structure in the upper mantle was recognized by Jeffreys in the 1930s who noted a distinct shift in the rate of change of the travel-times of P-waves with distance near 20° from the source. He ascribed this 20° discontinuity to a rapid change in seismic wavespeed with depth. In the 1960s-1970s detailed analysis of the seismic wave field in the distance range from 15° to 25° from earthquake and nuclear explosion sources, using seismic arrays, revealed two clear discontinuities in seismic wavespeed at depths near 410 and 660 km. From mineral physics results, these discontinuities can be associated with major phase changes in the silicate minerals of the mantle. A number of other discontinuities have been proposed. Only a feature near 520 km depth has a widespread occurrence in long-period observations, and appears to represent a small change over a 30-50 km interval in depth (Shearer, 1993). Many different styles of study have shown both the global presence of discontinuities near 410 and 660 km depth, and also significant variations in seismic structure within the upper mantle (for a review see Nolet et al., 1994).

The reduction of seismic wavespeeds in the lowermost mantle led Bullen to identify a subregion D'' of the lower mantle (region D). This zone situated just above the core-mantle boundary has proved to have heterogeneity comparable to that in the uppermost mantle. There are localized discontinuities in shear wavespeed, as first noted by Lay and Helmberger (1983), as well as narrow zones of "ultralow velocity" (Garnero *et al.*, 1998).

The need for a core at depth with greatly reduced seismic wavespeeds was recognized at the end of the last century by Oldham in his analysis of the great Assam earthquake of 1890, because of a zone without distinct P arrivals (a "shadow zone" in PKP, see *Seismic phases*). By 1914, Gutenburg had obtained an estimate for the radius of the core which is quite close to the current value. The presence of the inner core was inferred by Inge Lehmann in 1932 from careful analysis of arrivals within the shadow zone (*PKiKP*), which had to be reflected from some substructure within the core.

The nature of the transition form the outer core to the inner core has been a matter of some debate. Early analysis by Jeffreys, based on a limited number of reports of the travel-times of PKP phases, produced a model with a decrease in P-wavespeed just above the inner core (the

**Figure E1** The major divisions of the radial structure of the Earth: the gradations in tone in the upper part of the mantle indicate the presence of discontinuities at 410 and 660 km depth. The diagram is drawn to true scale, so that the Earth's crust appears only as the thin bounding surface.

**Figure E2** Radial reference earth model AK135, seismic wavespeeds  $\alpha$  (P),  $\beta$  (S): Kennett *et al.* (1995), attenuation parameters Q, density ( $\rho$ ): Montagner and Kennett (1996). Zones marked with gray tones show significant lateral heterogeneity and some level of anisotropy.

F-region in Bullen's notation). In contrast, Gutenburg working with seismograms recorded at Pasadena, California, favored a simple discontinuity with an increase in wavespeed in the inner core. The difficulties arise because of the very complex patterns of arrival expected for the PKP phase (see Kennett, 2002; Chapter 26). Modern analysis using the differential times between arrivals following different paths through the core, or matching observed and computed seismograms, favor a decrease in wavespeed gradient at the base of the outer core, but not a low velocity zone.

The times of arrival of seismic phases on their different paths through the globe constrain the variations in P- and S-wavespeed, and can be used to produce models of the variation with radius. A very large volume of arrival time data from stations around the world have been accumulated by the International Seismological Centre and are available in digital form. This data set has been used to develop high-quality travel-time tables that can in turn be used to improve the locations of events. With reprocessing of the arrival times to improve locations and the identification of the picks for later seismic phases, a set of observations of the relation between travel-time and epicentral distance have been produced for a wide range of phases. The reference model Ak135 of Kennett *et al.* (1995) for both P- and S-wavespeeds, illustrated in Figure E2, gives a good fit to the traveltimes of mantle and core phases. The reprocessed data set and the Ak135 reference model have formed the basis of much recent work

Figure E3 Contrast between the patterns of seismic wave propagation in the core for SKS to the left and PKP to the right. S wavelegs are shown in gray tone. Wavefronts are indicated by ticks on the ray paths at 1 min intervals.

on high-resolution travel-time tomography to determine three-dimensional variations in seismic wavespeed.

One of the difficulties in just using the travel-time relations comes from the sampling of the core by seismic phases. For arrivals traveling solely as P-waves the change in material properties at the core-mantle boundary means that the paths become steeper on entry into the core from Snell's law. Eventually, the effects of sphericity and the gradients in seismic wavespeed are sufficient to turn energy back to the surface but the outermost part of the core is not sampled by the PKP wave. In contrast, the P-wavespeed in the core is a little larger than the S-wavespeed at the base of the mantle and so the converted arrival SKS can sample the whole core. The differing patterns for PKP and SKS are shown in Figure E3 (see also *Seismic phases*). From travel-times alone, the P-wavespeeds at the top of the outer core depend on knowledge of the S-wavespeed throughout the mantle.

The use of the times of arrival of seismic phases enables the construction of models for P- and S-wavespeed, but more information is needed to provide a full model for Earth structure. The density distribution in the Earth has to be inferred from indirect observations and the main constraints come from the mass and moment of inertia. The mean density of the Earth can be reconciled with the moment of inertia if there is a concentration of mass toward the center of the Earth; which can be associated with a major density jump going from the mantle into the outer core and a smaller density contrast at the boundary between the inner and outer cores (Bullen, 1975). With successful observations of the free-oscillations of the Earth following the great Chilean earthquake of 1960, additional information could be extracted from the frequencies of oscillation on both the seismic wavespeeds and the density. Fortunately the inversion of the frequencies of the free-oscillations for a spherically symmetric reference model provides independent constraints on the P-wavespeed structure in the outer core. Even with the additional information from the normal modes the controls on the density distribution are not strong (Kennett, 1998) and additional assumptions such as adiabatic state in the core and lower mantle have often been employed to produce a full model. The reference model PREM of Dziewonski and Anderson (1981) combined the free-oscillation and travel-time information available at the time. A parametric representation of structure was employed in terms of simple mathematical functions to aid the inversion; thus a single cubic was used for seismic wavespeed in the outer core and again for most of the lower mantle. The PREM forms the basis of much current global seismology using quantitative exploitation of seismic waveforms at longer periods (e.g., Dahlen and Tromp, 1998).

In order to reconcile the information derived from the free-oscillations of the Earth and the travel-time of seismic phases, it is necessary to take account of the influence of anelastic attenuation within the Earth. A consequence of attenuation is a small variation in the seismic wavespeeds with frequency, so that waves with frequencies of 0.01 Hz (at the upper limit of free-oscillation observations) travel slightly slower than the 1-Hz waves typical of the short period observations used in travel-time studies. The density and attenuation models shown in Figure E2 were derived by Montagner and Kennett (1996) to link the wavespeed distributions from travel-time analysis to the freeoscillation results.

Figure E4 displays the travel-times for the AK135 model superimposed on the reported phases for a set of 104 test events (83 earthquakes, 21 explosions) assembled by Kennett and Engdahl (1991). These events have well-controlled locations and origin times with a rich set of later phase readings (57655 phases in all). As we can see the reference model provides a good representation of the features

Figure E4 Display of AK135 travel-times superimposed on the times of phases for the test events corrected to surface focus.

of the full set of phase picks (for explanation of the phase codes see *Seismic phases*).

The reference model AK135 (Figure E2) is isotropic and depends solely on radius. However, the real Earth both varies in three-dimensional and displays anisotropy in seismic parameters. The zones of largest variability are indicated in Figure E2 by bands of gray tone. These are also regions in which there is the strongest evidence for anisotropy in seismic properties, from differences in seismic wavespeeds depending on the direction of propagation or the polarization of the seismic waves.

The strongest levels of heterogeneity are found in the outermost 300 km with a strong contrast between the high wavespeeds beneath the ancient cores of continents extending to at least 250 km and the oceanic regime where the fast lithosphere is quite thin. The continental lithosphere also appears to be anisotropic, with evidence from the analysis of seismic surface waves and the shear wave splitting for SKS waves.

The process of subduction brings the cold oceanic lithosphere into the upper mantle and locally there are large contrasts in seismic wavespeeds, well imaged by detailed tomography, that extend down to at least 660 km and in some zones even deeper. Remnant subducted material can have a significant presence in some regions, e.g., above the 660 km discontinuity in the north-west Pacific and in the zone from 660 down to 1000 km beneath Indonesia.

## Mantle

The nature of mantle structure varies with depth and it is convenient to divide the mantle up into four major zones (e.g., Jackson and Ridgen, 1998).

Upper mantle (depth z < 350 km), with a high degree of variability in seismic wavespeed (exceeding  $\pm 4\%$ ) and relatively strong attenuation in many locations.

*Transition zone* (350 < z < 800 km), including significant discontinuities in P- and S-wavespeeds and generally high velocity gradients with depth.

Lower mantle (800 < z < 2600 km) with a smooth variation of seismic wavespeeds with depth that is consistent with adiabatic compression of a chemically homogeneous material.

D'' layer (2600 < z < 2900 km) with a significant change in velocity gradient and evidence for strong lateral variability and attenuation.

The two major discontinuities in seismic wavespeeds near depths of 410 and 660 km are associated with phase transformations in silicate minerals induced by the effects of increasing pressure, and represent changes in the organization of the oxygen coordination with the silicon atoms. The change in seismic wavespeed across these discontinuities occurs quite rapidly, and they are seen in both short- and long-period observations. Other minor discontinuities have been proposed, but only one near 520 km appears to have some global presence in long-period stacks but not short-period data. This 520-km transition may occur over an extended zone, e.g., 30–50 km, so that it still appears sharp for long-period waves with wavelengths of 100 km or more. Jackson and Ridgen (1998) provide a broad ranging review of the interpretation of seismological models for the transition zone and their reconciliation with information from mineral physics.

Frequently, the lower mantle is taken to begin below the 660 km discontinuity, but strong gradients in seismic wavespeeds persist to depths of the order of 800 km and it seems appropriate to retain this region in the transition zone. There is increasing evidence for localized sharp transitions in seismic properties at depth around 900 km that

appear to be related to the penetration of subducted material into the lower mantle.

Between 800 and 2600 km, the lower mantle has, on average, relatively simple properties which would be consistent with the adiabatic compression of a mineral assemblage of constant chemical composition and phase. Although tomographic studies image some level of three-dimensional structure in this region the variability is much less than in the upper part of the mantle or near the base of the mantle.

The D" layer from 2600 km to the core-mantle boundary has a distinctive character. The nature of seismic wavespeed distribution changes significantly with a sharp drop in the average velocity gradient. There is a sharp increase in the level of wavespeed heterogeneity near the core-mantle boundary compared with the rest of the lower mantle. The base of the Earth's mantle is a complex zone with widespread indications of heterogeneity on many scales, discontinuities of variable character, and shear wave anisotropy (e.g., Gurnis et al., 1998; Kennett, 2002). The results of seismic tomography give a consistent picture of the long wavelength structure of the D" region: there are zones of markedly lowered S-wavespeed in the central Pacific and southern Africa, whereas the Pacific is ringed by relatively fast wavespeeds that may represent a "slab graveyard" arising from past subduction. Discordance between P- and S-wave results suggests the presence of chemical heterogeneity rather than just the effect of temperature (e.g., Masters et al., 2000).

There are a number of lines of evidence which suggest the presence of topography on the core-mantle boundary, but the situation is complicated by the influence of the strong heterogeneity in D". The information from travel-times of seismic phases such as (PcP and PKP, PKKP) is compatible with long wavelength topography on the order of  $\pm 3$  km, but such variations are not required by this data. As noted by Buffet (1998), topography of several kilometers on wavelengths of several thousand kilometers is not sufficient to produce the torques between mantle and core inferred from variations in the length of the day. However, such topographic coupling could become important if the core-mantle boundary is rough at smaller wavelengths as suggested from some studies of seismic scattering.

Evidence for a discontinuity at the top of the D" region comes from the presence of an additional arrival between the direct mantle phase and the core reflection in the distance range  $65^{\circ}-90^{\circ}$ . This is not a universal phenomenon, but a D discontinuity is found in many parts of the world. The typical contrast in S-wavespeed is in the range 1.5%-3% at  $250 \pm 100$  km above the core-mantle boundary, with greater variability in P-wavespeed. The nature of the transition varies between different regions and in places may represent a transition zone up to 50 km thick. In some areas the fluctuations in travel-times and amplitude of the reflected phases suggest the presence of strong lateral gradients in discontinuity structure (e.g., Lay *et al.*, 1998).

Beneath the central Pacific Ocean and in a number of other locations, there is evidence for thin zones, around 20 km thick, at the core-mantle boundary with a marked reduction in P-wavespeed of at least 10% (see Garnero *et al.*, 1998). The inferred reduction in S-wavespeed in these ultralow velocity zones somewhat larger.

Since all waves sampling the core have to pass through the D'' region, the complexity of propagation in this region influences inferences made about deeper structure.

#### Core

The core-mantle boundary at about 2890 km depth marks a substantial change in physical properties associated with a transition from the silicate mantle to the metallic core (see Figure E3). There is a significant jump in density, and a dramatic drop in P-wavespeed from 13.7 to  $8.0 \text{ km s}^{-1}$ . The major change in wavespeed arises from the absence of

Figure E5 Comparison of P-wavespeed models for the core: IASP91, Kennett and Engdahl, 1991; PREM2, Song and Helmberger, 1992; SP6, Morelli and Dziewonski, 1993; AK135, Kennett *et al.* 1995.

shear strength in the fluid outer core, so that the P-wavespeed depends just on the bulk modulus and density. No shear waves can be transmitted through the outer core so that only the K propagation legs can be present (see *Seismic phases*).

The process of core formation requires the segregation of heavy iron-rich components in the early stages of the accretion of the earth (e.g., O'Neill and Palme, 1998). The core is believed to be largely composed of an iron-nickel alloy, but its density requires the presence of some lighter elemental components. A wide variety of candidates have been proposed for the light components, but it is difficult to satisfy the geochemical constraints on the nature of the bulk composition of the Earth.

The inner core appears to be solid and formed by crystallization of material from the outer core, but it is possible that it could include some entrained fluid in the top 100 km or so. The shear wavespeed for the inner core inferred from free-oscillation studies is very low and the ratio of P- to S-wavespeeds is comparable to a slurry-like material. The structure of the inner core is both anisotropic and shows three-dimensional variation (e.g., Creager, 1999). The variations are complex with some apparent variation between hemispheres, but may be influenced by the passage of phases such as PKIKP through the strong heterogeneity at the base of the mantle in D".

The fluid outer core is conducting and motions within the core create a self-sustaining dynamo which generates the main component of the magnetic field at the surface of the Earth. The dominant component of the geomagnetic field is dipolar but with significant secondary components. Careful analysis of the historic record of the variation of the magnetic field has lead to a picture of the evolution of the flow in the outer part of the core (e.g., Bloxham and Gubbins, 1989). The presence of the inner core may well be important for the action of the dynamo, and electromagnetic coupling between the inner and outer cores could give rise to differential rotation between the two parts of the core (Glatzmaier and Roberts, 1996). Efforts have been made to detect this differential rotation using the time history of different classes of seismic observations but the results are currently inconclusive.

Even though the main features of the variation in seismic wavespeeds through the core are well established, there are noticeable differences in the details of models proposed by different authors for the regions near the core-mantle boundary and the boundary between the inner core and outer core (Figure E5). The detailed structure just below the core-mantle boundary is primarily controlled by the properties of the multiple reflections SKKS, SKKKS,... from the underside of the core-mantle boundary. The most detailed models of the structure of the boundary region between the inner and outer cores come from matching of observed and calculated waveforms as in the PREM2 model of Song and Helmberger (1992). This work indicates the need for a reduction in seismic wavespeeds just above the inner core boundary, and is supported by studies of the differential times between the branches of the PKP phase that take different paths through the core. However, such studies are susceptible to the influence of heterogeneity and anisotropy in the inner core.

Differential time information was used in the construction of the AK135 model, which is close to PREM2, and differs from sP6 (Morelli and Dziewonski, 1993) that uses a single cubic representation for P-wavespeed throughout the whole core, in a similar way to PREM (Dziewonski and Anderson, 1981).

## ELSASSER, WALTER M. (1904–1991)

About 2000 years ago in China it was discovered that a lump of magnetic iron oxide (magnetite), or lodestone, takes up a preferred orientation when freely suspended. Ultimately this discovery led to the magnetic compass for navigation and surveying. Four centuries ago *Gilbert* (1600) (q.v.), in England, carried out precise laboratory measurements of the magnetic field around a lodestone. The magnetic records accumulated by the seafaring captains of the time made it clear to Gilbert that the magnetic field of Earth has the same form as that of a lodestone, and he concluded that Earth was itself a huge lodestone.

In 1835, Gauss demonstrated mathematically that the east-west, north-south, and vertical components of the field are observed to vary relative to each other in such a way as to place the origin of the field inside, rather than outside, the body of Earth.

Gilbert's plausible interpretation of the origin of the geomagnetic field stood for about three centuries, until Kelvin in 1862 established the incandescence of the interior of Earth, and Pierre Curie in 1895 studied the abrupt disappearance of magnetic effects in metals and minerals upon heating to hundreds of degrees. The origin of the geomagnetic field became a mystery once again.

Thermoelectric effects in the hot inhomogeneous interior of Earth were a favorite notion, creating electric currents and the associated magnetic fields. However, it was not obvious how to account for a magnetic field as strong as the observed polar 0.6 G, or for the observed secular variations of the field, with characteristic times as short as a few centuries.

Walter M. Elsasser became interested in the problem in the late 30s and investigated the possibility that the thermoelectric effects in the temperature variations in the convective liquid iron and nickel core might provide the observed secular fluctuations of the field observed at the surface of Earth (Elsasser, 1939). Two years later Elsasser (1941) studied the secular variations in some detail and showed that they could be modeled by several randomly oriented dipoles if those dipoles were confined to the liquid core ( $r < 0.5R_{\rm E}$ ).

The essential role of convection in providing the secular variation turned Elsasser's attention to the possibility that the magnetic field is induced directly by the convective motions in the electrically conducting core. Convinced by then that the thermoelectric effect was too weak to provide the observed magnetic field, Elsasser set about developing the formal mathematical theory of magnetic induction by fluid motions in a sphere (Elsasser, 1946a,b, 1947). Elsasser recognized the fact that the large scale (10<sup>3</sup> km) of the principal convective motions in the liquid iron core, combined with the substantial electrical conductivity  $\sigma = 10^{16} \text{ s}^{-1}$  (resistive diffusion coefficient  $\eta = c^2/4\pi\sigma = 10^4 \text{ cm s}^{-1}$ ), coupled the magnetic field and the liquid iron over periods of  $10^3-10^4$  years. This matched the comparable characteristic turnover and nonuniform rotation times of the liquid iron core. So he decomposed the geomagnetic field **B** into what he called the toroidal (azimuthal) and poloidal (meridional) components and expressed the poloidal field in terms of a toroidal vector potential, expanding the whole in spherical harmonics. The fluid velocity **v** in the core was expanded in a similar form so that the magnetohydrodynamic induction equation

$$\frac{\partial \mathbf{B}}{\partial t} - \eta \nabla^2 \mathbf{B} = \nabla \times (\mathbf{v} \times \mathbf{B})$$

providing the growth and decay of each magnetic mode in terms of the field and fluid interaction matrix on the right-hand side.

Elsasser showed that the principal magnetic field in the core is the toroidal magnetic field, created by the interaction of the nonuniform rotation of the convecting core with the main poloidal (dipole) component of the field. Up to this point the poloidal and toroidal fields had rotational symmetry, and Elsasser was aware of Cowling's (1933) theorem (see *Cowling's theorem*) that a magnetic field with rotational symmetry cannot be sustained by fluid motions. Elsasser added quadrupole terms to the fluid motions, thereby breaking the rotational symmetry.

Unfortunately the system of equations for the mode amplitudes showed no signs of converging. The mathematical effort was carried forward, using computers to implement the mathematical analysis, by Bullard (see *Bullard, Edward Crisp* and *Dynamo, Bullard-Gellman*) and others (see *Rikitake, Tsuneji*) but without success. Pekeris, Accad, and Shkoller (1973) got around the difficulties by using a fluid velocity field with strong helicity, so that it required only a small velocity to regenerate the field, and their formal result evidently converges satisfactorily. Gubbins (1973) was able to apply computers to the formal analysis to show that the general method could be made to converge, providing a reliable physical result.

Parker, working as a research associate with Elsasser, noted that the net magnetic circulation in meridional planes (representing the dipole field) is created directly by cyclonic convective cells that push up local  $\Omega$ -shaped loops in the azimuthal field. The cyclonic cells rotate the many  $\Omega$ -loops into the meridional planes, where they spread out and merge through resistive diffusion, producing large-scale magnetic circulation, i.e., the dipole component of the poloidal field. The effect is described by the sum of the azimuthal vector potentials  $\mathbf{A}_{\varphi}$  contributed by each small rotated -loop. The net effect is described by the *dynamo equation* 

$$\left(\frac{\partial}{\partial t} - \eta \nabla^2\right) \mathbf{A}_{\phi} = \Gamma(r) \mathbf{B}_{\phi}$$

where the scalar function  $\Gamma(r)$  (nowadays written  $\alpha(r)$ ) is essentially the rotational velocity of the convective cells multiplied by the fraction of space occupied by the cells. Combining this with the Elssaser' equation for the azimuthal field  $\mathbf{B}_{\phi}$  yields a complete set of *dynamo equations* (see *Dynamos, mean field*) easily solved in rectangular geometry in terms of *dynamo waves* (see *Dynamos, kinematic; Dynamo waves*), and showing in simple terms how the physics of Elsasser's induction works out in Earth and in the Sun (Parker, 1955).

Elsasser's fundamental dynamo concept, that the magnetic field of Earth is generated by the convection in the liquid iron core, was greeted with outspoken doubt by many eminent physicists. This negative attitude began to weaken only with the publication of his review

214

paper some years later (Elsasser, 1950). The gradual acceptance of Elsasser's conjecture has led to a vast literature over the years (Elsasser, 1956; Moffatt, 1978; Parker, 1979; Krause and Rädler, 1980), exploring a variety of solutions of the dynamo equations in diverse settings (see *Dynamo, Backus; Dynamos, planetary and satellite; Geodynamo*). It is now believed that the Elsasser's magnetohydrodynamic dynamo concept is the basis for most, if not all, the magnetic fields observed throughout the cosmos. The geomagnetic dynamo has been captured recently in a numerical dynamical model of the convecting core (Glatzmaier and Roberts, 1996), illustrating the progress since Elsasser pointed scientific thinking in the right direction.

In closing, it is interesting to reflect on Elsasser's fundamental contributions to other fields of science. He was the first to point out that electron diffraction is a direct and unavoidable consequence of the de Broglie wavelength of the particle. He was the first to recognize nuclear shell structure. Following his work on geomagnetism, Elsasser turned his attention to the statistical implications of the extreme complexity of biological cells and their reproduction process, publishing his profound conclusions in a book *Reflections on a Theory of Organisms* (Elsasser, 1998). This work was so far ahead of the field at that time that it was ignored until relatively recently, when others began to catch up (see introduction by Harry Rubin to the recent 1998 edition of Elsasser's book). It is perhaps no coincidence that it required a scientist of Elsasser's stature to crack the problem of geomagnetism. The reader is referred to Elsasser (1978) for an autobiographical account of his diverse experiences throughout his remarkable career.

## EM MODELING, FORWARD

Over the last decade, the electromagnetic (EM) induction community had three large international meetings entirely devoted to the theory and practice of three-dimensional (3-D) EM modeling and inversion (Oristaglio and Spies, 1999; Zhdanov and Wannamaker, 2002; Macnae and Liu, 2003; and references therein). As a result, a multitude of various kinds of forward modeling solutions have been revealed to the community. An advanced reader may find it interesting to browse through the above references on his own.

Three-dimensional EM numerical modeling is used today, (i) as an engine for 3-D EM inversion (see *EM modeling, inverse*); (ii) for verification of hypothetical 3-D conductivity models constructed using various approaches; and (iii) as a tool for various feasibility studies and studies to investigate various 3-D effects. During 3-D modeling we solve numerically, Maxwell's equations (here presented in the frequency-domain, with time dependence  $\exp(-i\omega t)$  assumed)

$$\nabla \times \mathbf{H} = \tilde{\sigma} \cdot \mathbf{E} + \mathbf{j}^{\text{ext}},\tag{Eq. 1a}$$

$$\nabla \times \mathbf{E} = \mathbf{i}\omega\boldsymbol{\mu} \cdot \mathbf{H},\tag{Eq. 1b}$$

where the generalized conductivity  $\tilde{\sigma} = \sigma - i\omega\varepsilon$  is a scalar or  $3 \times 3$  tensor function of  $x, y, z; \sigma, \varepsilon$ , and  $\mu$  are the Earth's electric conductivity, dielectric permittivity, and magnetic permeability, respectively;  $\mathbf{j}^{\text{ext}}$  is the impressed current source,  $\nabla = (\partial_x, \partial_y, \partial_z)$  stands for the spatial gradient,  $\times$  denotes the vector product,  $i = \sqrt{-1}$ . This allows us to calculate the electric **E** and magnetic **H** fields that propagate in a 3-D conductive earth within the volume of interest.

Besides *rigorous* 3-D forward problem solutions that solve the problem in three spatial coordinates x, y, z and time t (or frequency  $\omega$ ), there is a variety of so-called *approximate* solutions.

## Approximate solutions

Approximate solutions impose constraints on the conductivity models, frequency range, and/or EM field behavior. The reasoning behind the development of such approximate solutions is that until very recently, adequate methods for accurate numerical solutions of 3-D forward problems were not properly developed and computing resources were relatively limited. Even today, a proper solution of some forward problems may take hours or days of computer time. Additionally, approximate solutions may be useful tools at some stages of inversion. Generally, 1-D and 2-D forward problem solutions may be viewed as approximate since the conductivity  $\sigma$  is restricted to be a function of only one or two spatial variables. Both cases are a particular case of the 3-D problem, considered below in detail. To date, numerical solution of 1-D and 2-D forward problems have traditionally been used.

Other solutions imposing additional constraints on the conductivity models are so-called thin sheet solutions, where the 3-D inhomogeneities are collapsed in one or more conductive, or resistive thin sheets. The calculation within the inhomogeneities is entirely neglected and substituted by known conditions that match the EM field at both sides of the sheets.

Ideally, the rigorous solution for geoelectromagnetic problems has to be able to simulate the EM field in the earth for frequencies ranging from the direct current ( $\omega = 0$ ) up to frequencies of  $\omega \approx \sigma \varepsilon^{-1}$ , where  $\varepsilon$ is the Earth's dielectric permittivity. However, accurate simulation for so many decades of frequency is a complex numerical problem. This is why some numerical solutions constrain the frequency range. In geoelectromagnetics the most popular of these are the static limit, or direct current solutions, where only low frequencies are considered.

Lastly, there is also a variety of solutions, based on approximations of the Born-Rytov type, requiring a low contrast assumption. All of the above solutions are particular cases of strict rigorous solutions and require the same approach for their solution as more rigorous ones.

## **Rigorous solutions**

There are three commonly used methods to obtain the numerical solution: finite-difference (FD), finite-element (FE), and volume integral equation (IE). These are now discussed in turn.

#### Finite-difference method

The most commonly employed is the FD method. The foundation of this method, applied to geoelectromagnetics, is grounded in the work of Yee (1966). Maxwell's equations are reduced to a second-order partial differential equation (PDE) with respect to the total electric, or magnetic field, as

$$\nabla \times \nabla \times \mathbf{E} - i\omega\mu\tilde{\sigma} \cdot \mathbf{E} = i\omega\mu\mathbf{j}^{\text{ext}}$$
(Eq. 2)

An alternative way to write Eq. (1) using the scattered field formulation is

$$\nabla \times \nabla \times \mathbf{E}^{\mathrm{s}} - i\omega\mu\tilde{\sigma} \cdot \mathbf{E}^{\mathrm{s}} = i\omega\mu\mathbf{j}^{\mathrm{s}},\tag{Eq. 3}$$

where  $\mathbf{E}^{s} = \mathbf{E} - \mathbf{E}^{0}$  is the scattered electric field and

$$\mathbf{j}^{\mathbf{s}} = (\tilde{\sigma} - \tilde{\sigma}^0) \cdot \mathbf{E}^0 \tag{Eq. 4}$$

Here,  $\tilde{\sigma}^0$  is the conductivity of a reference model, which is chosen simpler than  $\tilde{\sigma}$ ,  $\mathbf{E}^0$  is the electric field excited by  $\mathbf{j}^{\text{ext}}$  in the reference model  $\tilde{\sigma}^0$ .  $\mathbf{E}^{\text{s}}$  of Eq. (3) is subject to the Dirichlet boundary condition  $\mathbf{E}^{\text{s}} \times \mathbf{n}|_{\partial V} = 0$ , where *V* is the computational volume, and  $\mathbf{n}$  is a normal to its boundary  $\partial V$ , although other boundary conditions are possible. The preferred forms Eq. (2) or Eq. (3) depend on the specific problem. For numerical modeling one needs to reformulate the problem on a numerical grid. Details of such reformulations are necessary to understand the essence of current FD (and other) numerical methods.

The approximation of Eq. (3) on the FD-staggered grid (SG; Yee, 1966) of  $m = n_x \times n_y \times n_z$  rectangular cells yields a linear system of 3m equations

$$\nabla'_{\rm SG} \times \nabla_{\rm SG} \times \mathcal{E} - i\omega\mu\Sigma \cdot \mathcal{E} = i\omega\mu \cdot \mathcal{J}, \qquad (\rm Eq. 5)$$

where  $\mathbf{E}^{s}$  is sampled at the edges of the cells, while  $\mathbf{H}^{s} = 1/i\omega\mu\nabla\times\mathbf{E}^{s}$  is sampled at the centers of the cell faces. In Eq. (5), the SG curl-curl operator  $\nabla'_{SG} \times \nabla_{SG} \times$ ,  $\Sigma$ ,  $\mathcal{E}$ , and  $\mathcal{J}$  are the grid approximations of the continuous curl-curl operator  $\nabla \times \nabla \times$ , conductivity  $\tilde{\sigma}$ , electric field  $\mathbf{E}^{s}$ , and current  $\mathbf{j}^{s}$ , respectively. Conductivity  $\tilde{\sigma}$  is uniform within each cell. A matrix form of Eq. (5) is

$$A_{\rm FD} \cdot E = S, \tag{Eq. 6}$$

where  $A_{\rm FD} = B - i\omega\mu\Lambda$ , *E* represents  $\mathcal{E}$  at the SG nodes, *S* represents the source  $\mathcal{J}$  and the boundary conditions (see Weiss and Newman, 2003; and

references therein). The  $3m \times 3m$  matrix  $A_{\rm FD}$  is large, sparse, with no more than 13 nonzero entries in each row. It has real-valued entries everywhere except those placed at the main diagonal, which are complex-valued. This means that although the matrix  $A_{\rm FD}$  is symmetric, it is not Hermitian. A matrix-free variant of the FD method allows for dynamical calculation of the matrix  $A_{\rm FD}$  and avoids its storage.

System (6) may be solved by many methods. For 3-D problems the direct methods of matrix inversion become prohibitive in terms of both time and storage. Most of the methods commonly used for the solution of Eq. (6) are variants of Krylov iteration (Greenbaum, 1997). For instance, the quasi-minimum residual (QMR) and biconjugate gradient (BiCG) iterations are applied to solve Eq. (6). However, both methods show similarly slow convergence rates. It is known that the convergence rate is governed by the condition number

$$\kappa(A_{\rm FD}) = \|A_{\rm FD}\| \|A_{\rm FD}^{-1}\|$$

where  $A_{\text{FD}}^{-1}$  is the inverse matrix, and  $||A_{\text{FD}}|| = \max ||A_{\text{FD}}u||/||u||$ , where  $||u|| = \sqrt{(u, u)}$ . Larger condition numbers produce a slower convergence rate. As a rule, system (6) is ill conditioned with  $\kappa(A_{\text{FD}})$  as large as  $10^9 - 10^{12}$ . These poorly preconditioned systems converge slowly, if at all. In order to obtain a faster solution, Eq. (6) must be transformed to a preconditioned form.

## Techniques currently in use to achieve better solution

Today the techniques include: preconditioning, decomposition by potentials, and static divergence correction. In what follows these important issues are briefly addressed.

*Preconditioning*. A preconditioned form of Eq. (6) is (Greenbaum, 1997)

$$(A_{\rm FD}M^{-1}) \cdot X = S, \tag{Eq. 7}$$

where  $X = M \cdot E$  is the 3*m*-vector of modified unknowns, the  $3m \times 3m$  matrix *M* is called the (right) preconditioner, and  $M^{-1}$  is the inverse of *M*. When Eq. (7) is solved to give an approximate solution *X*, the solution *E* of Eq. (6) is resolved from  $M \cdot E = X$ . The preconditioner *M* is sought so that  $A_{\text{FD}}M^{-1}$  turns out close to the identity matrix. It is desirable to choose *M* so that Eq. (7) is better preconditioner than Eq. (6), i.e.  $1 \approx \kappa (A_{\text{FD}}M^{-1}) \ll \kappa (A_{\text{FD}})$ . For moderate to high frequencies system (6) may be effectively solved with the Jacobi preconditioner,  $M = diag(A_{\text{FD}})$ . An alternative way to precondition Eq. (6) is to use an incomplete Cholesky decomposition,  $A_{\text{FD}} = M^{t}M$ , where the preconditioner *M* is an upper triangular matrix, and the superscript *t* means its transpose. If  $A_{\text{FD}} = A_1 + A_2$ , where  $A_1$  dominates over  $A_2$  then  $M = A_1$ , can be used as a preconditioner. In this case the preconditioned system is

$$(1 + A_2 A_1^{-1}) \cdot X = S, \tag{Eq. 8}$$

where  $A_1E = X$ . This preconditioning is typically applied to precondition the problem in the static limit.

Static limit. At low frequencies, or at low induction numbers (LIN)  $\lambda$ , i.e., when

$$\lambda = \sqrt{\omega\mu\sigma} \cdot \Delta \ll 1, \tag{Eq. 9}$$

where  $\Delta$  stands for the characteristic grid spacing, an iterative solution of Eq. (7) may encounter certain difficulties. A stagnation, or even divergence of the QMR (with Jacobi preconditioner) and spectral Lancsoz decomposition method (SLDM) (see Section SLDM) iterations has been reported. The main reason for the poor convergence is the following. Only one part of Eq. (3) contains the conductivity  $\tilde{\sigma}$  and becomes negligibly small as frequencies approach the static limit of Eq. (9). From Eq. (5) and Eq. (9), it follows that  $\|i\omega\mu\Sigma\cdot\mathcal{E}\|/\|\nabla'_{SG}\times\nabla_{SG}\times\mathcal{E}\|\approx\lambda^2\ll 1$ , since the operator  $\nabla'_{SG}\times\nabla_{SG}\times$  is roughly estimated as  $\Delta^{-2}$ , and Eq. (5) degenerates to

$$\nabla_{\mathrm{SG}}^{'} \times \nabla_{\mathrm{SG}} \times \mathcal{E} \approx \mathrm{i}\omega\mu \cdot \mathcal{J} \tag{Eq. 10}$$

The operator of Eq. (10) has a nontrivial null space, since  $\mathcal{E}$  can be augmented by the gradient  $\nabla'_{SG} \varphi$  of a scalar function  $\varphi$  and still satisfies Eq. (10). To solve Eq. (10), we notice that, when frequencies approach the static limit, the equation

$$\nabla_{\rm SG} \cdot (\Sigma \mathcal{E} + \mathcal{J}) = 0, \tag{Eq. 11}$$

which follows from Ampere's law, must be considered as a supplement to Eq. (10) for the Earth's volume and equation  $\nabla_{SG} \cdot \mathcal{E} = 0$  for the air volume. When these supplements are ignored and a Krylov iteration is applied directly to solve Eq. (10), the null space of Eq. (10) is responsible for poor convergence. To overcome this, the static divergence correction outlined further has been proposed. It dramatically improves convergence and exploits the Helmholtz decomposition.

Helmholtz decomposition. The Helmholtz potentials  $\Psi$ ,  $\varphi$  allow decomposition of the electric field  $\mathcal{E}$  into curl-free  $\nabla'_{SG}\varphi$  and divergence-free  $\Psi$  parts, so that

$$\mathcal{E} = \Psi + \nabla'_{SG} \varphi \tag{Eq. 12}$$

Imposing the Coloumb gauge condition

$$\nabla_{\rm SG} \cdot \boldsymbol{\Psi} = 0 \tag{Eq. 13}$$

renders the Helmholz's decomposition of Eq. (12) unique. Substituting Eq. (12) in Eq. (5) and Eq. (11) yields

$$\nabla_{\rm SG}^{'} \times \nabla_{\rm SG} \times \boldsymbol{\Psi} - i\omega\mu\boldsymbol{\Sigma}\cdot(\boldsymbol{\Psi} + \nabla_{\rm SG}^{'}\boldsymbol{\varphi}) = i\omega\mu\cdot\boldsymbol{\mathcal{J}}, \quad \text{(Eq. 14)}$$

$$\nabla_{\rm SG} \cdot (\Sigma \nabla'_{\rm SG} \varphi) = -\nabla_{\rm SG} \cdot (\Sigma \Psi + J), \qquad (\rm Eq. \ 15)$$

subject to a mixture of Dirichlet and Neumann conditions:  $\mathbf{n} \times \Psi = 0$ ,  $(\mathbf{n} \cdot \nabla_{SG})\Psi = 0$ , and  $\varphi = 0$  on the computational volume boundary,  $\partial V$ . Systems (13)–(15) are strongly elliptic and weakly coupled. It is an alternative and a better form of the traditional system (5) or (6). Again, a Krylov iteration is usually applied to solve this system.

Static divergence correction. When  $\lambda \ll 1$ , Eq. (14) degenerates to

$$\nabla'_{SG} \times \nabla_{SG} \times \Psi \approx i\omega \mu \cdot J, \qquad (Eq. 16)$$

or in a matrix form

$$B\Psi = S, \tag{Eq. 17}$$

where matrix *B* is a grid representation of the curl-curl operator. Equations (13), (15), and (16) form a complete system of equations in the static limit. Equations (13) and (16) are solved jointly to compute  $\Psi$  which is substituted into Eq. (15) to find  $\varphi$ . Given potentials  $\Psi$ , and  $\varphi$ , the field *E* is found from Eq. (12). This solution is an effective preconditioner of a type given in Eq. (8), the so-called LIN preconditioner with M = B, if the system (13)–(15) is solved in the static limit (Weiss and Newman, 2003). This preconditioner is very effective at low to moderate frequencies and accelerates convergence. At high frequencies, however, the LIN preconditioned Krylov iteration can fail to converge or give much slower solution times than Jacobi preconditioning. On the basis of these ideas, a multigrid preconditioner for systems (13), (14), and (15) have also been developed (Ariliah and Ascher, 2003). This preconditioner uses single multigrid W-cycles to approximate inversion of matrices of the systems (15) and (16). It gives a preconditioned system with a grid-independent bound on its condition number. This means that for low frequencies the convergence rate does not depend on frequency and conductivity. Once frequency gets larger, the condition number increases quadratically and the convergence rate becomes slower.

The techniques presented in this section are more fundamental than mere mathematical tricks for accelerating the solution convergence. They are deeply rooted in the physics of the EM induction problem and so they allow us to more precisely describe it.

#### Resume

The main attraction of the FD approach for EM software developers is its relatively simple numerical implementation, especially when compared to other approaches, and as well as its effectiveness for many of EM problems. The drawback is that convergence of an iterative solution of Eq. (6) is not guaranteed even after a preconditioning. The large computational volume needed for stabilization of the EM field at boundaries is another limitation.

The FD method has been extended to fully anisotropic 3-D media (see *Anisotropy, electrical*). Time domain FD solutions have also been developed and implemented (Commer and Newman, 2004; and references therein).

#### Finite-element method

In the FE method the whole modeling volume V is decomposed into elementary volumes (such as prisms, tetrahedra, or more complex shapes) that specify the geometry of the conductivity model. Accordingly, the electric field of Eq. (3) (or its potentials) is decomposed as

$$\mathbf{E}^{s} = \sum_{j=1}^{m} \alpha_{j}(x, y, z) \mathbf{E}_{j}(\omega), \qquad (\text{Eq. 18})$$

where *m* is the number of nodes (as a rule, they coincide with the vertices of elementary volumes) and  $\mathbf{E}_j$  is the value of electric field at *j*th node. Functions  $\alpha_j$  of Eq. (18) are specified. The coefficients  $\mathbf{E}_j$  of decomposition (18) are sought using the Galerkin method: Eq. (3) is multiplied by  $\alpha_i$  and integrated over *V*, Eq. (18) is then substituted into the result to give

$$\sum_{j=1}^{m} \int_{V^{s}} \alpha_{i} (\nabla^{2} - i\omega\mu\tilde{\sigma}) \alpha_{j} dr' \mathbf{E}_{j} = i\omega\mu \int_{V^{s}} \alpha_{i} \mathbf{j}^{s} dr', \qquad (\text{Eq. 19})$$

or in matrix form

$$4_{\rm FE} \cdot E = S, \tag{Eq. 20}$$

where the  $3m \times 3m$  system matrix is  $A_{FE} = B - i\omega\mu C$ . Here *E* represents the 3m-vector of the components of electric field at nodes,  $B_{ij} = \int_{V^s} \alpha_i \nabla^2 \alpha_j dr'$ ,  $C_{ij} = \int_{V^s} \alpha_i \tilde{\sigma} \alpha_j dr'$ , and  $S_i = i\omega\mu \int_{V^s} \alpha_i J^s dr'$ . To derive Eq. (19) we used the theorem  $\nabla \times \nabla \times \mathbf{E} = \nabla \nabla \mathbf{E} - \nabla^2 \mathbf{E}$ . As in the case of the FD approach, we arrive at a nonsymmetric sparse system of linear equations (20). All numerical techniques to improve the solution accuracy and performance that were outlined above hold for system (20) and generally for the FE approach. The main attraction of the FE approach is that it is believed to be better able to account for geometry (shapes of ore-bodies, topography, cylindrical wells, etc.). This attraction is counterbalanced by a nontrivial and usually time-consuming construction of the finite elements themselves. The FE approach has been implemented by many developers (see Mitsuhata and Uchida, 2004; and references therein). Integral equation method

With the IE method (Weidelt, 1975; among others), Maxwell's equations (2) are first reduced to a second-kind Fredholm's IE

$$\mathbf{E}(\mathbf{r}) = \mathbf{E}_0(\mathbf{r}) + \int_{V^s} \underline{\underline{G}}_0(\mathbf{r};\mathbf{r}') (\tilde{\sigma} - \tilde{\sigma}_0) \mathbf{E}(\mathbf{r}') d\mathbf{r}'$$
(Eq. 21)

with respect to the electric field. This is known as the scattering equation (SE). To derive the SE, the Green's function technique is usually applied. In Eq. (21), the free term  $\mathbf{E}_0$  is known,  $\underline{G}_0$  is the 3×3 dyadic for the Green's function of the 1-D reference medium, and  $V^{s}$  is the volume where  $(\tilde{\sigma} - \tilde{\sigma}_0)$  differs from zero. A discretization of the SE yields the linear system  $A_{\text{IE}} \cdot E = S$ , provided that both conductivity  $\tilde{\sigma}$  and the unknown electric field **E** are constant within each cell. The system matrix  $A_{\rm IE}$  is complex and dense, with all entries filled, but more compact than the  $A_{\rm FD}$ , or  $A_{\rm FE}$  matrices. Again, to get a well preconditioned system matrix  $A_{\rm IE}$ , the modified iterative-dissipative method (MIDM) has been successfully developed (Singer, 1995) and implemented (Avdeev et al., 2002; among others). It is surprising that the MIDM-preconditioned system matrix  $A_{IE}$  has such a small condition number,  $\kappa(A_{\text{IE}}) \leq \sqrt{C_l}$ , where  $C_l$  is the lateral contrast of conductivity. The main merit of the IE approach is that only the scattering volume  $V^{s}$  is subject to discretization. This reduces the size of the matrix  $A_{\rm IE}$  dramatically, as all other methods require a larger volume to be discretized. However, most EM software developers avoid the IE method because accurate computation of the matrix  $A_{\rm IE}$  is a tedious and nontrivial problem.

For completeness, I mention the existence of surface IE solutions that assume a constant value of conductivity within the inhomogeneities (Chew, 1999).

#### Spectral Lancsoz decomposition method

Another efficient FD approach is the SLDM (Davydycheva et al., 2003; see references therein). In order to solve Eq. (6), the Lanczos spectral decomposition,  $B = QTQ^{-1}$ , is applied. Here Q is the orthogonal matrix, so that  $Q^{t}Q = 1$ , and T is a real-valued symmetric three-diagonal matrix. Entries of both matrices Q and T are sought by the Lanczos iterative process (Greenbaum, 1997). Techniques presented in Section Technique currently in use ... also hold for the SLDM. SLDM is considered as the method of choice when multifrequency modeling is required because it solves Maxwell's equations at many frequencies for a cost only slightly greater than that for a single frequency. For such numerical effectiveness the SLDM slightly sacrifices its versatility. It assumes that conductivity  $\tilde{\sigma}$  and current j<sup>ext</sup> of Eq. (1) are frequency independent, which means that the induced polarization effects cannot be taken easily into account. The SLDM has been extended to anisotropic media. Davydycheva et al. (2003) proposed a special conductivity averaging and optimal grid refinement that reduce grid size and accelerate computation. They claim that their new scheme outperforms other FD schemes by an order of magnitude.

#### Conclusion

Regardless of what method is employed, the initial forward problem (1) is always reduced to a system of linear equations

$$A \cdot X = S \tag{Eq. 22}$$

Nowadays, the system is commonly solved iteratively by a preconditioned Krylov iteration. The properties of the matrix A are determined by which method (FD, FE, or IE) is applied to solve the forward problem. In this respect, only two aspects are important, (i) how accurate the system (22) represents Maxwell's equations, and (ii) how well preconditioned the system matrix A is. Competition between various modeling approaches (FD, FE, and IE) is today focused entirely on these two issues. The ultimate goal of 3-D modelers is first, to design a more accurate approximation to Maxwell's equations within a coarser grid discretization. The second important challenge is to find a faster preconditioned linear solver. As a result of this competition between methods, we now have several very effective codes for numerical modeling of 3-D EM fields at our disposal.

The methods described in this article have many important geophysical applications (see *EM, land uses, EM, industrial uses, Transient EM induction*, and *EM, regional studies*), such as induction logging, airborne EM, magnetotellurics (see *Magnetotellurics*), geomagnetic deep sounding (see *Geomagnetic deep sounding*) and controlled source EM (see *EM, marine controlled source*). While they use Cartesian geometry, some implementations are also available to simulate 3-D spherical earth conductivity models (see *Induction from satellite data*).

## **EM MODELING, INVERSE**

The forward problem of electromagnetic (EM) induction involves solution of Maxwell's equations in the electrically conducting Earth, excited by appropriate external sources. Inverse modeling of EM data reverses this process, using data, generally observed on the surface, to image conductivity variations within the Earth. For natural source methods such as magnetotellurics (MT) the frequency-dependent response of the Earth to large-scale sources is determined by statistical estimation of transfer functions (essentially local ratios of field components) from EM time series data (see Robust EM transfer function estimates). For controlled source methods source amplitudes and phases are known accurately, and a more direct computation of the Earth response is possible. In either case, at the inversion stage the external sources are taken as fixed and known, and Earth conductivity is adjusted to match the estimated response. In general, lower frequency EM variations penetrate to greater depths, so response functions estimated over a range of frequencies allow depth variations of electrical conductivity in the Earth to be resolved. With sufficient data coverage on the surface, lateral variations of conductivity can also be mapped. In this article we focus on the MT inverse problem. Although active source EM techniques often require more complex modeling codes to account for the greater spatial complexity of sources, theory, and methodology for active source inversion is otherwise quite similar.

Developments in inverse modeling of EM induction data closely parallel those in other subsurface geophysical imaging techniques, such as seismology. Initial efforts focused on one-dimensional (1D) interpretations, with data from one site inverted to obtain information about the local conductivity-depth profile. An extensive and essentially complete theory was developed, including exact analytical solutions to idealized 1D inverse problems. However, it soon became apparent that lateral variations of conductivity must be taken into account for a proper interpretation, and two-dimensional (2D) inversion methods were developed for profiles of data across a dominant geoelectric strike. Finally, as more powerful computational resources have become available, methods for full three-dimensional (3D) inversion have been developed. Although in principle a straightforward generalization of the 2D case, 3D inverse modeling remains a challenging computational problem. Development of new algorithms for 3D inverse modeling is thus still very much an area of active research. Other areas of active research include treatment of conductive anisotropy, and appraisal of nonuniqueness in multidimensional EM inverse problems.

## **One-dimensional inversion**

For uniform external sources with time dependence  $e^{i\omega t}$  impinging on a 1D Earth of conductivity  $\sigma(z)$ , the quasistatic approximation to Maxwell's equations (omitting displacement currents) reduces to the second order linear homogeneous partial differential equation (PDE)

$$E''_{x}(z,\omega) - \mathrm{i}\omega\mu_{0}\sigma(z)E_{x}(z,\omega) = 0, \qquad (\text{Eq. 1})$$

with orthogonal electric and magnetic fields related by

$$E'_{x}(z,\omega) = i\omega\mu_{0}H_{y}(z,\omega).$$
 (Eq. 2)

In Eqs. (1) and (2), primes denote the derivative with respect to z. The 1D MT inverse problem is to find the conductivity profile  $\sigma(z)$  (or equivalently, resistivity  $\rho(z) = \sigma(z)^{-1}$ ), given measurements of the impedance  $Z(\omega) = E_x(0, \omega)/H_y(0, \omega)$ , or the equivalent inductive length scale  $c(\omega) = E_x(0, \omega)/E'_x(0, \omega)$ , at the surface z = 0. Although the relationship between the data ( $Z(\omega)$ ) and model parameters ( $\sigma(z)$ ) is nonlinear, this 1D inverse problem has an extensive literature and is now well understood. Whittall and Oldenburg (1992) provide a comprehensive review of both the mathematical theory and of practical

methods for 1D inversion of MT data. Note that other sorts of EM induction data (e.g., the ratios of internal to external fields for sources of a fixed spherical harmonic degree encountered in global induction studies) can be transformed to equivalent MT responses, so the same theory and methods can be applied more generally.

An apparent resistivity and phase can be defined in terms of the impedance:

$$\rho_{a}(\omega) = (\omega\mu_{0})^{-1} |Z(\omega)|^{2} \quad \phi(\omega) = a \tan(Z(\omega)).$$
 (Eq. 3)

If conductivity is independent of depth  $(\sigma(z) \equiv \sigma)$  then  $\rho_a(\omega) \equiv \sigma^{-1}$ and  $\phi(\omega) \equiv \pi/2$ . In this case computation of the conductivity from the measured impedance is trivial. For the realistic case where conductivity varies with depth, the apparent conductivity ( $\sigma_a = \rho_a^{-1}$ ) is a function of frequency (Figure E6). Conversion from apparent conductivity as a function of frequency ( $\sigma_a(\omega)$ ) to actual conductivity as a function of depth ( $\sigma(z)$ ) is the essence of the 1D EM inverse problem (Figures E6 and E7).

Exact measurements of  $Z(\omega)$  at an infinite number of frequencies determines  $\sigma(z)$  uniquely. However, as with all practical inverse problems, real data are finite in number and imprecise, so solutions to the MT inverse problem are highly nonunique. In general, MT data constrain only the product of conductivity and layer thickness (the conductance), not the actual conductivity or layer thickness. Furthermore, the resolution of MT data tends to decrease with increasing depth, and the actual resistivity of a section beneath a more conducting layer is typically poorly determined.

A number of approaches for constructing specific solutions to the inverse problem have been proposed. The simplest involve approximate functional transformations of  $c(\omega)$  or  $Z(\omega)$  to  $\sigma(z)$ . Although

**Figure E6** Apparent conductivity (inverse of apparent resistivity), and phase from a five layer 1D model (Figure E7). (After Whittall and Oldenburg, 1992).

**Figure E7** Examples of 1D inversions of the synthetic data of Figure E1. Dashed line gives actual layered model used to generate the data. (a) Heuristic Schmucker inversion of Eq. (4). (b) Layered inversion, with the unknown structure defined by five layers of unknown thickness and conductivity. (c) Minimum structure inversion, obtained by minimizing the norm of  $\sigma'(z)$ , subject to fitting the data within error bars. (d)  $D^+$  inversion, the model which best fits the synthetic data. Each line corresponds to a thin layer of finite conductance, appropriately scaled to conductivity. (After Whittall and Oldenburg, 1992).

not true inversions (the conductivity profiles generated do not generally reproduce the observed response functions), these transformations provide reasonable rough estimates of conductivity profiles in many situations, and their derivations provide physical insight into the inverse problem. Perhaps the simplest example is the so-called Schmucker inversion. Given  $c(\omega_j)$  at a finite set of frequencies, define

$$z_j^* = \Re[c(\omega_j)] \quad \sigma_j^* = (2\omega_j\mu_0)^{-1}\Im[c(\omega_j)]^2.$$
 (Eq. 4)

A plot of  $\sigma_j^*$  vs the discrete set of depths  $z_j^*$ , can be shown to provide a reasonable zero order approximation to the conductivity profile. An example for the synthetic data of Figure E6 is given in Figure E7a. Whittall and Oldenburg (1992) provide heuristic justification for this simple approach, and describe a number of similar approximate inversions.

More rigorous inversion of MT data can be accomplished with standard methods of nonlinear geophysical inversion (e.g., Parker, 1994). These methods can generally be formally reduced to minimization of a penalty functional of the form

$$\begin{split} \mathcal{J}(\mathbf{m},\mathbf{d}) &= (\mathbf{d}-\mathbf{f}(\mathbf{m}))^{\mathrm{T}} \mathbf{C}_{\mathbf{d}}^{-1} (\mathbf{d}-\mathbf{f}(\mathbf{m})) \\ &+ (\mathbf{m}-\mathbf{m}_0)^{\mathrm{T}} \mathbf{C}_{\mathbf{m}}^{-1} (\mathbf{m}-\mathbf{m}_0). \end{split} \tag{Eq. 5}$$

Here **d** is the data vector of dimension  $N_d$  (e.g., real and imaginary parts of the complex impedance  $Z(\omega_j)$  estimated at a discrete set of frequencies),  $C_d$  is the covariance matrix of data errors (typically diagonal), **m** is the  $N_m$ -dimensional conductivity model parameter vector (e.g.,  $\sigma_j$  for a finite number of layers), **f**(**m**) defines the forward mapping, obtained by solving Eq. (1) at the appropriate frequency, **m**<sub>0</sub> is a prior (or preferred) value of the conductivity parameter **m**, and **C**<sub>**m**</sub> is the covariance of the unknown model parameters used to regularize the inversion (often given as a "roughening operator"  $\mathbf{C}_m^{-1}$ ). The two terms on the right-hand side of Eq. (5) penalize data misfit, and the norm or size (in some general sense) of the model parameter **m**, respectively.

If the conductivity profile is described in terms of a small number of parameters (e.g., 3-5 layers of unknown thickness and conductivity, for a total of 6-10 unknown parameters; see Figure E7b), the second term explicitly penalizing **m** is typically omitted. However, frequently the conductivity model is overparameterized, with a large number of thin layers of unknown conductivity. In this case there are essentially an infinite number of parameter vectors that fit the data equally well, so some sort of penalty on the model size (i.e.,  $(\mathbf{m} - \mathbf{m}_0)^T \mathbf{C}_{\mathbf{m}}^{-1} (\mathbf{m} - \mathbf{m}_0))$  is required to make the problem well-posed. Once the model parameterization and penalty functional are defined, any of a number of standard search algorithms can be used to seek the minimum of  $\mathcal{J}$ . Some specific approaches are described in Parker (1994). In general, these involve linearizing the forward mapping  $\mathbf{f}(\mathbf{m})$ , though for the 1D inverse problem global Monte Carlo search strategies which do not require explicit calculation of derivatives, such as simulated annealing or the genetic algorithm, have been successfully applied.

One very popular linearized approach is the "minimum structure" inversion. In this approach, the model penalty in Eq. (5) is the norm of the first or second derivative of  $\sigma(z)$ , and the minimizer of  $\mathcal{J}$  is the simplest (in the sense of flatness or smoothness of the conductivity profile) consistent with the achieved data misfit (Figure E7c). These minimum structure models are less likely to contain features that are not required by the data. Several different gradient-based optimization algorithms have been used for minimum structure inversions; further details can be found in Whittall and Oldenburg (1992) and Parker (1994).

The 1D MT inverse problem is somewhat unusual in that a number of exact nonlinear inversion algorithms are available. These are important from a theoretical perspective since they provide a constructive proof of existence and uniqueness of inverse solutions. However, these exact nonlinear algorithms all require perfect and complete data, so some adaptation is necessary to apply these to real finite noisy data sets. Generally a two-step procedure is used (Whittall and Oldenburg, 1992): first the incomplete noisy data must be fit to a physically realizable response at all frequencies; then the exact inversion is applied to convert the completed response into the unique corresponding conductivity profile. The most important example of this approach is the so-called  $D^+$  inversion of Parker (1980). Using the representation of  $c(\omega)$  in terms of the Sturm-Liouville spectrum of the differential operator in Eq. (1) to complete the estimated response, Parker showed that the best fitting conductivity model for real data sets would generally consist of a finite number of infinitely thin layers of finite

cally realistic, the  $D^+$  inversion is very useful because it provides a rigorous assessment of the degree to which a real data set is consistent with the assumption of a 1D conductivity profile. The nature of the best fitting profile is also instructive with regard to the nonuniqueness of MT data: only conductance, and the rough distribution of conductance with depth, can be resolved by MT data, not the actual value of conductivity at any depth (Figure E7).

#### Model appraisal

Many particular conductivity profiles will fit any data set equally well, so assessment of which features are common to all acceptable solutions is an important part of the inverse problem. The classical approach to model appraisal for linear problems is Backus-Gilbert theory, based on construction of spatial averages of model parameters that are constrained by the data. For the nonlinear EM inverse problem this resolution analysis requires linearization, and thus only provides a rough characterization of nonuniqueness. Constrained inversion provides an alternative approach to inverse solution appraisal. For example, to test if a particular conductive layer is required, the inversion can be run with conductivity in the appropriate depth range constrained to a low value. If the data cannot be fit adequately subject to this constraint, but can be when the constraint is relaxed, higher conductivity is required on average over this depth range. This general idea can be formalized to construct upper and lower bounds on the total conductance in a given depth range. Details of these, and related appraisal methods for the 1D EM inverse problem are given in Whittall and Oldenburg (1992).

## **Two-dimensional inversion**

For 2D MT modeling a fixed geoelectric strike is assumed, with conductivity  $\sigma(y, z)$  varying across the strike (y), and with depth (z), but not along the strike (x). In this case the MT forward problem decouples into two modes: the transverse electric (TE) or E-polarization mode, with electric currents flowing only in the *x*-direction parallel to the geologic structure, and the transverse magnetic (TM) or B-polarization mode, with electric currents flowing only in the *y*-direction perpendicular to the strike. In both modes the horizontal magnetic fields are still perpendicular to the electric fields, oriented across strike for TE, and along strike for TM. Now there are distinct impedances for TE and TM modes

$$Z_{xy} = E_x/H_y, \quad Z_{yx} = E_y/H_x,$$
 (Eq. 6)

as well as vertical field transfer functions (or "tippers") in the TE mode  $T = H_z/H_y$ . As for the 1D case the impedances are often transformed to apparent resistivities and phases, using Eq. (3). Data for 2D interpretation are generally collected along a profile crossing the presumed geoelectric strike. These data are commonly displayed as cross-strike pseudosections, with frequency on the vertical axis (Figure E8). Conversion of these images to conductivity sections, merging information from both modes, and replacing frequency by depth, is the goal of 2D inversion (Figure E8).

For the TE mode, Maxwell's equations can be reduced to a 2D scalar diffusion equation for the along strike electric field

$$\nabla^2 E_x - \mathrm{i}\omega\mu_0 \sigma E_x = 0. \tag{Eq. 7}$$

This is analogous to the 1D equation of Eq. (1). For the TM mode, Maxwell's equations can be reduced to a scalar equation in the along strike magnetic field

$$\nabla^2 B_x + \sigma^{-1} \nabla(\sigma) \cdot \nabla(B_x) - \mathrm{i}\omega \mu_0 \sigma B_x = 0.$$
 (Eq. 8)

Discretizing Eqs. (7) and (8) with a finite-difference or finite-element approximation results in systems of linear equations that can be solved by a number of approaches, including forming and factoring the banded coefficient matrix, and iterative Krylov space solvers such as biconjugate gradients (e.g., Press *et al.*, 1986).

Although existence and uniqueness of solutions to idealized 2D inverse problems has been proven, theory is far less complete than for the 1D case. In particular, there are no exact analytical procedures for constructing inverse solutions to 2D problems, and there is no general theory to establish consistency with a 2D interpretation for practical datasets.

Some approximate rapid schemes for converting 2D pseudosections to conductivity images have been developed and used. These are mostly based on rewriting the induction equations in integral form, and then using a Born scattering approximation to reduce to an approximate linear inverse problem. Although these methods can be very fast, images constructed are not guaranteed to actually fit the data. With increases in computing power, approaches based on minimizing a penalty functional of the form (5) have become most popular. In principle this can be accomplished with a straightforward extension of the 1D methods, but with the 2D forward, Eqs. (7) and (8) replacing Eq. (1) for computation of the forward mapping. However, for 2D problems there are many more unknown model parameters and data sets are much larger, so issues of computational efficiency become much more central.

Minimization of a penalty functional such as Eq. (5) is most directly accomplished through some sort of gradient based search. The most straightforward scheme is based on computing the Jacobian, i.e., the  $N_d \times N_m$  matrix of first derivatives of the forward mapping

$$\mathbf{G} = \frac{\partial \mathbf{f}}{\partial \mathbf{m}},\tag{Eq. 9}$$

which can be accomplished most simply by solving nonhomogeneous versions of Eqs. (7) and (8) for every frequency, for each of the  $N_m$  columns of **G**. Using the fact that sources and receivers are symmetric in the governing equations ("reciprocity") computation of **G** can generally be accomplished more efficiently by solving one forward problem for each data point, with a source located at the data site. With **G** available, the inverse problem can be linearized, and standard methods of linear inverse theory can be applied to find model parameters which more closely fit the data. Using the updated model parameters, **G** (which depends on the model conductivity) is recomputed and the inverse model further refined. These steps are iterated until no further reduction in  $\mathcal{J}$  is possible. Details on several general schemes for implementing such a linearized iterative search, including the most commonly used for EM inverse problems, are given in Parker (1994), Siripunvaraporn and Egbert (2000), and Rodi and Mackie (2001).

The reciprocity approach improves efficiency of the Jacobian computations considerably, but construction and storage of G still requires significant computer time and memory. A variety of computational approaches have thus been proposed to make 2D inversion more practical. These include using approximations to the data sensitivities based on simpler 1D models (Smith and Booker, 1991), and constructing only a part of G to guide the linearized search (Siripunvaraporn and Egbert, 2000). A very common approach used now is to directly minimize J using a nonlinear conjugate gradient (NLCG) approach (Press et al., 1986; Rodi and Mackie, 2001), completely avoiding construction and storage of G. Each step in the NLCG search for the (local) minimum requires computation of the gradient of  $\mathcal{J}$ ; this can be shown to require two TE and TM forward solutions for each frequency. NLCG is attractive because it completely avoids forming or inverting large matrices. However, because many more iterations can be required compared to schemes which make use of the Jacobian, the number of forward solutions may not be significantly reduced,

(a) Parkfield Line 1: Data

**Figure E8** Example of a 2D MT data set and inversion. Pseudosections of (a) TE apparent resistivity; (b) TE phase; (c) TM apparent resistivity; TM phase, from an MT survey near Parkfield California. (d) Resistivity section obtained by inversion of TE and TM data, using a 2D minimum structure inversion. (After Siripunvaraporn and Egbert, 2000).

particularly in comparison with data space search schemes based on a partial sensitivity computation (Siripunvaraporn and Egbert, 2000). Nongradient based search schemes such as the genetic algorithm have been tried for 2D EM inverse problems, but searching the comparatively large parameter space required to represent 2D conductivity variations has not proven practical as yet.

Although a number of computationally feasible 2D MT inversion schemes have been shown to perform quite well on synthetic data, there are a number of complications with real data. Significant expert user intervention is thus often still required for successful 2D inversion of MT data. One challenging problem is that near surface small-scale geology is often very complicated, and can almost never be represented by a single 2D model that matches the regional geoelectric strike. Even if only superficial, these structures can galvanically distort electric fields, resulting in frequency-independent "static shifts" of apparent resistivity curves. Correction for these static shifts has been found to be essential for correct interpretation of deeper structure. In the context of inversion, additional model parameters are required to account for these distortions. Estimation of these surface distortion parameters has been integrated into some 2D inversion codes, but separate distortion analysis is also generally now seen as a critical step in 2D MT interpretation. Because phases are less effected by distortion initial inversions of field data often emphasize fitting of phase data, with apparent resistivities given less weight, and introduced later in a multistage inversion sequence.

Deeper structure can also result in 3D complications. For example, the EM response of a structure elongated along strike, but of finite length, will depend on how close one is to the ends of the structure. In general the TE mode, for which electric currents must flow through the ends of the structure, is most severely effected. As such, TM mode data are also often given higher weight, particularly for initial stages of inversion. Regional structure may also pose difficulties for 2D inversion. For example, a nearby coastline may not be parallel to the local geology. Since regional structure generally has a greater influence at longer periods, this complication may be ameliorated by emphasizing fit to shorter period data, but this of course limits the depth of investigation.

A final, and very important potential complication in 2D interpretation is conductive anisotropy, which may well be ubiquitous in the crust, and perhaps also the upper mantle. Allowing for conductivities that depend on the direction of current flow significantly increases the size of the model space, and as a result ambiguity and nonuniqueness in EM inversions. Some 2D inversion codes now allow for anisotropy, but there is so far little real understanding of resolution and trade-offs when this richer model space is allowed for.

More generally, methods for model appraisal and characterization of nonuniqueness in 2D EM inversion is an area of active research. Linearized resolution analysis can be used if sensitivities are calculated, but the requirement of linearization is perhaps even more of a limitation than for the 1D case. Testing for required features through constrained inversion is also an option for 2D inversion, but methods for constructing rigorous bounds on conductance that have been developed for the 1D EM inverse problem do not generalize in any obvious way to higher dimension.

## Three-dimensional inversion

Three-dimensional inversion is a natural extension of 2D inversion, allowing for arbitrary variations of conductivity within the Earth. For the 3D MT problem two possible source polarizations must be considered as in the 2D case, but now there is no preferred coordinate system where the induction equations simplify or decouple. In the general 3D case the MT impedance tensor (i.e.,  $2 \times 2$  frequency domain transfer function matrix relating electric to magnetic fields at a site) has four complex elements:  $Z_{xx}, Z_{xy}, Z_{yx}, Z_{yy}$ , along with a more general vertical field transfer function giving local ratios of vertical to horizontal magnetic fields  $(T_x, T_y)$ . Model results for both polarizations are required to form the impedance elements and transfer functions which can be fit in the inversion. The forward problem generally involves solving a vector diffusion equation, formulated variously in terms of electric or magnetic fields, or some sort of potentials. For example, in terms of the 3D vector electric fields E the forward problem can be expressed as a PDE

$$\nabla \times \nabla \times \mathbf{E} - i\omega\mu\sigma\mathbf{E} = 0, \tag{Eq. 10}$$

which is to be solved subject to boundary conditions appropriate to the source assumptions. Integral equation formulations are also used for 3D modeling and inversion. All formulations are readily derived from the usual quasistatic approximation to Maxwell's equations. Factoring the banded coefficient matrix obtained from a finite-difference or finite-element discretization of Eq. (10) is practical for the analogous 2D problem, but prohibitively expensive in 3D. As a result the forward 3D problem is almost always solved with iterative techniques.

Few analytical results are available for the 3D EM inverse problem. As for the 2D problem, efforts have focused on regularized inversion through numerical minimization of a penalty functional such as Eq. (5). Most of the discussion of 2D inversion methods is applicable to the 3D case, but computational challenges are even greater. In particular, the number of model parameters is typically so large that storing the full Jacobian **G** is all but impossible. NLCG, which avoids computing **G** altogether, is thus the most common approach to 3D inversion. Other approaches which have had some success include using very coarse parameterizations, and data space schemes which avoid storing all of **G**.

As of this writing there is relatively little practical experience with 3D inversion. In addition to the severe computational challenges, there are few data sets of sufficient density to truly resolve 3D structures. Data sets collected in industry applications are the most extensive, and much of the relevant experience with 3D inversion is in the private sector, and with active source EM, often for near-surface applications. Even with data sets that are not sufficiently extensive to truly image 3D structure, 3D inversion may be useful for obtaining more reliable interpretations of profile data across approximately 2D structures. Development of more efficient 3D inversion schemes, and learning how to use these for interpretation of diverse EM data sets is an area of active research.

## Introduction

Mineral, petroleum, environmental, and geotechnical companies routinely measure electrical conductivity properties of Earth materials to map near-surface geological structures, locate economic resources, and define environmental and engineering problems. Targets may be more electrically conductive than the host environment, for example in the case of many mineral deposits (Ohleoft, 1985) and for the location of groundwater (McNeill, 1990). Alternatively, in the petroleum industry the focus is often on regions that are less conductive than the host, either in the case of a hydrocarbon-filled layer, or for an impermeable formation such as salt domes that trap hydrocarbons (Hoverston *et al.*, 1998). For environmental and geotechnical studies, high-frequency (>1 MHz) EM methods can also be used in a technique called ground-penetrating radar (Daniels *et al.*, 1988). At such high frequencies, electrical conductivity is less important than the dielectric properties of the materials.

To measure the electrical conductivity, the primary methods are either galvanic electrical techniques, in which a constant electrical current is applied to the Earth, or EM induction techniques, in which electrical currents are induced to flow in the Earth by a time-varying external field. The external field can be either magnetic or electrical, and the Earth's response is measured with a *magnetometer* (q.v.), an electric dipole coupled to the ground, or a combination of both. The time-varying signals originate either from natural sources, or applied, controlled sources.

EM methods in common use by industry can be broadly categorized in terms of the type of source fields. If the source of the externally varying field is sufficiently distant from the location of measurement, the source is approximately plane-wave, and is said to be onedimensional (varying in only one direction). On the other hand, if the source and the measurement are close, then the source is said to be three-dimensional (varying in all spatial dimensions). This latter category can be further subdivided into techniques that use a continuously varying controlled source field, usually in the form of a sine wave, known as frequency-domain electromagnetics (FEM), and those that require a source that abruptly switches on and off as a square wave, known as time-domain electromagnetics (TEM) or *transient electromagnetic induction* (q, v). 224

EM methods have been adapted by industries to a wide range of environments. There is a rapidly growing marine EM(q.v.) industrial sector (Chave et al., 1991; Constable et al., 1998) in which the source field is either due to natural changes in Earth's magnetic field or a transmitter is towed behind a ship, and seafloor electrical and magnetic receivers measure the induced signals. Marine EM measurements of the subseabed electrical conductivity are complementary to seismic methods, and help reduce the risk by identifying more suitable drilling targets. Aircraft and helicopters have been modified to carry a wide range of EM sensors, often with a transmitter loop between nose, wingtips, and tail, and with a secondary magnetic receiver towed behind the aircraft (Palacky and West, 1991). Airborne measurements have long been used in mineral exploration by rapid imaging of electrically conductive basement structures, often through many meters of overburden (weathered materials). More recently, these techniques have become important in natural resource management for mapping surface salinity and deeper saline aquifers. Drillhole EM techniques are widely used in the petroleum industry to determine the electrical conductivity properties of the sequences surrounding the borehole, and in mineral and environmental industries to image the extent of structures away from the borehole (Dyck, 1991).

## Plane wave source methods

The most common types of plane wave methods are known as VLF (very low frequency), AMT (audio-magnetotellurics (q.v.)), and CSAMT (controlled-source magnetotellurics (q.v.)). The VLF method uses a distant vertical electric dipole (denoted  $E_z$ ) that results from a time-varying current in a long wire orientated vertically above the ground (McNeill and Labson, 1991). Such electric field dipoles are developed as military radio transmitters and operate in the 15–24 kHz range, and are used for global-scale communication with submarines. There are many such transmitters around the world, thus providing a VLF signal in most parts of the globe.

The vertical flow of current generates horizontal magnetic field (denoted  $B_x$  and  $B_y$ ) components, each perpendicular to the direction of propagation, and a small electric field  $(E_x)$  in the direction of propagation. When the electric field  $E_x$  is incident on a boundary between two materials of different conductivity, electric charges are induced at the interface. This modifies  $E_x$  to produce a "current channeling" effect, which produces a secondary magnetic field that has an anomalous vertical component  $B_z$ . It is this component that is measured in a VLF survey. It is also possible to measure the ratio of the amplitudes of the horizontal electric and magnetic field components at the Earth's surface to determine the apparent resistivity and phase in the same manner as the magnetotelluric method (Becken and Pedersen, 2003). The primary advantage of the VLF method is that as the source-field is always present and predictable, the anomalous  $B_z$  field can be measured quickly with a roving magnetometer to provide a surface map of the electrical conductivity structures.

Mineral and petroleum exploration can be carried out using the magnetotelluric (q.v.) method (Vozoff, 1991; Zonge and Hughes, 1991). To provide the highest resolution in the top few kilometers of Earth, frequencies in the bandwidth 1 Hz to 20 kHz are used. At the high-end of the bandwidth, these frequencies are in the audio range, hence the name AMT. Source-fields are either naturally occurring lightning strikes at equatorial latitudes (essentially a large vertical electric field  $E_z$  as for the VLF method), or provided by a controlledsource that consists of a distant applied electric or magnetic dipole field. In the AMT or CSAMT method, horizontal and orthogonal components of the electric ( $E_x$  and  $E_y$ ) and magnetic ( $B_x$  and  $B_y$ ) fields are measured to yield an apparent resistivity and phase as a function of frequency. Forward modeling (q.v.) and inverse modeling (q.v.)provide a depth-dependent image of electrical conductivity. Lateral coverage is slower than the VLF method due to the requirement of measuring the electric fields with grounded electrodes.

#### Frequency-domain electromagnetic (FEM) methods

In FEM methods, a time-varying current of a known frequency is applied in a transmitter loop of wire at some location, as shown in Figure E9 (Frischknecht et al., 1991). The loop itself may consist of many turns of wire. Electrical currents flowing in a loop generate a primary (p), time-varying magnetic dipole field that will be horizontal  $(B_{v}^{p})$  if the loop is orientated vertically, or vertical  $(B_{z}^{p})$  is the loop is flat on the ground. The time-varying magnetic dipole fields induce eddy currents to flow in Earth, which in turn generate secondary (s) magnetic fields  $B^{s}$ , as shown in Figure E10. A receiver at a nearby location, which can be a second loop of wire, or a magnetometer (q.v.) sensor, measures a combination of the primary fields,  $B^{p}$ , which is known, and the induced secondary fields  $B^{s}$ . The relative contribution of these fields depends on the proximity and orientation of the receiver to the transmitter, and the electrical conductivity of the Earth between the two. The difference in fields is usually measured as a combination of relative amplitude and a phase difference, or as in-phase and out-of-phase (quadrature) components.

In most commercial systems, measurements are made at one or more frequencies, typically in the range 1-100 kHz. Variations in electrical conductivity with depth can be determined by measurements made at different frequencies, and by changing the orientation of the coils. Lateral mapping can be achieved by moving either one or both coils. Depth of penetration is relatively small, limited by the power than can be produced by the transmitter.

FEM methods are widely used in environmental and geotechnical studies, but are also becoming more widespread in *marine EM* (q.v.) exploration for petroleum targets. A particularly common configuration is known as a ground conductivity meter (McNeill, 1980), for which the skin-depth of signal penetration is greater than the loop separation. In this case, the quadrature (or out-of-phase) component

**Figure E9** The arrangement of transmitter and receiver loops in frequency-domain electromagnetic (FEM) systems. Current flowing in the transmitter coil generates a primary magnetic ( $B^{p}$ ) field that induces eddy currents in a conductor. The resulting secondary magnetic fields ( $B^{s}$ ) are measured with a receiver loop.

**Figure E10** The combination of primary ( $B^p$ ) and secondary ( $B^s$ ) fields recorded with a FEM system. The measured response can be determined in terms of an amplitude difference and/or a phase difference  $\phi$ .

**Figure E11** Distribution of eddy currents beneath a time-domain transmitter. At time  $t_1$ , immediately after switch-off, eddy currents flow close to the surface; at progressively later times ( $t_2$  to  $t_4$ ) eddy currents spread out and down.

of the secondary field is linearly proportional to the ground apparent resistivity, which allows rapid spatial mapping of electrical conductivity to be made by foot, vehicle, or helicopter.

#### Time-domain electromagnetic (TEM) methods

In TEM systems in Figures E11 and E12, the applied electric current in a transmitter loop is switched on and off, in the form of a square wave (Nabighian and Macnae, 1991). In the time intervals when the current is on, a static primary magnetic field  $B^p$  is established. When the transmitter current in the loop is extinguished, the primary field collapses almost instantly, and this rapid change in primary field generates large eddy currents in the Earth, close to the surface. Such eddy currents in turn yield a secondary magnetic field  $B^s$  that can be measured with a receiver loop, or a magnetometer sensor. Eddy currents continue to flow after switch-off (typically for a few milliseconds) and become broader and deeper. The resulting secondary magnetic field also reduces in amplitude, in Figure E12. Energy is lost as heat, and the rate of decay depends on the electrical conductivity of Earth.

**Figure E12** Waveforms encountered in time domain EM systems. (a) The top figure shows the applied current in the transmitter loop and the resulting primary magnetic field. (b) Secondary magnetic fields are measured in the times when the current is switched off, and which are observed to decay with time as eddy currents dissipate.

TEM methods are widely used in the mineral exploration industry, and are increasingly being used for environmental studies. There are two significant advantages of TEM over FEM methods. Firstly, as measurements of signals in the receiver loop or magnetometer sensor need only be made in the intervals when the primary field is switched off (i.e.,  $B^{p} = 0$ ), it is easier to detect the small secondary field  $B^{s}$ decay. Secondly, larger eddy currents can be induced as the primary field changes much more rapidly than in FEM systems. The measured decay in the secondary field can be converted to an apparent resistivity as a function of time. Modeling and inversion techniques can then be used to determine the electrical conductivity of Earth, typically as a function of depth. TEM loops used in the minerals industry are often of dimensions of hundreds of meters, with applied currents of tens of amperes, to provide conductivity models to depth of several hundred meters. For environmental studies the loops are typically 20 m, with targets in the top 50 m.

## Grounded wire methods

Methods that involve an injection of time-invariant electrical current into the ground are generally denoted galvanic. Pathways, and resulting current densities, are determined by Earth's electrical conductivity, and are typically measured as a horizontal electric field ( $E_x$  and  $E_y$ ) by a grounded dipole.

A variation on this approach is to measure the resulting secondary magnetic field  $B^{s}$  due to the subsurface current distribution (Edwards *et al.*, 1978; Edwards and Nabighian, 1991). The magnetometric resistivity (MMR) technique is used in mineral exploration and has proved to be useful in imaging basement structure beneath overburden. Two advantages over traditional ground dipole measurements are that data can be acquired rapidly as there is no requirement to have grounded electrodes, and that the secondary magnetic field is the integral sum of the contributions from all the current elements around the measurement's location. The MMR method is therefore less sensitive to near-surface inhomogeneities (Edwards, 1988).

**Figure E13** (a) Schematic of a ground-penetrating radar system to detect subsurface structure. The cross section shows interpreted reflections from the radargram in the lower figure. The airwave and groundwave are signals that propagate between the transmitter and receiver through the air and the top few centimeters of the ground, and are therefore almost constant across the profile. (b) Reflections of high frequency (in this case 200 MHz) EM waves shown as a typical grayscale radargram in the lower figure.

#### Ground-penetrating radar (GPR)

All methods described above are for variations in EM fields that occur at frequencies of 100 kHz, or lower. At these frequencies, EM fields diffuse into the Earth, and are primarily sensitive to electrical conductivity. On the other hand, at sufficiently high frequencies of 1 MHz or more, applied EM fields behave as waves and the main physical parameter of importance is the dielectric permittivity, usually given the symbol  $\varepsilon$ . The dielectric permittivity determines the reflection and transmission characteristics of interfaces between layers.

In GPR surveys, pairs of interchangeable radar antennas are used as a transmitter and receiver, as shown in Figure E13 (Daniels *et al.*, 1988). A pulse of high-frequency signal is directed into the ground, and the EM echoes are recorded. Depths of penetration are typically about 50 m for 10 MHz, 5 m for 100 MHz, and 0.5 m for 1000 MHz.

In environmental studies, the water content dominates the dielectric properties, as the dielectric permittivity of water is typically ten times greater than that of solid grains. Thus, GPR is used to map depths to water tables and soil moisture content. For geotechnical studies, GPR studies are effective at mapping near-surface engineering structures, including pipes, cavities, and metal objects.

## Summary

There continues to be growth in the use of EM methods for resource exploration, and for environmental and engineering applications. These methods are generally rapid and noninvasive, and provide both a lateral and vertical image of electrical conductivity and dielectric permittivity properties of Earth. The industry has adapted these methods to operate in a wide range of environments, particularly in the fields of land, marine, airborne, and downhole studies.

## **EM, LAKE-BOTTOM MEASUREMENTS**

Magnetic fields set up by electrical currents flowing in the Earth's ionosphere and magnetosphere diffuse into the Earth's interior, and induce electrical currents to flow in the oceans and in conductive regions in the Earth's interior. Longer period magnetic field variations have a greater depth of penetration than shorter period variations. By relating the variations in the electric field to those in the magnetic field at different locations and over a range of different periods, it is possible to reconstruct the distribution of electrical conductivity within the Earth, and from that information, to constrain the temperature, composition, fluid and volatile content, and state of Earth materials. This is the magnetotelluric (MT) method (see *Magnetotellurics; Galvanic distortion; EM, land uses*).

In order to penetrate deep into the lithosphere and below, longperiod MT measurements are required. Other methods involving only magnetic field measurements (see *Geomagnetic deep sounding*; *EM*, *regional studies*) are valid for field variations with periods longer than 2–4 days, and provide information on electrical conductivity of the mantle at depths below 400 km (Schultz *et al.*, 1987) (see *Mantle*, *electrical conductivity, mineralogy*). Conversely, the MT method is usually employed to investigate periods many decades shorter than this, generally less than 0.2 days. Consequently most MT investigations are restricted to the crust and uppermost mantle. By extending the range of MT investigations to longer periods, finer structural details may be resolved at depth, and information on anisotropy within the crust and mantle may be returned.

The electric field is measured by monitoring the electrical potential across (typically) two orthogonal pairs of metal salt electrodes grounded to Earth and separated by a fixed distance. Electrode noise is a consideration for MT. There is long-period electric field measurement drift due to variations in electrochemical conditions in the soil, moisture content, and thermal effects (Perrier and Morat, 2000), and to electrokinetic effects (Trique *et al.*, 2002). To improve the signal-to-noise ratio, a number of deeply penetrating MT investigations have taken place making use of extremely long electrode separations, by using leased telephone cables on land (Egbert *et al.*, 1992), or abandoned submarine telecommunications cables on the seafloor (see *Conductivity, ocean floor measurements*).

Schultz and Larsen (1987) proposed that the thermally and electrochemically stable environment of lake bottoms might provide an ideal environment to extend MT into periods of 0.2–4 days and below, thus spanning the gap in coverage left by conventional MT and magnetic field methods. While lake-bottom MT shares common features with ocean bottom MT, the high conductance of marine sediments and the conductive seawater overburden at most marine study sites shields the seafloor from the high frequency signals that penetrate to the bottom of lakes, and that can provide higher resolution information on shallow crustal and upper mantle conductivity structure. While contamination of the EM fields by water motions (such as mesoscale eddies) impose a low frequency limit to MT in the oceans, this is generally not a significant consideration in lakes.

A prototype lake-bottom MT station was installed in Lake Washington, in Seattle, Washington, to form an array of Ag-AgCl electrodes, with electrode separations of 800–1300 m. This configuration provided three nonorthogonal components of the electric field, any two of which could be rotated into orthogonal components. A fluxgate magnetometer was buried on the adjacent shore, and high-quality MT data resulted. The MT regional strike direction was seen to be coincident with the strike delineated by regional seismicity and tectonics. The effects of a channeled current were seen, attributed to an Eocene suture zone to the south of the site (Schultz *et al.*, 1987).

A multiyear lake-bottom MT deployment followed in the Archean Superior craton of northern Ontario, Canada (Schultz et al., 1987). More than 2 years of MT data were collected from Carty Lake, following the configuration at Lake Washington. Three zones in the mantle were identified, centered at depths of 280, 456, and 825 km, and roughly coincident with major seismic discontinuities, where the conductivity increased abruptly (Figure E14). The ability to discriminate the jump centered at around 456 km was attributed to MT data with periods of 1 h to 1 week, which were made possible by the stable lake-bottom installation. No other MT experiment to date has produced resolving power sufficient to discriminate the 456 km conductivity increase. The conductance of the upper mantle here was roughly an order of magnitude higher than that predicted by a standard olivine model using a standard geotherm. It was determined that either the upper mantle geotherm was erroneously biased downward, or a dry olivine upper mantle model was inappropriate.

Jones *et al.* (2001a,b, 2003) report on the lake-bottom deployment of compact MT instruments designed for marine use, and of electric dipole receivers inserted through the ice to the bottom of frozen lakes, with magnetometers nearby on shore. These installations in roughly 20 lakes were made to probe to the depth of the top of the asthenosphere beneath the Slave craton in northwestern Canada, in a region of diamondiferous kimberlite pipes. Their investigations serendipitously revealed a highly conductive zone at depths of 80 to below 100 km in the mantle that is interpreted to represent interconnected carbon or graphite along mineral grain faces. Jones *et al.* (2003, 2004) determined that the Superior craton MT data of Schultz *et al.* (1993) and those of the Slave craton indicate that while both provinces differ in shallow structure, on average the deeper mantle sections are nearly identical. Jones *et al.* (2003) compared the lake-bottom MT data against earlier data from the region, and found that these depths had previously been beyond the

**Figure E14** Electrical conductivity model for lake-bottom MT site, Carty Lake, Superior craton, Canada. The thick curve is the model of  $\log_{10}$  conductivity vs depth that has the minimum size of jumps in conductivity (min<sub>d</sub>  $\log \sigma/dz$ ) of all models that fit the data. Note the jumps in conductivity centered at 280, 456, and 825 km. The thinner curve is a model with the same properties, but with the lake-bottom MT data with periods of 2 h to 6 days deleted, showing that the peak at 456 km can only be resolved if the lake-bottom data are present. The thin vertical bars represent the best-possible fitting model comprised of infinitely thin zones of finite conductance,  $\tau$ .

limits of penetration of conventional MT, but were now resolvable because of the extended bandwidth available to lake-bottom MT.

Golden *et al.* (2004a,b) carried out lake-bottom MT measurements in Woelfersheimer lake near Frankfurt am Main, in 2003. These prototype experiments lead to a successful lake-bottom deployment in Iceland. While the analysis of these data is ongoing with the aim of better imaging the putative mantle plume beneath Iceland, a lower noise level is seen for the Icelandic lake-bottom MT data than for nearby conventional MT deployments.

Lake-bottom electromagnetic deployments have now been used at numerous sites in North America, Europe, and Iceland. The experience indicates that this environment provides a means of extending MT observations into the mid-mantle, and for improving the ability to resolve finer structural details than shorter duration, more noise-prone conventional MT installations.

# EM, LAND USES

Land-based electrical and electromagnetic (E&EM) geophysical methods have been applied in mapping the electrical conductivity, or the reciprocal resistivity, structure of the Earth for applications as varied as general geological mapping; waste site characterization; contamination delineation; hydrogeological investigations; exploration for oil and gas, mineral, geothermal, sand, gravel, limestone, and clay; geotechnical investigations of building and road construction sites; location and identification of subsurface utilities; unexploded ordnance detection; and precision agriculture. Geophysical methodologies are almost as varied as the applications. The electric or magnetic fields or a combination of both are measured for plane wave or controlled sources in either the time or the frequency domain. Imaging of subsurface conductivity structure can extend from simple contouring of the data, to rigorous and computer-intensive, multidimensional inverse modeling. The depths of investigation can be a function of operating frequency, decay time, or the geometric array, ranging from meters to tens of kilometers. Figure E15 shows a schematic of the frequency range for commonly used E&EM methods and approximate depths of investigation for an Earth of 100  $\Omega$ m.

The behavior of E&EM fields is governed by Maxwell's equations (Ward and Hohmann, 1988). The physical earth parameters determining the response are the electrical conductivity ( $\sigma$ ), or its reciprocal resistivity ( $\rho$ ), the magnetic permeability ( $\mu$ ), and the dielectric permittivity ( $\varepsilon$ ). The geophysical EM spectrum ranges from ground-penetrating radar (GPR) at hundreds of MHz to low frequencies approximating a direct current (dc) as shown in Figure E15.

Land-based EM systems employ frequencies within the quasistatic approximation in which displacement currents are ignored, such that inductive currents predominate and field propagation are diffusive.

**Figure E15** The geophysical EM spectrum showing common exploration methods and the corresponding frequency range, or equivalent time, and approximate depth of investigation for a 100  $\Omega$ m half-space. The dashed line related to the resistivity/IP/MMR methods indicate the depth of investigation is related to the array geometry and not the operating frequency.

GPR systems operate in the high-frequency range where displacement currents dominate and field propagation is a wave phenomenon. In the *dc* limit, the electric field is a potential governed by the Poisson equation. In most applications it is assumed  $\mu = \mu_0$  (free space), because magnetic materials are often anthropomorphic artifacts, such as drums and pipelines. E&EM techniques can directly map the ionic content of the pore water, an indicator of the subsurface water chemistry and clay content, which is more difficult to achieve with wavefield methods such as GPR.

## Electrical resistivity

Electrical current at frequencies near the dc limit is injected into the ground over an array of current electrodes using a transmitter, and the resulting voltage is measured over a similar array of voltage electrodes. Current can be injected either galvanically or capacitively. The depth of investigation and resolution are determined by the electrode array and spacing. A description of the wide variety of electrode arrays can be found in Telford *et al.* (1990). Inhomogeneities in the Earth alter the current flow from what would be present with a uniform half-space, and are considered as secondary current distributions. Using modern multielectrode equipment and continuous systems, data are measured in profile or array configurations so that lateral and vertical resistivity variation can be determined through data inversion.

With a multielectrode galvanic system, 20–100 electrodes are usually placed equidistantly in an array, which can be both on and below the surface. A computer-controlled switch box connects four electrodes to input current and measure the resulting voltage. A series of configurations are measured and stored one after the other, and data are stacked until a certain noise level is reached or an upper limit on the number of measurements is attained. Several systems are commercially available and the use of multielectrode geoelectric measurements has increased dramatically over the past 5–10 years. Electrical resistance tomography (ERT) is a term frequently used to describe such systems. Applications are as diverse as precision agriculture, hydrogeological investigations, waste site characterization, road and building foundation investigations, and archaeological studies. Permanent or semipermanent arrays are often used to monitor infiltration and containment migration problems.

Continuous systems make measurements continuously as the instrument is towed over the ground. The Danish pulled array continuous electrical sounding (PACES) system (Sørensen, 1996) uses galvanically coupled steel cylinder electrodes mounted on a tail. The French use spiked wheels as electrodes or capacitively coupled electrodes mounted inside plastic wheels (Panissod *et al.*, 1998). In the United States the OhmMapper system uses a capacitively coupled dipole-dipole array (Pellerin *et al.*, 2004).

The depth of investigation for electrical resistivity systems is limited by the power needed to deliver the required current and the wires needed to support the array. A general estimate for depth of investigation is 40%–60% of the array geometry. Hence for a transmitter-receiver separation of 10 m, the expected depth of investigation would be roughly 5 m. For large depths this entails the use of large amounts of wire, a logistical difficulty. Interpretational complexity increases as different geological structures are crossed. The electrical resistivity method is most practical in the 1–50 m depth range.

A question for production surveys of multielectrode systems is which electrode configurations to use. The choice depends upon optimizing resolution capabilities and the signal-to-noise ratio. Standard electrode configurations include the Wenner and Schlumberger arrays where the potential electrodes are inside the current electrodes along a profile; the dipole-dipole where the current electrodes are offset from the potential electrodes along a profile; and the pole-dipole and polepole configurations that utilize a distant electrode away from an electrode array. Practically, the Wenner and Schlumberger arrays are most robust in the presence of cultural noise with a high signal-to-noise ratio, the dipole-dipole array most rapid for deployment over large areas, and the pole-pole array fully general in that all arrays are present. The continuous systems, such as the PACES and OhmMapper, employ array configurations based on the design of the instrument.

Two-dimensional inversion is the state of the practice for profileoriented, electrical resistivity data (Loke and Barker, 1996). Fast approximate inversion procedures applicable to large data sets are becoming common along with three-dimensional inversion applicable to large pole-pole arrays and monitoring systems.

## Induced polarization

When electrically polarizable minerals are present in the subsurface, induced polarization (IP) at the particle interfaces causes the secondary currents in the vicinity to be out of phase with the applied current (Fink *et al.*, 1990). Although some IP effects are associated with ionic double layers on any silicate surfaces, it is clays and sulfides that tend to exhibit the largest response, thus providing more direct information on lithology than electrical conductivity alone. Historically the IP method has been used successfully in delineating porphyry-copper deposits. More recently IP is used to discriminate between claybearing and clean sand units in groundwater prospecting. As shown in many case histories and methodology studies, IP is one of the most powerful techniques for environmental applications. In the 1960s the use of IP was proposed for landfill characterization and after many years of GPR, conductivity meters and electrical resistivity surveys, the use of IP is being shown to be the most accurate tool of the trade.

For accurate IP measurements nonpolarizable electrodes, most often lead/lead chloride or copper/copper sulfate, are needed resulting in high survey costs. However, alternative solutions are emerging as smart electrodes, correction schemes for use of ordinary polarizable electrodes, and measuring strategies allowing for efficient data collection over large areas are being used.

## Magnetometric resistivity

Analogous to the electrical resistivity method, the magnetometric resistivity (MMR) method (Edwards and Nabighian, 1991) is based on the measurement of low-frequency magnetic fields associated with noninductive current flow in the ground. Instead of potential electrodes the magnetic field is measured with coils or magnetometers. Though not widely utilized, the technique has been successfully used in mineral exploration, geothermal investigations, and geological mapping related to environmental applications. Strengths of the method include it being relatively insensitive to small conductive bodies, and when employing a vertical electric source, layered structures are not excited and the MMR response is due solely to three-dimensional targets.

## **Controlled-source frequency-domain electromagnetics**

A number of configurations can be used with controlled-source frequency-domain EM systems (Spies and Frischknecht, 1991). The most common is the magnetic dipole-dipole or "Slingram" method that employs a small loop, dipole transmitter and small loop, dipole receiver at multiple-frequencies (Frischknecht et al., 1991). Measurements can be made of the real component, which is in-phase with the transmitted signal, and the out-of-phase, or quadrature, component. The ground conductivity meter (GCM) is a subset of the Slingram method in that it operates where the low frequency inductive approximation is valid and the quadrature component is linearly proportional to the apparent ground conductivity. These methods offer the advantage that ground contact is not necessary, meaning that operation is fast, minimal personnel are required, and continuous data acquisition can be easily implemented. They have been widely used as profiling instruments with the subsequent interpretation based on the simple apparent conductivity representation.

Slingram/GCM data have a number of limitations with regard to quantitative inversion. The secondary field that carries information about the subsurface conductivity is measured in the presence of the primary fields, which can be orders of magnitude larger. This necessitates a compensation of the primary field so that the measured in-phase component only comes from the secondary field. Accuracy of the compensation depends heavily on the transmitter-receiver distance; hence for every transmitter-receiver separation and for every frequency, the instrument must have a compensation circuit. Instruments with coil separations of less than 60 m and a connecting cable between the transmitter and receiver are difficult to calibrate and coil separation errors are detrimental to the accuracy of the in-phase component, unless the coil separation is so large and field conditions favorable that a good relative accuracy is obtainable. The quadrature component is relatively insensitive to close separation geometry.

The in-phase component of magnetic dipole-dipole systems is reliably measured with fixed boom systems where the transmitter and receiver coils are in a rigid frame. For practical reasons these systems are often small. Small coil separations a few meters above a resistive ground effectively constitute a nonconductive environment enabling a primary field zeroing and gain calibration. For coil separations exceeding a few meters it is awkward to get far enough away from the ground. Consequently, calibration is difficult, impeding a quantitative assessment of the reliability of the data. Calibration can be performed with calibration coils, but it is still a time-consuming and cumbersome process.

There is an ongoing debate about the value of having more than one frequency for geological mapping with small fixed-boom systems. One side claims that differences in investigation depths are pronounced enough for multifrequency measurements to be useful. The other side maintains that for conductivity mapping purposes one frequency is sufficient because the skin depth is large compared with the coil separation for all appropriate frequencies, meaning that the sensitivity is controlled by the coil separation. Sounding data can be obtained by using two dipole orientations (horizontal coplanar and vertical coplanar) and measuring at different heights, however using multiple coil separations rather than data at different elevations is preferable. The resolution kernels for soundings at different elevations become almost parallel at relatively shallow depth thus reducing the independence of the data.

For quadrature data the equivalent half-space is linear in conductivity and inversion reduces to a simple transformation. However, the inverse problem is only linear with respect to conductivity at lowinduction number, an assumption that can be poor in many nearsurface environments. An accurate inversion should take into account the system response: phasing of the instrument, correction for measurement elevation, and calibration factors, as well as the departures from the low-induction number approximation.

## Plane wave electromagnetics

Magnetotellurics is arguably the most developed of all EM methods because of the elegance of the plane wave source assumption. Used for deep sounding of the Earth's crust the method has also been used extensively for oil and gas and geothermal exploration. The complex impedance of the Earth is inferred from measurements of the natural electric and magnetic field—or more accurately the voltage measured across orthogonal electric dipoles and induction coils. The MT source below 1 Hz is due to currents in the magnetosphere and above that from worldwide lightning. At about 1 Hz the natural signal strength is low, but schemes have been developed to compensate. The remote reference technique makes use of the simultaneous measurements of the field at multiple sites to removes bias and cultural noise.

The audio magnetotelluric (AMT) and the controlled-source AMT (CSAMT) methods are applied to hydrological and resource exploration targets (Zonge and Hughes, 1991) with depths of investigation from tens to hundreds of meters. The AMT method employs natural signal in the 100 kHz to 10 Hz range; the CSAMT methods uses an artificial source, traditionally a grounded electrical dipole that dominates the natural field although other systems use a magnetic dipole source that augments the low-energy signal at frequencies above 1 kHz. With both approaches the source must be far enough away from the receiver array so that the source has lost its dipolar geometry and is plane wave, but close enough to have an appreciable signalto-noise ratio. For a grounded electrical dipole source this distance, usually measured in skin depth, can be several kilometers and for a magnetic dipole hundreds of meters.

The RMT method, making use of EM fields from commercial and military radio transmitters and ambient signals, operates in the frequency range between 10 kHz (VLF transmitters) and 1 MHz (AM transmitters) (Tezkan, 1999). The VLF transmitting network will be discontinued in the near future because submarines now are using satellites for communication, hence there will be a lack of signal in the lower frequency range severely limiting the use of the method. It has been used for mapping waste sites and other contaminated areas. The CSAMT and RMT methods have the significant advantage of being able to exploit the multidimensional inversion software that has been well developed in the MT community.

#### **Time-domain electromagnetics**

With the time-domain, also known as the transient electromagnetic method (TEM) the Earth is excited by a loop carrying current on the surface of the Earth. The current is abruptly turned off and currents within the Earth are induced to maintain continuity of the magnetic field. The magnetic field decays as the electric currents diffuse through the ground. Magnetic field measurements can be made in, out or coincident with the transmitter loop. Traditionally, only the vertical component is measured, but much information is available in the horizontal components.

The TEM has gained popularity over the past decade. Being an inductive method, it is particularly good at mapping the depth and extent of good conductors, but is relatively poor at distinguishing conductivity contrasts in the low conductivity range. Clay and saltwater intrusion constitute conductive features of special interest in aquifer delineation. Hence, the method has been used extensively in hydrogeophysical investigations.

The very early time EM (VETEM), and equivalent high-frequency domain systems have been constructed in the nanoseconds range (Wright *et al.*, 2000) for depths of investigation of less than a few meters. The response in this range spans the region between diffusion and wave propagation so the data contain information on the conductivity and permittivity in areas of high conductivity where the GPR signal is greatly attenuated.

EM Modeling, Inverse EM, Industrial Uses EM, Marine Controlled Source Magnetotellurics Robust Electromagnetic Transfer Functions Estimates Transient EM Induction

## EM, MARINE CONTROLLED SOURCE

## Background

Controlled source electromagnetic (CSEM) mapping of the electrical conductivity of the seafloor depends on a simple concept of physics. If a time-varying EM field is generated near the seafloor, then eddy currents are induced in the seawater and subjacent crust in accordance with Faraday's law. The outward progress of the currents with time depends on range and electrical conductivity. In particular, the apparent speed in the seawater will be slower than that in the less-conductive crustal zones. Measurements at a remote location of the electric and magnetic fields associated with the eddy currents may be inverted for the crustal resistivity structure, if the resistivity and thickness of the seawater are known.

The concept is easily verified theoretically through an examination of the governing differential equations. The Maxwell interrelationships between the electric field  $\mathbf{E}$  and the magnetic field  $\mathbf{B}$  in an isotropic, homogeneous material may be combined as the damped wave equation

$$-\nabla \times \nabla \times \mathbf{B} = \mu \sigma \frac{\partial \mathbf{B}}{\partial t} + \mu \varepsilon \frac{\partial^2 \mathbf{B}}{\partial t^2}, \qquad (\text{Eq. 1})$$

where  $\sigma$ ,  $\mu$ , and  $\varepsilon$  are the conductivity, permeability, and permittivity of the material, respectively. A similar equation may be written for the magnetic field vector **B**. Equation (1) may be rationalized by measuring length and time in units of characteristic length *L* and characteristic time  $\tau = \mu \sigma L^2$ . There results

$$-\nabla \times \nabla \times \mathbf{B} = \frac{\partial \mathbf{B}}{\partial t} + \frac{\varepsilon}{\mu \sigma^2 L^2} \frac{\partial^2 \mathbf{B}}{\partial t^2}.$$
 (Eq. 2)

The second term on the left-hand side of Eq. (2) usually is neglected in comparison with the first term and the physics simplified to a diffusion process because the scale *L* of the experiment is large compared with  $(\varepsilon/\mu\sigma^2)^{1/2}$  or  $1/377\sigma$ . The omission is equivalent to the neglect of the magnetic effects of displacement current in comparison with conduction current. The critical scale is largest for very resistive crystalline rock, having a value of the order of few tens of meters. A feel for the time taken for an EM disturbance to diffuse through a uniform medium may be gained by evaluating the characteristic time  $\tau$  for a few typical cases. If the scale *L* is set to 1 km and the parameter  $\mu$  takes its free space value, then  $\tau$  has value 3.8 s for seawater, typical conductivity 3 Sm<sup>-1</sup>, and 1.2, 0.42, 0.12, 0.042 s for crustal resistivities of 1, 3, 10, and 30  $\Omega$ m, respectively. (The characteristic times are approximate and should be treated as upper limits by as much as a factor of 10 for practical systems.)

CSEM is usually used to explore crustal regions. The rocks that are often a simple two-phase system consisting of the resistive grain matrix and conductive pore fluid. Archie's law (Archie, 1942) relates measured bulk resistivities to porosity estimates. In a general form, it is

$$\rho_{\rm f} = a \rho_{\rm w} \phi^{-m}, \tag{Eq. 3}$$

where  $\rho_{\rm f}$  is the measured formation resistivity,  $\rho_{\rm w}$  is the resistivity of seawater,  $\phi$  is the sediment porosity, *a* is a constant, and *m* the cementation factor. The latter two parameters can be derived from laboratory measurements and vary between 0.5 < a < 2.5 and 1.5 < m < 3. Resistivity values for marine sediments near the seafloor where the porosity is often in excess of 0.5 may be as low as 1  $\Omega$ m.

## Practical methods: response of a layered earth

A practical CSEM system consists of a transmitter capable of generating an EM disturbance and one or more receivers which detect the disturbance at some later time as it passes nearby. In common with land-based systems used for mineral prospection, the transmitter and the receiver may be electric and/or magnetic dipoles. Usually, for marine exploration, both the transmitter and the receivers are near or on the seafloor, as shown in Figure E16. Further, the system response can be described in frequency domain or time domain. Both use a continuous waveform and are essentially equivalent. In particular, delays in time domain are related to phase changes in frequency domain.

A study of the nature of the response of a layered earth to a time domain controlled source system is a useful learning exercise, as some of the physics is counterintuitive. Disturbances from the transmitter diffuse through the seawater and the seafloor and are seen at the receiver as at least two distinct arrivals separated in time depending on the conductivity contrast between seawater and subjacent crust. If the layered seafloor increases in resistivity with depth, then disturbances propagate laterally more rapidly at depth than immediately beneath the seafloor. The received signal viewed at different ranges in logarithmic time has many of the characteristics of refraction seismic, even though the process is diffusive, and the signal can be processed using seismic methods. We use two basic configurations for marine exploration: the horizontal magnetic dipole-dipole and the horizontal electric dipole-dipole. System geometries can be broadside or in-line. The two geometries yield different information (Yu and Edwards, 1991; Yu et al., 1997). For example, the in-line electric dipole-dipole is sensitive to the vertical resistivity whereas its broadside cousin is sensitive to the horizontal resistivity perpendicular to the line joining the dipoles. The EM fields impressed in the crust by both the horizontal magnetic dipole and the horizontal electric dipole have two polarizations. The polarizations are characterized by the absence of a vertical magnetic field and a vertical electric field, respectively. They average the resistivity in two different ways. If these averages are different, then the medium appears to be only laterally isotropic. Data collected over layered Earth structures must be interpreted using software including anisotropy either as multiple fine isotropic layers or, better, as a few anisotropic layers.

By way of example, a summary of the layered earth responses for the electric dipole-dipole system for the in-line configuration, following Chave and Cox (1982), Edwards and Chave (1986), and Cheesman *et al.* (1987) is presented here. The seawater has a finite thickness  $d_0$  and an electrical conductivity  $\sigma_0$ . The permittivity of the air is  $\varepsilon$ . The subjacent crust has N layers with thicknesses  $d_1, d_2, \ldots, d_{N-1}$ and conductivities  $\sigma_1, \sigma_2, \ldots, \sigma_N$ , respectively. A current I is switched on at time t = 0 and held constant in a transmitting electric dipole of

Figure E16 A towed electric seafloor array. Transmitter and receiver electrodes are interchangeable and pairs can be connected to generate many dipole-dipole configurations.

length  $\Delta l$ . The expression for the Laplace transform of the step-on transient electric field at the seafloor for the in-line electric dipoledipole geometry, dipole separation *L*, is given in terms of *s*, the Laplace variable. It is

$$\frac{I\Delta l}{2\pi s}[F(s) + G(s)], \tag{Eq. 4}$$

where F and G are the Hankel transforms

$$F(s) = -\int_0^\infty \frac{Y_0 Y_1}{Y_0 + Y_1} \lambda J_1'(\lambda L) d\lambda, \qquad (Eq. 5)$$

$$G(s) = -(s/L) \int_0^\infty \frac{Q_0 Q_1}{Q_0 + Q_1} J_1(\lambda L) \mathrm{d}\lambda, \qquad (\text{Eq. 6})$$

and the included Laplace transform of the source dipole moment is  $I\Delta l/s$ . If the magnetic effects of displacement currents in the earth are neglected, then the parameters  $Y_0$  and  $Q_0$  are given for the sea layer as

$$Y_0 = \frac{\theta_0}{\sigma_0} \left[ \frac{\sigma_0 u_a + s\varepsilon\theta_0 \tan h(\theta_0 d_0)}{s\varepsilon\theta_0 + \sigma_0 u_a \tan h(\theta_0 d_0)} \right]$$
(Eq. 7)

and

$$Q_0 = \frac{\mu_0}{\theta_0} \left[ \frac{\theta_0 + u_a \tan h(\theta_0 d_0)}{u_a + \theta_0 \tan h(\theta_0 d_0)} \right],$$
 (Eq. 8)

where the EM wavenumbers in the ground and in the air are given by  $\theta_0^2 = \lambda^2 + s\mu\sigma_0$  and  $u_a^2 = \lambda^2 + s^2\mu\varepsilon$ .

The parameters  $Q_1$  and  $Y_1$  are evaluated through the downcounting recursion relationships

$$Y_{i} = \frac{\theta_{i}}{\sigma_{i}} \left[ \frac{\sigma_{i} Y_{i+1} + \theta_{i} \tan h(\theta_{i} d_{i})}{\theta_{i} + \sigma_{i} Y_{i+1} \tan h(\theta_{i} d_{i})} \right],$$
 (Eq. 9)

and

$$Q_i = \frac{\mu_0}{\theta_i} \left[ \frac{\theta_i Q_{i+1} + \mu_0 \tan h(\theta_i d_i)}{\mu_0 + \theta_i Q_{i+1} \tan h(\theta_i d_i)} \right],$$
 (Eq. 10)

where the starting values are  $Y_N = \theta_N / \sigma_N$  and  $Q_N = \mu_0 / \theta_N$ , respectively. The wavenumbers  $\theta_i$  are defined by  $\theta_i^2 = \lambda^2 + s\mu\sigma_i$ .

The Y and Q functions denote the polarizations characterized by the absence of a vertical magnetic field and a vertical electric field, respectively. The Y function yields the DC "resistivity" response at late time (Edwards, 1997).

The corresponding form for the broadside electric dipole-dipole geometry is as given in expression (4) but with alternative definitions for F and G.

The methods for inverting the Hankel and Laplace transforms are fully described in the theoretical papers listed above. All other geometries are a linear combination of the in-line and broadside responses.

The frequency domain response of the dipole may be obtained by multiplying the step-on response by *s* to get the impulse response and then replacing *s* by  $i\omega$  where  $\omega$  is the angular frequency of the harmonic current. The inverse Hankel transform becomes a complex function having a phase and an amplitude.

The theory may be extended to include the effects of anisotropy caused by interbedding. The coefficient of anisotropy k is defined by  $k = \sqrt{\sigma_h/\sigma_v}$ , where  $\sigma_h$  and  $\sigma_v$  are the tangential and normal conductivities in any given layer. The coefficient cannot be smaller than unity. We modify the form of  $\theta$  only in expression (9) to  $\theta^2 = k^2 \lambda^2 + s\mu\sigma$ . In both expressions (9) and (10),  $\sigma$  is replaced by  $\sigma_h$  whereever it occurs.

#### Response curves

The step-on response of a double half-space to the in-line electric dipole-dipole system is shown in Figure E17. The seawater is assigned a conductivity of  $3 \text{ Sm}^{-1}$  while the subjacent crust has conductivities of 3, 1, 0.1, and 0.3 Sm<sup>-1</sup>, respectively. The vertical axis has been scaled to yield the DC apparent resistivity at late time. The horizontal axis is in logarithmic time for a transmitter-receiver separation *L* of 260 m. (Absolute time may be estimated for any system, given a conductivity  $\sigma$  and a value for *L*, as  $\mu_0 \sigma L^2/c$ , where *c* is a constant with a value of about 5. Progress of disturbances through several zones of differing conductivity may be obtained by summing such estimators.)

The curves have three characteristics from which the conductivity of the crust may be obtained. There is late-time variation in amplitude (Label 1), which is less sensitive with increasing conductivity contrast. There is an early time change in amplitude which depends on the seafloor conductivity (Label 2). The location in time of this initial change is a strong function of seafloor conductivity (Label 3). A robust estimate of determining apparent resistivity from time-domain curves may be obtained from the maximum in the early time gradient of the response curve. The same information may be gleaned from amplitude and phase curves in the frequency domain.

## Electromagnetic refraction

Cross sections of the diffusion of current from a 2D electric dipole at the junction of two half-spaces representing seawater and the subjacent crust may be used to illustrate the origin of the two arrivals. The diffusive process is plotted as a series of contour maps for increasing time steps, as shown in Figure E18a through E18f. The magnetic field is out of the slide, the electric field is in the plane. The model is 500 m<sup>2</sup> and the seawater and crust have conductivities of 3 and 0.5 Sm<sup>-1</sup>. The contours, originally shown by Edwards (1988), are current streamlines and the shading is proportional to the size of the electric field.

The process can be considered as a form of EM refraction, even though it is diffusive, because of the similarity of the lateral movement of the current flow pattern and the seismic head wave. Consider the direction of the Poynting vector  $\vec{P} \sim \vec{E} \times \vec{B}$ . Clearly, the first arrival at a receiver dipole is a disturbance that has propagated through the more resistive zone, the crust. In the progress of the diffusion, energy migrates upward from the lower medium through the seafloor. At later times the signal that propagates through the seawater arrives and at the static limit (DC) symmetry is reached about the surface. The maps are consistent with the type curves presented earlier.

#### Seismic style displays

An impulse response may be obtained as the derivative with respect to logarithmic time of the step-on response. In the displays that follow, the normalized impulse response is plotted as a function of logarithmic time and logarithmic transmitter-receiver separation. The amplitude scaling, which varies from figure to figure, yields the same curve at every offset for a simple double half-space. The curve just moves to later time as the separation increases. The in-line electric dipole-dipole response has two peaks in the double half-space impulse response corresponding to energy that has propagated through the sea and the crust, respectively. The crustal peak is always at earlier time. Its broadside cousin also has two features but of different sign. The crustal peak is positive whereas the seawater trough at later time is negative.

#### The air wave

Of particular concern to companies that explore in shallow waters such as the shelf seas is the so-called air wave. Some portion of the EM energy travels upward to the sea surface, through the air to the vicinity of the receiver and then downward to the receiver on the seafloor. The up-over-down path can in some instances be faster than any direct path through the seawater or the

**Figure E17** Normalized step-on responses calculated on the interface between two half-spaces to the in-line electric dipole-dipole system. The conductivity of the upper half-space is  $3 \text{ S m}^{-1}$ , for the lower half-space conductivities of 0.3, 0.1, 1, and  $3 \text{ S m}^{-1}$  have been assigned. The separation between transmitter and receiver is 260 m. For a conductivity contrast between seawater and subjacent crust larger than 10 the arrival through the signal through the seawater at later times can be clearly separated from the earlier arrival through the crust. In addition, three different effects are noticeable: (1) Amplitude variations at late times depend on the conductivity; (3) the location in time to the initial change is a function of the seafloor conductivity (after Edwards and Chave, 1986).

subjacent crust. Compare the two models shown in Figure E19a and E19b and the stacked impulse response of these models shown in Figure E19c through E19f, for the in-line and broadside geometries. The sea layer in the first model is infinitely thick while that in the second has a finite thickness of 200 m. As the transmitter-receiver separation increases, the air wave which initially appears at later time appears to move to relatively earlier times and at large separations contaminates the disturbance traveling through the crust. From a practical point of view, the air wave signature is easily removed in the inversion of data provided sufficient dynamic range in the receiver electronics is available to record it properly.

#### The resistive zone at depth

In the second example, the responses of a double half-space model modified by the inclusion of a rapid increase in resistivity at a depth of 200 m have been computed. They are shown in Figure E20b and compared with the base response of the half-space model, Figure E20a. The stacked impulse responses for the in-line and broadside geometries are shown in Figure E20c through E20f. Notice the distinct refraction visible in the early time crustal response when the EM disturbance sees the resistive buried zone. The location of the refraction in space and its slope on the log time vs log separation diagram may be used to infer the depth to and conductivity of the resistive zone.

## **Case histories**

## Gas hydrates in Cascadia

A report of an EM survey for gas hydrate off the west coast of Vancouver Island, Canada, is presented by Schwalenberg *et al.* (2005) using apparatus originally developed by Yuan and Edwards (2000). Natural gas hydrates are ice-like solids found in seafloor sediments. They consist of gas molecules, mainly methane, contained in a cage-like clathrate structure of water molecules. They form under low-temperature and high-pressure conditions, typically in the uppermost few hundreds of meters of sediments in water depth exceeding about 500 m. The global abundance of methane frozen in hydrate exceeds the amount of all other known fossil hydrocarbon resources. Hydrate clearly has a huge potential as a future energy resource. A gas hydrate deposit can be generally identified in a seismic section by the occurrence of a bottom-simulating reflector (BSR) which is associated with the base of the hydrate stability field. The base is a transition zone between hydrate-bearing sediments above it and free gas and water below it. The location of the zone is temperature controlled and depends on the ambient geothermal gradient. The target area is located on the accretionary prism of the Cascadia margin in close vicinity of ODP Site 889, as shown in Figure E21. Here, several seismic blank zones were observed over a vent field which covers an area of roughly  $1 \text{ km} \times 3 \text{ km}$ . The largest, blank zone 1 is called the Bullseye vent and has a seafloor diameter of about 400 m.

The CSEM experiment was conducted in SW-NE direction, into the prevailing wind and current, along a profile intersecting the Bullseye and approaching the other vent sites, making measurements at 28 sites with a spacing between sites of 250 m. The seafloor array is towed in direct contact with the soft marine sediments, as sketched in Figure E22. At the forward end, a heavy weight (pig) is attached to keep the system in contact with the seafloor. It is followed by a transmitter dipole (TX) 124 m long and, in this experiment, just two receiver dipoles (RX1) and (RX2), each 15 m long located at distances  $r_1$  and  $r_2$  of 174 and 292 m from the transmitter cable, respectively. While the system is operated in the time domain, using a square current waveform with a peak-to-peak amplitude of 20 A and a period

**Figure E18** Diffusion in a double half-space. (a–f) Contour maps showing the diffusion proceeding with time of a current from a 2D electric dipole at the interface of two half-spaces representing seawater ( $3 \text{ Sm}^{-1}$ ) and subjacent crust ( $0.5 \text{ Sm}^{-1}$ ). The model is 500 m<sup>2</sup>. Contours are current streamlines of the electric field and the shading is proportional to the size of the field (after Edwards, 2006).

of 6.6 s, the data analysis and inversion to a multilayered model is completed in frequency domain using phase data only in the band from 0.5 to 100 Hz.

Approaching the DC limit

(a)

(c)

(e)

Simplified results for a half-space model are plotted in Figure E23a for both receiver separations over a compatible seismic section, Figure E23b. Two pronounced resistivity anomalies are visible along the profile which are in striking agreement with the seafloor projections of the vent sites from the seismic section. The resistivity values within the anomalous zones are higher for the larger separation RX2 than those for RX1 and rise up locally to more than 5 m over the regional background, which lies between 1.1 and 1.5  $\Omega$ m. The gas hydrate concentrations derived from the resistivity profile, shown

in Figure E24, over the vent sites exceeds 50% at maximum and about 25% on average of the available pore space.

At DC - symmetry about interface

The resolution of the CSEM method does not permit a detailed analysis of the distribution of the resistive elements within the blank zones but it does provide an integrated value. Assuming that the increase in resistivity is due to a higher hydrate concentration, the latter may be converted to total mass of hydrate and then to total available methane. A rough estimate can be made for the Bullseye vent assuming a cylindrical volume, with diameter and depth of 400 and 200 m, respectively. Twenty five percent of the available pore space corresponds to 3.8 million m<sup>3</sup>. With a solid to gas ratio of hydrate of 1:164, the related methane gas volume at STP is 0.62 billion (US) cubic meters.

**Figure E19** The airwave. The normalized impulse responses of the models in (a) and (b) to an electric dipole-dipole system on the seafloor are shown as functions of logarithmic time and transmitter-receiver separation. Panels (c) and (d) refer to in-line and panels (e) and (f) to broadside geometries (after Edwards, 2006).

The development of software for the interpretation of data like these in 3D is progressing and is clearly needed. Everett and Edwards (1993) and Unsworth *et al.* (1993) have 2.5D programs available in both frequency and time domains.

## Buried channels, New Jersey

The marine EM group at the Woods Hole Institution of Oceanography and colleagues at the Geological Survey of Canada have built a small-scale coaxial magnetic dipole-dipole system that is contracted for mainly shallow geotechnical surveys. The system is a major improvement of systems described by Cheesman *et al.* (1990, 1991) and Webb and Edwards (1995). Among many other geological problems, they investigated the nature of the infill in a buried channel offshore New Jersey (Evans *et al.*, 2000). The buried channel represents one example of a feature in a shallow section that is analogous to a feature seen in deeper oil-bearing strata. The magnetic dipole system is dragged in contact with the seafloor. The three transmitter-receiver spacings are 4, 13, and 40 m.

Data collected in the frequency domain were processed to give an apparent porosity for each spacing. The maximum depth of investigation was about 20 m. Bounds on physical properties are greatly aided

**Figure E20** The resistive zone at depth. The normalized impulse responses of the models in (a) and (b) to an electric dipole-dipole system on the seafloor are shown as functions of logarithmic time and transmitter receiver separation. Panels (c) and (d) refer to in-line and panels (e) and (f) to broadside geometries (after Edwards, 2006).

by complementary seismic survey. The latter identified the structure but alone offered no information on nature of the infill. The porosity traces and seismic section are shown in Figure E25a,b. Clearly, there is an excellent correlation between the buried channels visible on the seismic section and an increase of porosity. The channels seem to incise the regional seismic reflector.

## Conductivity variations at the mid-ocean ridge

Electrical conductivity varies with the porosity, temperature, degree of partial melt, and the composition of Earth materials. Nowhere are these

parameters more variable than at the mid-ocean ridge. There are numerous published case histories of marine CSEM surveys in this environment. They are often combined with a complementary magnetotelluric measurements. The reader is referred to such publications as Sinha *et al.* (1997) or Evans *et al.* (1994). The methodology originated at Scripps Institution of Oceanography, pioneered by C.S. Cox and S.C. Constable.

MacGregor *et al.* (2001) completed a CSEM survey in the vicinity of the Valu Fa Ridge in the Lau Basin. They used fixed receivers and towed a horizontal long wire receiver just above the seafloor. Their survey lines and receiver locations are shown in Figure E26/Plate 15a.

**Figure E21** Bathymetry map of the target area on the Cascadia margin. The vent field is located on a bench between two topographic highs in vicinity of ODP sites 889/890. CSEM measurements were conducted along the profile crossing the Bullseye, the largest of 4 vent sites. Lines A, B, and C are EM profiles from a previous survey (after Schwalenberg *et al.*, 2005).

**Figure E22** Geometry of the in-line dipole-dipole configuration. A current signal is produced by an onboard transmitter and sent through the coaxial winch cable to the transmitter bipole on the seafloor. Two receiver dipoles at distances  $r_1$  and  $r_2$  record the signal after it passes through the seawater and the sediments. A heavy weight (pig) attached to the front of the system keeps the array on the seafloor while moving along the profile. Moving the ship and taking in the winch cable pulls the array forward and causes a vertical movement of the pig. Solid and dotted line present the winch cable in idle and moving state, respectively. The wheel represents the curve over which the marine cable appears to move while in motion (after Schwalenberg *et al.*, 2005).

The corresponding analyis of the data is displayed in Figure E27/Plate 15b as a crustal cross section of the electrical resistivity anomaly across the axis of the ridge. The colors indicate the deviations (as a logarithmic multiplication factor) from a background model, in which resistivity varies only with depth beneath the seabed. The dark blue layer at the top represents the water, with the top of the crust showing as pale green. A large conductive anomaly can be seen at depths of 1 to 6 km beneath the seafloor, beneath the axis of the ridge, and extending off the axis to the west for

nearly 10 km. The anomaly is interpreted as being due to the presence of an axial magma chamber, and an overlying region in which the porosity is occupied by highly conductive hydrothermal fluids. Also shown is a plot of seismic P-wave velocity anomaly (gray contours), calculated with reference to an equivalent background seismic model, and superimposed on the resistivity anomaly. The section was obtained by 2.5D regularized inversion of frequency domain CSEM data. The uppermost panel shows the variation in seafloor depth along the profile.

**Figure E23** Panel (a) shows the bulk resistivities derived from CSEM data show anomalous resistivities exceeding 5  $\Omega$ m over background resistivities between 1.1 and of 1.5  $\Omega$ m. The anomalous areas coincide spatially with the surface expression of a series of seismic blank zones displayed in Panel (b) (after Schwalenberg *et al.*, 2005).

**Figure E24** Gas hydrate concentrations derived from Archie's law using two different sets of Archie coefficients. The first set (a = 1.4, m = 1.76, n = m) is based on core data from ODP Leg 146 (Hyndman *et al.*, 2001). A recent reevaluation yielded a second set based on log data (a = 1, m = 2.8, n = 1.94) (Collett and Riedel, personal communication 2005). In this figure a regional gas hydrate concentration profile derived from the baseline resistivities in Figure E20b has been subtracted from the "total" hydrate concentrations. Thus, the profiles represent the additional amount of hydrate and are coincident for both sets of Archie coefficients (after Schwalenberg *et al.*, 2005).

#### Commercial outlook

In the last 5 years, there been a surge of interest from the exploration community in the use of marine CSEM methods for hydrocarbon exploration (Edwards, 2006). There are marine geological terranes in which the interpretation of seismic data alone is difficult. There are

regions dominated by scattering or high reflectivity, such as is found over carbonate reefs, areas of volcanics, and submarine permafrost. Complementary geophysical techniques are required to study these regions. EM was at first not high on the list of alternatives. There was a pervasive belief that the high electrical conductivity of seawater

**Figure E25** The magnetic dipole-dipole system has been used to find out the nature of the infill of buried paleochannels on the New Jersey continental margin. The apparent resistivities recorded at the three receivers shown in Panel (a) have been converted to apparent porosities using Archie's law. A clear correlation between locally higher porosities and the seismic image of the paleo-channels shown in Panel (b) is evident (after Evans *et al.*, 2000).

Figure E26/Plate 15a The CSEM transmitter tracks superimposed on a bathymetry map of the Valu Fa Ridge. The receiver locations are shown as white dots (courtesy M.C. Sinha).

precluded the application of EM systems for exploration even though academics had put forward methods specifically designed for the marine environment. The tide turned when a few surveys commissioned from universities proved very successful and over the last 5 years, exploration managers and investors have become aware of the importance of CSEM. Morgan Stanley, a well-known member of the New York Stock Exchange and Investment Manager, reported in August 2004 that in their view the implications of CSEM imaging on offshore drilling, service, and field development activity will be one of the most frequently discussed topics in the oil service industry over the next 12 months. They see a growth in annual revenues from a mere \$30 million to \$600–900 million in less than 5 years—one quarter of

**Figure E27/Plate 15b** A section through the Valu Fa Ridge showing the logarithmic variation in electrical conductivity and the anomaly in seismic P-wave velocity as color shading and black contours respectively (courtesy M.C. Sinha).

the current spending-on offshore seismic and compare the technological revolution with the growth of 3D seismic in the early 1990s. McBarnet (2004) summarizes recent commercial activity and identifies the players involved.

## EM, REGIONAL STUDIES

#### Introduction

Images of the electrical conductivity can help decipher the architecture of the Earth's interior. The *magnetotelluric* (q.v.) method (MT) is one of the few tools capable of imaging from the Earth's surface through to the mantle. Regional studies of EM are conducted to image the conductivity distribution of the subsurface on the scale of a few kilometers to hundreds of kilometers, both in lateral and depth extensions.

The electrical resistivity ( $\rho$ ) and its inverse the electrical conductivity ( $\sigma$ ) characterize charge transport within materials. They are intrinsic material properties, independent of sample size. Rocks and rock-forming minerals vary in their electrical properties, with conductivities ranging from 10<sup>6</sup> to 10<sup>-14</sup> S m<sup>-1</sup>.

The MT method is based on the induction of electromagnetic fields in the Earth (see *Natural sources for EM induction studies*). The MT impedance tensor Z and the geomagnetic response functions (see *Induction arrows and Geomagnetic Deep sounding*) are the Earth's response to electromagnetic induction (see *Transfer functions; Robust electromagnetic transfer functions estimates*) and thus carry the information about the conductivity distribution of the subsurface.

The word "regional" is not clearly defined. It merely means that the size of the area under investigation is somewhere between "local" (see EM, industrial uses; EM, land uses) and "global" (see Induction from satellite data). However, most regional studies of EM are initiated to add to our understanding of processes that drive major tectonic and geological events (see also EM, tectonic interpretations). Typical examples may be the investigation of large mountain chains, which are formed in subduction or collision zones. Transform faults are expressions of dynamic processes in the Earth's lithosphere. Such large-scale faults can be traced for hundreds to thousands of kilometers on the Earth's surface and there is growing evidence that some of them penetrate the mantle lithosphere. A tectonic regime can be presently active or a fossil. Suture zones, for example, give evidence for past collisions of continents and the closure of former oceans. Most continents consist of Archean nuclei (cratons), which are enclosed by Proterozoic and Phanerozoic tectonic belts and suture zones. Many of the old structures are covered today by huge sedimentary basins. Geophysical deep sounding methods, like seismics or MTs, are arguably the only means to unravel information on the position and structure of such features deep in the Earth's interior.

Tectonic activity generally also involves processes such as formation of new structural fabrics as well as the generation and emplacement of magmas. Chemical reactions due to metamorphism can release vast amounts of fluids or can cause the precipitation of minerals such as ore and graphite. Melt, fluids, and ore deposits are electrically conductive materials. Inclusions of small fractions of these conducting phases can make an entire rock conductive, and if widely enough interconnected, even an entire region. Hence, zones of high electrical conductivity in the Earths crust and mantle hint at present or past traces of a dynamic Earth.

## Experiment design

The design of a regional EM study will depend strongly on the target. The geometry of a fault zone, for example, is totally different from that of a subducting slab in a subduction zone. A fault is a narrow, subvertical structure that begins at the surface of the Earth and ends somewhere deep in its interior. Hence, the study of a large fault could have "local" and "regional" components. Locally, a fault may be investigated by one or several short profiles across its surface trace and with a very dense spacing of sites. It is one of the strongholds of the MT method that it is capable of imaging vertical structures (which is difficult with seismics). On the regional scale, a fault zone may widen (distributed shear) or bend to one direction (listric fault) and hence, a much wider area in the vicinity of the fault must be sampled at the surface.

The sounding depth of any electromagnetic method depends on the frequency contents of the induced fields and on the subsurface conductivity (skin effect). High-frequency signals will probe the shallow subsurface while low-frequency fields penetrate a much wider and deeper induction space. Particularly in noisy environments, active EM methods like *transient EM* (q.v.) and controlled source EM (q.v.) can be a good choice but the sounding depth of these methods is restricted to the first few hundred meters, in favorable conditions perhaps a few kilometers. For the really deep targets we can only rely on natural source MT.

For the more shallow investigation, MT instruments based on induction coil magnetometers will be preferred over fluxgate magnetometers which are more useful for low-frequency work. Electric field sensors for MT are nonpolarizing electrodes (see *Magnetotellurics*). A complete recording system contains some kind of analog signal interface to the sensors, multichannel analog to digital converters, typically with 24-bit accuracy, and digital data storage capacity. An integrated GPS provides accurate timing and position. Modern induction coil magnetometers can be used over a wide frequency range from approximately 10 kHz to 1 mHz and equipment based on these wideband induction coil magnetometers is often called broadband (BB). Fluxgate magnetometers, on the other hand, typically operate in the frequency range from 0.1 Hz to dc and such long-period MT instruments are called LMT. For regional EM studies BB, LMT, or a combination of both types of instruments can be deployed.

Today, there is a clear tendency for MT experiments in which a large number of recording instruments operate simultaneously and with a much denser site spacing than perhaps a few years ago. Another development is toward 3D MT for which instruments must be distributed over an area or aligned in a grid instead of simply following profiles. But a combination of a profile and some wider distributed sites can also be a very useful setup. A dense site spacing, preferably in combination with good areal coverage, enhances model resolution, avoids spatial aliasing, reduces the number of equivalent models, and generally stabilizes inversion results. Any interpretation of anomalies from the deep crust or mantle will be more sound if crustalscale anomalies are properly resolved instead of having to rely on assumptions.

For practical reasons, it is often necessary however, to make simplifying assumptions when interpreting MT data collected for regional EM studies. A full 3D inversion, is in most cases, not feasible due both to computational requirements and the lack of areal data coverage required to constrain such an inversion (see *EM modeling, inverse*). The complexity reduces considerably if the subsurface can be approximated by a 2D conductivity distribution. In order to determine the 2D conductivity distribution of the subsurface either forward modeling (see *EM modeling, forward*) or inversion is applied to the data. It is at this point that an accurate assessment of the dimensionality of MT data is important. In the case of 2D isotropic Earth structure, the MT equations reduce to fitting two elements of the impedance tensor and one element of the geomagnetic response functions.

Another very important aspect of modern regional EM studies is interdisciplinary work. Electrical conductivity models can provide valuable information but can only add to our knowledge of a more complicated nature. Hence, an interpretation of conductivity models should always consider information from other geoscience disciplines. It is equally important to ensure that colleagues from other fields fully understand the outcome and possible consequences of regional EM studies for their own work.

The following sections give three examples of regional EM work. The case studies are from different tectonic regimes; the observed conductivity anomalies have different causes and the regional extents of the studies (the size of the models) are very dissimilar.

# The electrical image of the active Dead Sea transform fault

Figure E28a/Plate 15c may serve as an example for the outcome of a 2D inversion of MT data. The MT data shown were recorded along the innermost 10 km of a much longer profile, centered on the Dead Sea transform in the Arava Valley in Jordan. A dense site spacing of 100 m in the center of the MT profile was supplemented by more widely spaced sites near the profile ends. The derived image is a so-called minimum structure model in a sense that the inversion

algorithm attempts to find a trade-off between data misfit and model smoothness. The resistivity values are color-coded. Zones of high conductivity, which are generally the better resolved parameters in any MT model, are shown in red and yellow colors.

For the shallow crust, the inversion model reveals a highly conductive layer from the surface to a depth of  $\sim 100$  m on the eastern side of the profile. However, the most prominent feature on the MT image is a conductive half-layer confined to west of the fault and beginning at a depth of approximately 1.5 km. The surface trace of the Arava Fault

**Figure E28/Plate 15c** Three examples of regional EM studies. The resistivity values are color coded; red and yellow colors indicate zones of high conductivity: (a) Magnetotelluric profile crossing the Dead Sea Transform Fault, locally known as the Arava Fault (AF), modified after Ritter *et al.* (2003). The most prominent feature in the resistivity model are the sharp lateral contrasts under the surface trace of the AF. (b) Two-dimensional electrical resistivity model of a profile across the western part of the Iberian Peninsula (Iberian Massif), modified after Pous *et al.* (2004). The high conductivity zones coincide with the transitions of suture zones of the Variscan orogen. Labels are R, high-resistivity zones; C, high-conductivity zones; SPZ, South Portuguese Zone; OMZ, Ossa Morena Zone; and CIZ, the Central Iberian Zone. (c) MT model across the Andes, modified after Brasse *et al.* (2002). The most consistent explanation for the broad and deep reaching highly conductive zone is granitic partial melt. Reflection seismic data and the location of the Andean Low-Velocity Zone (ALVZ) are superimposed on the MT model. The Quebrada Blanca Bright Spot (QBBS) marks a highly reflective zone in the middle crust of the forearc.

(AF) correlates with a sharp vertical conductivity boundary at the eastern edge of this feature. The high conductivity may be due to brines in porous sedimentary rocks.

The interpretation that crystalline rocks are situated east of the fault cannot be derived from the MT data. Coincident seismic data, however, reveal a strong increase in P-wave velocities (to values exceeding  $5 \text{ kms}^{-1}$ ) east of the AF, where the MT model indicates higher resistivities (Ritter *et al.*, 2003). The seismic velocities are consistent with crystalline basement rocks; however the observed resistivities (50–250  $\Omega$ m) are unusually low for unfractured crystalline rocks. Both the seismic and MT observations may be explained by fractured crystalline rocks with interconnected fluid-bearing veins.

A lithological change across the fault may be the cause of the deeper conductivity contrast, however, the near-surface conductors, on opposite sides of the fault, are in similar lithology (alluvial fan deposits). This suggests that an impermeable fault-seal may be arresting crossfault fluid flow transport at shallow depths. Additionally, the interconnected fluid-bearing veins, posited to exist within the Precambrian basement, do not appear linked to the deep conductor west of the fault. Thus, a fault-seal may be restricting fluid transport at greater depths as well.

The image of the AF in Jordan appears to be an exception, as it shows a distinct lack of an electrically conducting deformation zone at its center. Typical for many of the active faults are subvertical regions of high conductivity. Fluids distributed within the fracture network of the damage zone generally explain the observed high conductivity. Fluid transport within the rock opens pores and cracks, increasing the mobility of solutes such as salts, calcite, or quartz, thereby increasing the bulk conductivity.

The most intensively studied example of any fault is the San Andreas Fault (SAF) in California. Unsworth *et al.* (1997) demonstrated that its internal structure can be imaged with MT measurements. Several short profiles across the SAF image a highly conductive structure down to several kilometers depth. At Parkfield, the anomalous conductivity is confined to a zone centered on the SAF and extending from the surface to 2-5 km depth. At Hollister, the prominent zone of high conductivity is loosely bound between the San Andreas and Calaveras faults, extending to mid-crustal depths beneath the SAF (Bedrosian *et al.*, 2004). Ritter *et al.* (2005) examine how electrical images of different fault zones are linked to specific architectural units, the hydrogeology, and seismicity within the fault.

## Fossil faults in suture zones

Exhumed fossil shear zones, in contrast to upper crustal faults, often expose structures which originated below the depth of predominantly brittle deformation (though they may have experienced brittle deformation during reactivation). These shear zones can be similarly conductive, but in these cases, bulk conductivity may be dominated by electron transport, for example in an interconnected graphite network. Graphite coatings lower shear friction and hence add to the mobility of faults. Once created, graphite is stable over very long time spans allowing shear zones to remain conductive long after activity ceases. The critical observation is that the shearing process itself can lead to the interconnection of conductive material (Jödicke *et al.*, 2004; Nover *et al.*, 2005).

The SW Iberian Peninsula constitutes the southern branch of the Iberian Massif, the best exposed fragment of the Variscan Fold Belt in Europe. It was built up by an oblique collision between three continental blocks: the South Portuguese Zone (SPZ), the Ossa Morena Zone (OMZ), and the Central Iberian Zone (CIZ). These blocks are separated by suture zones. In its evolution through time, this area experienced sequences of volcanic rifting, continental collision, and the closure (subduction) of oceans. To unravel traces of these past geodynamic processes by imaging the present Earth's crust is a key question but also a major challenge for geophysical deep sounding methods.

Pous *et al.* (2004) interpret a 200 km long MT profile across this part of the Iberian Massif. The model in Figure E28b (see also Plate 15c) reveals several high conductivity zones which coincide with the transitions of three Variscan terranes (SPZ, OMZ, and CIZ). A general north-dipping trend of the structures appears in the upper crust of the SPZ and OMZ. Fluids in shallow crustal faults could be the cause for the high conductivities observed in C1 and C2. Palaeozoic cover sequences and plutonic intrusions are depicted in the upper to middle crust as high resistivity zones (R1–R3).

The most striking features in the model are the zones of high conductivity which cut across the entire crust (C3 and C6 in Figure E28b and Plate 15c). Most interestingly, these deep reaching zones of enhanced conductivity correlate with the transitions SPZ/OMZ and OMZ/CIZ and it is plausible to conclude that these zones are the (electrical) expressions of suture zones. Another interesting feature of the model in Figure E28b (see also Plate 15c) is the presence of a high conductivity layer (C4) extending over the entire OMZ at middle to lower crustal depth 15–25 km. The top part of this conductive layer is spatially correlated with a broad reflector (derived from reflection seismic data). The preferred explanation of Pous *et al.* (2004) for the high conductivity at greater depth is the presence of interconnected graphite. Mylonitization and shearing along a lower crustal detachment zone could explain both the seismic and the MT observations.

Pous *et al.* (2004) concluded that the enhanced conductivity in the suture zones of the Iberian Massif is generally caused by interconnected graphite enrichment along shear planes. Laboratory measurements on rock samples (Serie Negra)—rocks which were exhumed during Variscian transpression—confirmed the presence of interconnected graphite. Graphite can either accumulate in the schistosity surfaces produced by folding and metamorphism or form metallic films developed in mature faults.

*Electrical anisotropy* (q.v.) is sometimes found in fossil regimes. Typical observations for electrical anisotropy are phase values exceeding 90° (Weckmann *et al.*, 2003) and a stripy appearance (alternating between zones of higher and lower resistivity) of conductive zones. Some parts of the model in Figure E28b (see also Plate 15c) were also found to be electrically anisotropic. These zones are indicated by dashed white lines.

# Electrical conductivity image from an active subduction zone

Brasse et al. (2002) report on long-period MT studies from the central Andes between latitudes 19.5° and 21° S along two almost parallel profiles of 220 and 380 km lengths. The investigation area extends from the Pacific coast to the southern Altiplano Plateau in the back arc of the South American subduction zone. The main geoelectrical structure resolved is a broad and probably deep reaching highly conductive zone in the middle and deeper crust beneath the high plateau (see the large red block in Figure E28c and Plate 15c). The Andean Continental Research Program (ANCORP) seismic reflection profile revealed highly reflective zones below the Altiplano, in good correlation with the upper boundary of the Altiplano conductor (see Figure E28c and Plate 15c). This highly conductive domain furthermore coincides with low seismic velocities (ALVZ), a zone of elevated  $V_p/V_s$  ratios and high heat flow values. Considering all observations, granitic partial melt is the most consistent explanation for this zone of high conductivity.

Schilling and Partzsch (2001) demonstrated that the observed conductivities can be explained with partial melt rates exceeding 14% by carrying out laboratory measurements and theoretical calculations. Assuming a solid rock conductivity of  $\sigma_{\text{rock}} = 0.001 \text{ S m}^{-1}$  and a melt conductivity of  $\sigma_{\text{melt}} = 10 \text{ S m}^{-1}$  then the resulting bulk conductivity is  $1 \text{ Sm}^{-1}$ . This would correspond to a melt rate of 10% and 10 Sm<sup>-1</sup> represents an upper limit for the conductivity of granitic melt.

The presence of saline fluids, however, cannot the excluded. Particularly for the upper parts of the Altiplano conductor this would also explain the strong seismic reflectivity in the middle crust. An unexpected result of the MT image is the lack of correlation with the down-going slab (NAZCA reflector) or the Quebrada Blanca Bright Spot (QBBS). If the high reflectivity of the QBBS would be caused by large volumes of entrapped fluids ascending through the crust, however, then this should lead to a significant increase in the electrical conductivity. Obviously, the MT data contradict this interpretation, and it is also possible that the reflector is due to some strong structural contrast. The down-going slab and the domains immediately above it could become electrically conductive (i) because of water-rich sediments being transported in the subduction system or (ii) by release of fluids in the blueschist-eclogite transition zone in 80-100 km depth. Modeling studies show that such a conductor is compatible with the data (see Schwalenberg et al., 2002; and H. Brasse, personal communication) but it is not required to fit the data. Hence, if an electrically conductive slab exists, it is obscured by the overwhelming lateral influence of the high conductivity zones associated with the Pacific Ocean in the west and the Altiplano in the east.

## **EM, TECTONIC INTERPRETATIONS**

Studies of electromagnetic induction in the Earth are used to construct models of the variation of electrical conductivity in 1, 2, or 3 dimensions. Although the goal of some studies is the delineation of mineral or geothermal resources, the aim of many such investigations of conductivity structure is an improved understanding of tectonic processes. On a local scale these may include studies of active fault zones or volcanoes, while regional-scale studies include investigations of subduction zones, orogenic belts (regions of mountain building), and even, using seafloor measurements, spreading ocean ridges and mantle hot spots.

Electromagnetic (EM) methods can be used to study active tectonic processes primarily because fluids (molten rock or aqueous solutions) are typically either formed or released during these processes. In comparison to background values of the electrical resistivity of crustal rocks (~100s-1000s  $\Omega$ m), both partial melts and aqueous fluids are highly conductive and can have the effect of lowering the bulk resistivity of host rocks, to the extent that they form ideal targets for detection using EM techniques such as magnetotelluric (MT) sounding. The degree to which the bulk resistivity of a rock is reduced by the presence of fluids depends primarily on two factors. The first of these is the resistivity of the fluid itself, but more important is the degree to which the fluid forms an interconnected network and, thus, a continuous electrically conductive path through the host rock. For example, simple numerical calculations of the bulk resistivity of a two-phase system (Figure E29) shows that isolated pockets of fluid (e.g., molten rock) with a resistivity of 0.1–0.25  $\Omega$ m have little effect on the bulk resistivity of a solid host rock with a resistivity of 1000  $\Omega$ m even if the melt forms 10% by volume. In contrast, a connected melt of as a little as 1% by volume, distributed through the host rock, reduces the bulk resistivity by a factor of nearly 100. The minimum amount of melt or aqueous fluid that is necessary for the fluid to be connected is surprisingly small and possibly less than 1% (Minarik and Watson, 1995).

An excellent example of the manner in which the presence of both partial melt and aqueous fluids facilitates the use of EM methods to investigate tectonic processes is presented by the results of the electromagnetic sounding of the lithosphere and asthenosphere beneath (EMSLAB) study of the Juan de Fuca subduction zone off the Pacific Coast of North America (Wannamaker *et al.*, 1989). The two-dimensional model of electrical resistivity (Figure E30), derived from MT data along a transect of over 300 km in length, shows several regions of anomalously low resistivity. In particular, a thin region of low resistivity dipping to the east below the North American continent is interpreted as being due to the presence of residual oceanic sediments on

**Figure E29** (a) A simple model of a two-phase material consisting of a regular array of cubic cells of resistivity  $\rho_1$  surrounded by a matrix of resistivity  $\rho_2$ . (b) The manner in which the bulk resistivity of the material varies with the volume fraction of the low resistivity material.

the surface of the subducted plate. Given the resistivity of seawater ( $\approx 0.3 \ \Omega m$ ), a porosity of around 1%–2% is sufficient to account for the observed bulk resistivity of this feature over most of its length. It is also likely that as the plate subducts the increase in temperature with depth leads to the release of additional fluid from hydrated minerals. Low resistivity closer to the surface just to the east of the subduction trench results from the presence of fluids in the accretionary prism formed as the bulk of the oceanic sediments are scraped from the surface of the subducted plate. In the eastern part of the model the large low resistivity region at depths of 20–50 km is interpreted to be due to water rising from the top of the subducted plate as it is released by further dehydration reactions.

The low resistivity region in the western part of the EMSLAB model illustrates the influence of partial melting on resistivity structure. This feature is interpreted to be due to several percent of partial melt associated with regional upwelling connected to the Juan de Fuca Ridge which lies only about 100 km further to the west. An MT study of the Mid-Atlantic Ridge in Iceland (Oskooi *et al.*, 2005) has likewise detected low resistivity inferred to be associated with partial melting at a spreading ridge, and 7% of partial melt has also been calculated as being necessary to explain the low resistivity of the convection plume associated with the Hawaiian islands hot spot (Constable and Heinson, 2004).

Whereas, subduction zones mark the boundaries between oceanic and continental plates, continent-continent collision leads to the rapid uplift of mountain belts. For example, the Southern Alps of New Zealand, which result from the collision of the Pacific Plate with the Australian Plate along the Alpine Fault, are estimated to have undergone 20 km of uplift in the last 26 million years. Similarly, the ongoing collision between the Indian subcontinent and the Asian continent has led to the uplift of the Himalaya and the Tibetan Plateau. Major orogenic events such as these appear to be typified by the presence of crustal low resistivity regions resulting from the presence of

**Figure E30** The role played by fluids in influencing the electrical structure associated with tectonic processes illustrated by the electrical resistivity model of the Juan de Fuca subduction zone at latitude 44°–46°N. Note the vertical scale changes at 5 and 150 km. (After Wannamaker *et al.*, 1989).

interconnected fluids. Beneath the Southern Alps low resistivity has been interpreted as being due to the release and upward migration of fluids as the development of a crustal root (i.e., a thickening of the crust beneath the region of uplift) leads to dehydration reactions as cooler material is pushed to greater depth (Ingham, 1996; Wannamaker et al., 2002). A somewhat more complex situation is interpreted to exist beneath the Himalaya and the Tibetan Plateau. Here, significantly enhanced crustal electrical conductivity, detected over a distance of nearly 600 km beyond the original collision zone (Wei et al., 2001; Li et al., 2003), illustrates the difficulty that can occur in differentiating between reduced resistivity due to partial melting and that due to the presence of aqueous fluids. Numerical modeling has been used to place limits on the conductance (the product of the conductivity and thickness) of the region of anomalously low resistivity beneath the Tibetan Plateau. The calculated minimum conductance of this area (6000 S) has then be used, with assumptions concerning the likely resistivity values for partial melt and saline fluids, to estimate the volume fractions of these, and the required thickness of the low resistive layer, which would be necessary to explain both the MT and seismic reflection data. The preferred model of a thin layer containing saline fluids lying above a much thicker layer of partial melt, shows the importance in such situations of synthesis of EM data with data from other geophysical techniques.

Many models that have been proposed to explain the physics of the generation of earthquakes have concentrated on the role played by fluids within fault zones. The formation of a fractured, cataclastic zone along an active fault allows percolation of fluids into the damaged zone, and there has been considerable debate over the possibility that the weakness of many faults may therefore result from the presence of high pressure fluids in the fault zone. As a consequence there have been a number of EM studies aimed at detecting and delineating conductive zones associated with faults, and which have interpreted these in terms of the presence of fluids. For example, a series of MT transects of the San Andreas Fault (Unsworth et al., 1999, 2000; Bedrosian et al., 2002) have suggested a correlation between the presence of an electrically conductive zone along the fault trace and whether the fault zone is locked or not. The existence of a significant fault zone conductor (FZC) on a creeping segment of the San Andreas at Hollister has been associated with a higher fluid content within the fault zone. Whether the presence of fluid in the fault zone facilitates creep of the fault, or is itself a result of creep leading to the opening of fractures, remains somewhat uncertain. However, in contrast, locked segments of the fault zone exhibit only minor FZCs. At Parkfield, the most intensively studied segment of the San Andreas Fault because of its regular recurrence interval for earthquakes, the base of a moderate FZC coincides with the depth beneath which microearthquake activity is observed. Estimates of the fluid resistivity suggest that to achieve the measured bulk resistivity within the FZC at Hollister and Parkfield the porosity must be between 10% and 30%.

Similar conductive zones have been noted to be associated with other major transform faults, although some prominent faults do not exhibit FZCs (e.g., Ritter *et al.*, 2003). Nevertheless, the potential importance of understanding the relationship between fluids, FZCs, and the genesis of earthquakes is illustrated by MT measurements (Tank *et al.*, 2005) on the North Anatolian Fault, which marks the boundary between the Eurasian and Anatolian Plates in northern Turkey. These show that the hypocenters of both the mainshock and aftershocks of the  $M_{\rm W} = 7.4$ , 1999 Izmit earthquake were located close to a boundary between resistive and conductive zones.

One other obvious manifestation of tectonism is represented by volcanic activity and there have been numerous EM studies of active volcanoes (e.g., Ogawa *et al.*, 1998; Muller and Haak, 2004). Although, the low resistivity of molten rock (~0.1  $\Omega$ m) suggests that the magma chamber of a volcano ought to present a highly significant electrical target for EM measurements, there are in reality a number of complicating factors which make detection of magma chambers difficult. These include the existence of zones of low resistivity which are the result of either thermal alteration of rocks or the presence of hydrothermal systems associated with volcanic vents. These low resistivity regions normally occur close to the surface and therefore, because EM fields attenuate with depth more rapidly in a low resistivity material (the skin-depth effect), have the effect of decreasing the ability to resolve deeper structural features. Other complicating factors arise from the three-dimensional nature of the electrical structure associated with volcanoes, and the fact that measurements may also be significantly affected by topography.

## ENVIRONMENTAL MAGNETISM

## Introduction

Environmental magnetism, which has rapidly developed into an established science from its beginnings some 25 years ago, involves the application of magnetic methods to environmental materials, in order to measure their magnetic properties. The environmental materials in question encompass soils, sediments, dusts, rocks, organic tissues, and man-made materials. Their magnetic properties vary according to the mineralogy, concentration, grain size, morphology, and composition of the magnetic minerals present. These (nondirectional) magnetic properties can act as sensitive recorders of environmental and climatic information, both for the present day and through geological time. Paleo- and rock magnetists use magnetic measurements to identify which magnetic minerals were responsible for acquiring a record of the Earth's magnetic polarity at their time of formation. Environmental magnetists seek to identify the causal links between magnetic properties and ambient climatic, environmental and postdepositional processes. The magnetic properties can then be used, inversely, to identify natural and human-induced changes in climate and environment on both site-specific and regional scales and over current and geological timescales.

Environmental magnetism has become a valued and widely applied methodology because: magnetically distinctive assemblages of magnetic grains—dominantly iron oxides, oxyhydroxides, and sulfides occur virtually ubiquitously throughout the natural and built environment; these assemblages vary according to their source and depositional history; and sensitive magnetic measurements (i.e., to concentrations of less than 1 part per million for weakly magnetic minerals, like hematite, and less than 1 part per billion for strongly magnetic minerals, like magnetite) can be made relatively cheaply and rapidly compared with other types of mineralogical analysis.

#### Historical material

As early as 1926, magnetism was used to examine environmental processes, in a glacial setting. Gustav Ising measured the magnetic susceptibility and natural magnetic remanence of annually laminated lake sediments from Sweden. He found that the magnetic properties of the sediments varied seasonally and with distance from their ice margin source. The lake sediment layers deposited in the springtime were much more magnetic than those deposited in winter. Ising interpreted these magnetic changes as reflecting the high specific weight of magnetite grains and thus their response to different rates of flow of glacial meltwater. More magnetite grains were carried at higher rates of (springtime) flow. More than 40 years later, John Mackereth measured magnetic properties of sediments from Windermere, in the English Lake District. His work sparked new interest in the sources of magnetic minerals found in lake sediments and their surrounding catchment soils.

Since the mid-1970s onward, magnetic analyses have been applied to the sediment records of over 100 lakes worldwide. The last 20 years have seen the application of environmental magnetism to solve diverse and global-scale research questions, including: high-resolution correlation of sedimentary units (in marine, lacustrine, and marine-to-terrestrial settings); identification of the flux and timing of detrital inputs (ice-rafted debris, aeolian dust) in the deep-sea sedimentary record; unraveling of postdepositional diagenetic processes in sediments; identification of ferrimagnet formation, and destruction in different types of soils; discovery of sedimentary magnetic mineral contributions by magnetotactic bacteria; identification of natural magnets in a range of different organisms (insects, fish, humans); use of magnetism as a quantitative proxy for paleorainfall in the famous loess/soil sequences of East Europe and East Asia; archaeological prospection; sourcing of fluvial sediments; and mapping of particulate pollution sources and loadings, especially from vehicles (Figure E31). More than 130 magnetic laboratories worldwide are presently engaged in environmental magnetism research.

## Essential concepts and applications

The environmental magnetic approach can briefly be summarized as the investigation of magnetic mineralogies in natural and anthropogenic samples by measurement of both their induced and remanent responses to a series of artificially induced magnetic fields. The speed of magnetic measurements, compared with other types of mineralogical analysis, and their nondestructive nature, enables measurement of large numbers of samples, a key advantage in obtaining highresolution (spatial and/or temporal) environmental data. For any environmental sample, a large number of different magnetic parameters could be measured in order to characterize its magnetic properties and investigate its magnetic mineralogy. In practice, a reasonably small number of magnetic measurements can often provide sufficient information to identify its major magnetic constituents (Figure E32). Table E1 and Figure E33 (Maher et al., 1999) summarise some of the magnetic parameters used routinely in environmental magnetism and typical values for a range of magnetic minerals. Figure E34 shows how magnetic ratio parameters can be used to discriminate between different grain sizes in ferrimagnets. Environmental materials normally contain mixtures of magnetic minerals and magnetic grain sizes. Work is in progress to extend the capability of magnetic methods in order to identify, quantify, and ascribe specific environmental histories/origins to the individual magnetic components within such mixed samples. In the meantime, independent and complementary analyses are also often used, in order to more fully characterize sample mineral properties and compare the magnetic data with other environmental proxies (such as oxygen isotope ratios or sample geochemistry).

The carriers of the magnetic properties of rocks are normally the iron oxides, magnetite, titanomagnetite, maghemite, and hematite. Until recently, because of their significance as paleomagnetic recorders, the titanium-substituted magnetites and maghemites, formed at high temperatures in igneous rocks, were a particular focus of intensive rock magnetic research. Additional rock magnetic attention was also given to hematite, formed at lower temperatures in terrestrial settings by oxidation of iron minerals, during weathering and transport, or postdepositionally by oxidizing pore fluids. Weathering, erosion, and transport of these lithogenic minerals can provide one pathway for the supply of magnetic minerals to a range of environmental materials (soils, sediments, dusts). However, a key advance brought about in environmental magnetism has been the identification of a diverse range of processes and pathways of ferrimagnet formation at or near the Earth's surface, as described below.

Direct bacterial formation of magnetite and greigite, of submicrometer grain size, has been discovered (e.g., Blakemore, 1975; Bazylinski, 1991). A range of microaerobic and anaerobic magnetogenic species actively assimilate iron from the extracellular environment, to form

**Figure E31** Magnetic minerals in the environment and examples of major areas of application of environmental magnetism (adapted from Thompson and Oldfield, 1986).

distinctive, intracellular chains of ferrimagnetic crystals, some exhibiting unique crystal morphologies (e.g., bullet, boot, and blade shapes). These biogenic crystals normally fall within a narrow grain size range, from  $\sim$ 20 to  $\sim$ 50 nm, and behave as interacting, stable single-domain grains, resulting in strong and stable magnetic behavior. As a result, the torque of the Earth's magnetic field is transferred effectively to the bacterial cell, so that when the bacteria swim, they move along the Earth's field lines. Magnetogenic bacteria, and/or their bacterial magnetofossils (Figure E35), have been found in diverse sedimentary environments, including marine (Petersen et al., 1986), lake (Spring et al., 1993), brackish (Stolz, 1992), and saltmarsh (Sparks et al., 1989) sediments, ocean waters (Bazylinski et al., 1988), soils (Fassbinder et al., 1990), rivers (Bazylinski, 1991), and sewage ponds (Moench and Konetzka, 1978). In terms of population numbers, Petersen et al. (1986) estimated for some lake sediments in South Germany a population density of 10<sup>7</sup> magnetogenic bacteria ml<sup>-1</sup>. In pure culture, the amount of magnetite produced by magnetogenic bacteria has been estimated at about 0.2 g per 10 g (wet weight) of bacteria (equivalent to  $\sim 10^{11}$  bacterial cells; Frankel, 1987). Other organisms have also been found to synthesize ferrimagnets, including insects (bees, termites, butterflies), fish, birds, and humans.

Nanocrystalline magnetite/maghemite has also been found to form inorganically, in situ, and at ambient temperatures (<50°C) within well-drained (generally oxidizing), buffered soils (pH range  $\sim 5-8$ ), as a result of release of iron by weathering and subsequent repeated redox cycles (Mullins, 1977; Maher and Taylor, 1988). Magnetite is a mixed  $Fe^{2+}/Fe^{3+}$  iron oxide; its *in situ* formation (in the trace amounts responsible for the observed magnetic enhancement in soils) requires the initial presence in the soil matrix of some Fe<sup>2+</sup>. This pathway of ferrimagnet formation may be mediated by the action of ironreducing bacteria, which use iron-in the absence of oxygen-as the terminal electron acceptor in their digestion of organic matter. They release the resultant  $Fe^{2+}$  into the extracellular environment, where it may partially oxidize to form magnetite (Lovley et al., 1987) and/or by surface adsorption cause other soil iron oxides and oxyhydroxides to dissolve, with possible magnetite formation via a green rust phase (Tamaura et al., 1983). (Action of such Fe-reducing bacteria may also

contribute to authigenic formation of magnetite in suboxic sediments of the deep-sea floor, see below.) Unlike bacterial magnetite, which is biologically constrained in crystal size and shape by the intracellular membrane structures into which it is precipitated, extracellular, pedogenically formed magnetite is variable in grain size (1–500 nm) and does not display the unique crystal morphologies observed in bacterial magnetite chains. DNA screening of magnetically enriched topsoils has shown that populations of magnetotactic bacteria are too low (<10<sup>2</sup> bacteria g<sup>-1</sup>) to account for observed soil ferrimagnetic concentrations (Dearing *et al.*, 2001), whereas the action of one iron-reducing bacterium can mediate the extracellular formation of hundreds of ferrimagnetic grains.

So-called "botanical," nanocrystalline magnetite (1-50 nm) has recently been identified (by transmission electron microscopy and electron diffraction analyses) in grass plant cells. The magnetite is located within the inorganic cores of the plant iron storage compound, phytoferritin (Gajdardziska-Josifovska *et al.*, 2001). Upon breakdown of the organic material, this botanical pathway may constitute another (as yet unquantified) contributor to soil ferrimagnets.

Depending on sedimentation rate and organic matter content, deepsea sediments can contain authigenic and diagenetic magnetic oxides and/or sulfides, in addition to any detrital magnetic minerals. Generally, as the amount of sedimentary organic matter increases, microorganisms use available oxidants (electron acceptors) in order to metabolize the organic material, with iron oxides being reduced once available nitrate and manganese oxides have been used up. Finally, when the iron oxides too have been reduced, sulfate is used as the oxidant, with the potential to form some magnetic iron sulfides (such as greigite), if this process does not proceed through to formation of pyrite (e.g., Snowball and Thompson, 1988; Tric et al., 1991). Thus, magnetic iron oxides and sulfides can form and dissolve in deep-sea sediments, depending on sedimentary geochemical conditions (Karlin et al., 1987; Langereis and Dekkers, 1999). In turn, the latter are often influenced by changes in climate, especially in generating variations in amounts of organic matter and rate and type of sediment delivery.

In addition to these low-temperature sources of ferrimagnets, two high-temperature pathways have also been identified. Combustion

## ENVIRONMENTAL MAGNETISM

Figure E32 A flowchart indicating how a relatively small number of magnetic measurements can be used to discriminate between the major magnetic minerals found in environmental samples (reproduced with permission from Maher *et al.*, 1999).

Table E1 Typical magnetic properties of natural minerals (reproduced with permission from Maher et al., 1999)

	$T_{\rm c}$	$M_{ m s}$	χ	ARM	SIRM
Mineral	(°C)	$(Am^2kg^{-1})$	$(\mu m^3 kg^{-1})$	$(mAm^2kg^{-1})$	$(Am^2kg^{-1})$
Magnetite (soft)	575	92	560	18	9
Magnetite (hard)	575	92	400	110	22
Titanomagnetite (soft)	200	24	170	80	7
Titanomagnetite (hard)	200	24	200	480	12
Hematite	675	0.5	0.6	0.002	0.24
Ilmenohematite	100	30	25	480	8
Greigite	300	20	120	110	11
Pyrrhotite	300	17	50	80	4.5
Goethite	150	0.5	0.7	0.005	0.05
Iron	770	220	2000	800	80
Paramagnet	1/T	-	$\sim 1$	0	0
Diamagnet	const	-	-0.006	0	0

Note:  $T_c$ , Curie temperature or thermomagnetic behaviour;  $M_s$ , saturation magnetization;  $\chi$ , initial AC susceptibility; ARM, anhysteretic remanence grown in a 100 mT peak alternating field biased with a 0.1 mT DC field; SIRM, isothermal remanence grown in a 1 T DC field.

of organic matter in soils can form ferrimagnets from other soil iron oxides and oxyhydroxides (Longworth *et al.*, 1979), while fossil fuel combustion also releases magnetite-bearing, pollutant particles into the atmosphere (Puffer *et al.*, 1980; Hunt *et al.*, 1984, and see below).

**Figure E33** A magnetic hysteresis (magnetization vs field) loop for a typical natural sample containing a mixture of ferrimagnetic and paramagnetic minerals and some of the magnetic parameters routinely used in environmental magnetism (reproduced with permission from Maher *et al.*, 1999).

The magnetic properties of environmental samples are largely dominated by the strongly magnetic ferrimagnets. However, high-field magnetic experiments (i.e., using DC fields of >2 T) can be used to selectively investigate the weakly magnetic minerals goethite and hematite, even when ferrimagnet concentrations are high. In samples deficient both in ferrimagnets and imperfect antiferromagnets, the weak paramagnetism of iron-bearing silicates and the negative, diamagnetic susceptibility of carbonate can be significant (Hounslow and Maher, 1999).

## Applications

In modern process studies, the magnetic properties of contemporary soils have been used to identify soil-forming processes (Maher, 1986, 1998), to relatively date weathering surfaces (Pope, 2000), to "fingerprint" different soil types and soil horizons in order to monitor soil erosion and identify sediment sources (e.g., Walling et al., 1979; Dearing et al., 1985; Oldfield et al., 1985), and to identify relationships between modern climate and modern soil magnetic properties (Maher and Thompson, 1995; Han et al., 1996), in order to make paleoclimatic estimates from paleosols ("fossil" or buried soils). This latter approach has been applied to the famous loess/paleosol sequences of the Chinese Loess Plateau, which span quasicontinuously the entire Quaternary period. These alternating windblown loess and soil layers represent colder (and drier) climate stages, when loess deposition proceeded with little soil formation, and warmer, wetter stages, when loess was still deposited but weathering and soil formation also occurred to varying degrees. The magnetic susceptibility values of the soil layers are  $\sim 3-5$  times higher than the intervening loess units, reflecting in situ pedogenic formation of ferrimagnets (Figure E36). To isolate the in situ, soil-formed magnetic signal, the pedogenic susceptibility ( $\chi_{ped}$ ) was defined for each soil as the maximum susceptibility value ( $\chi$ ) of the *B* horizon minus the  $\chi$  of the parent loess. Modern soils, across the Chinese Loess Plateau and the loessic Russian steppe display strong positive correlation between pedogenic  $\chi$  (and other magnetic parameters, such as frequency-dependent susceptibility, anhysteretic remanence), and annual rainfall (Heller et al., 1993; Maher et al., 1994, 2002). Applying this modern rainfall/ magnetism couple to the paleosusceptibility values of the buried soils

**Figure E34** The grain size dependence of selected magnetic properties for magnetite: magnetic remanence ratio (the susceptibility of the anhysteretic remanence/the saturation remanence) and demagnetization (the median destructive field of the anhysteretic remanence) data for discrimination of magnetic grain size in ferrimagnets (from Maher, 1988).

252

enables calculation of paleorainfall values through the Quaternary. Higher average rainfall is identified for the early to mid-Holocene than at the present day, indicating stronger northward and westward incursion of the rain-bearing summer monsoon winds across the SE Asian continent. Conversely, during glacial stages, rainfall decreased by up to 50%. Kukla *et al.* (1988) contest this magnetism/rainfall relationship, and suggest that the loess/paleosol magnetic variations are controlled by variations in the flux of the weakly magnetic loess—loess flux is higher, and soil magnetic properties weaker, in the northwest of the Loess Plateau. But the loessic Russian steppe, where there is no loess deposition at the present day, also demonstrates the rainfall/magnetism correlation observed in China, indicating the key influence

**Figure E35** Transmission electron micrograph of bacterial magnetofossils, some with the unique "bullet" and "boot" morphologies, extracted from Cretaceous chalk, Culver Cliff, United Kingdom (photo: M. Hounslow, reproduced with permission from Maher *et al.*, 1999).

of climate, rather than dust flux, in controlling soil magnetic properties in these areas. Finally, the loess/paleosol magnetic variations correlate with the deep-sea oxygen isotope record, showing that the Asian monsoon systems are interlinked with the processes of midlatitude ice sheet growth and decay.

Increasingly, magnetic measurements are also being applied to pre-Quaternary paleosols, in order to identify their soil-forming processes and environments. For example, the magnetic properties of paleosols of Permian age appear to record glacial-interglacial fluctuations in low-latitude Pangea (e.g., Tramp *et al.*, 2004).

Soils and weathering bedrock can also be considered as sediment precursors. If they display distinctive magnetic properties, preserved through both erosion and subsequent deposition as sediment, then it may be possible to construct soil-sediment magnetic linkages and quantitatively identify changes in rates of flux of those sources through time. For instance, Caitcheon (1993) demonstrated that magnetism can be used to identify sources of suspended and bedload sediments at stream tributary junctions. The tributary contributions to the resultant downstream mix were also quantifiable. Further developments in quantitative sediment source ascription encompass multivariate statistical unmixing of sediment magnetic properties against potential source magnetic properties, using various types of algorithms, including multiple regression, maximum likelihood unmixing (Shankar et al., 1994) and linear programming (Walden et al., 1997). For example, Shankar et al. (1994) estimated that natural catchment sources contributed >97% of stream bedload upstream of an iron ore mine, but that mine waste contributed  $\sim$ 50% of the downstream bedload. An UK-based study of suspended sediment sources (Gruszowski et al., 2003), based on magnetic, geochemical, and radionuclide signatures (in the catchment of the River Leadon), was able to estimate relative contributions of ~43% from subsurface (subsoil and channel bank) sources, and  $\sim 27\%$  from topsoil (arable and grassland) sources. The most recent development in tracing of fluvial sediment sources is based on the magnetic signatures of magnetic minerals carried as inclusions within host silicate grains (Hounslow and Morton, 2004). By removing any discrete magnetic grains (through premeasurement acid treatment),

**Figure E36** The interbedded loess (pale color) and paleosols (darker layers) of the Chinese Loess Plateau, at Luochuan (central Loess Plateau) together with magnetic susceptibility (in units of  $10^{-8} \text{ m}^3 \text{kg}^{-1}$ ) and sedimentary logs ( $S_0$ , modern soil;  $S_1$ , Paleosol 1,  $L_1$ , Loess 1) for the arid western plateau, and the increasingly humid central and southeastern plateau. Note that the loess/soil sequences are thicker in the west and have increasingly high magnetic susceptibility values toward the southeast.

253

the sample magnetic properties reflect only magnetic inclusion signatures. As the magnetic inclusions occur within host particles, they are not subject to any hydraulic sorting effects and are protected from any postdepositional, diagenetic alteration/erasure.

Providing a temporal dimension on historical and/or geological timescales, lake, estuarine, and deep-sea sediments can form natural records both of detrital fluxes and productivity in their aquatic communities. The measured magnetic properties of such sediments can thus reflect changes in allogenic inputs through time and/or authigenesis and/or postdepositional diagenesis. Magnetic methods are thus often embedded within other, multiproxy analyses in order to discern the relative significance of these possible inputs. Quantitative "unmixing" of sediment magnetic properties in terms of possible sediment sources, as described above, is increasingly applied in lake sediment studies (e.g., Thompson, 1986; Yu and Oldfield, 1993; Egli, 2004). In the context of allogenic influx, and at the land catchment-scale, much environmental magnetic work has focused on using the magnetic properties of lake sediments to construct source-sediment linkages (as above) but also to identify sedimentation rates through time (e.g., Bloemendal et al., 1979; Dearing and Foster, 1986; Loizeau et al., 1997), often related causally to catchment disturbance, whether natural or anthropogenic. Lake sediments can receive detrital inputs from fluvial supply and from aeolian flux, of dust, volcanic ash, and pollutants. Magnetic oxides can form *in situ*, through the direct bacterial actions of magnetogenic bacteria and/or the extracellular mediation of the iron-reducers (as above). In organic-rich conditions, dissolution of magnetic minerals may occur (e.g., Hilton and Lishman, 1985) while, with a source of sulfate, magnetic iron sulfides may be precipitated (e.g., Snowball and Thompson, 1988; Roberts et al., 1996). Hence, the magnetic properties of lake sediments need to be evaluated on a site-specific basis, and with appropriate age control, in order to identify the key magnetic sources through time, and, inversely, to thus reconstruct past environmental and/or climatic changes. Dearing (1999) provides a review of lake sediment magnetic records for the Holocene period. Where fluvial detrital flux of magnetic minerals can be shown to be of primary importance, changes in hydrological regime, including rainfall (Foster et al., 2003), stream power (e.g., Dearing et al., 1990), snow melt (Snowball et al., 2002), flood frequency and magnitude (Thorndycraft et al., 1998) may be recorded in lake sediment sequences. Conversely, changes in sediment source (e.g., Reynolds et al., 2004) or changes in source magnetic properties, such as results from fire-induced magnetic mineral formation (e.g., Rummery, 1983), may be identifiable. In historical times, anthropogenic pollution particles have been a dominant contributor to the magnetic properties of some lake and estuarine sediments (e.g., Locke and Bertine, 1986; Battarbee et al., 1988; Kodama et al., 1997).

As for lake sediments, the magnetic properties of deep-sea sediments can vary as a result of changes in detrital flux (e.g., aeolian dust, iceberg-rafted debris, and bottom-water transport), bacterially produced or mediated mineral authigenesis of magnetic oxides or sulfides, and/or postdepositional diagenesis. Hence, environmental magnetic properties of marine sediments can also act as proxy indicators of environmental and climatic change, over geological timescales. Sediment redox cycles, influenced by hydrological runoff, sedimentation rates, and organic matter content, can be identified from sediment magnetic properties, as magnetic minerals form, dissolve, and re-form through the diagenetic zone. Sediment magnetic properties in restricted basins like the Mediterranean are very sensitive to even small changes in climate, effectively amplifying the variations in such regions (e.g., Langereis and Dekkers, 1999). Conversely, in the oxic/suboxic sediments of the Atlantic, sediment magnetic properties dominantly reflect differences in detrital sediment sources (although where detrital flux is low, bacterial magnetofossils may constitute a significant contributor to sediment magnetism). Schmidt et al. (1999), for instance, identified major sediment sources at the present-day for the South Atlantic, including the riverine runoff from the Amazon Basin and dust flux

from the African continent. For the North Atlantic, statistical analysis of a multivariate magnetic data set representing >300 surface sediments across the ocean identified the present spatial distribution of iceberg-rafted debris, dominantly from Greenland and the Labrador Sea/Baffin Bay regions, and two distinctive North African dust plumes (Watkins and Maher, 2003). Mapping and sourcing of iceberg-rafted debris for past glacial stages enables reconstruction of ocean surface currents and testing of ocean circulation models. With regard to aeolian fluxes, robust identification of dust flux to the deep-ocean sedimentary records during past glacial and interglacial stages is important, as dust may play an active role in climate change. Dust can change the radiative properties of the Earth's atmosphere but can also "fertilize" iron-deficient areas of the world's oceans, such as the Southern Ocean, stimulating marine productivity and resulting in drawdown of carbon, with resultant reduction in atmospheric CO<sub>2</sub> levels (Martin, 1990). Dust from the arid/semiarid zone of Africa is characterized by the presence of hematite and/or goethite, weakly magnetic iron oxides with distinctive high-field magnetic properties (Robinson, 1986; Watkins and Maher, 2003). It has thus been possible to identify the flux and provenance of dust by magnetic measurements of suitable deep-sea and lake sediments (e.g., Maher and Dennis, 2001; Kissel et al., 2003; Larrasoaña et al., 2004). Other applications of magnetic measurements to deep-sea sediments include: core correlation; tracing of turbidite flow paths (Abdeldayem et al., 2004), and identification of hydrothermal alteration zones (Urbat and Brandau, 2003).

# Current investigations, controversies, and gaps in current knowledge

Recent innovations in environmental magnetism include the use of magnetic measurements of roadside tree leaves and soils as natural pollution monitors (e.g., Matzka and Maher, 1999; Knab et al., 2000; Hanesch et al., 2003); magnetic mapping and in situ measurement of magnetic susceptibility in order to identify levels of contaminants in lake sediments (Boyce et al., 2004); magnetic identification of dust flux to ice cores (Lanci et al., 2001); and identification and correlation of volcanic tephras (e.g., Andrews et al., 2002). Development of new measurement techniques continues, such as the use of first-order reversal curves (FORC) diagrams to identify magnetic mineral compositions and grain sizes (e.g., Pike et al., 2001; Carvallo et al., 2004). FORC may be suitable for addressing the problem of investigating the weakly magnetic minerals, hematite and goethite even when magnetite is the dominant mineral (Muxworthy et al., 2004). Remanence measurements at high fields (>2 T) and low temperature (77 K) may also provide a new means of defining the concentration and grain size of these minerals in this context (Maher et al., 2004). Finally, to achieve standardized accuracy as well as precision, interlaboratory calibration is an ongoing research activity internationally (e.g., Sagnotti et al., 2003).

#### Summary/conclusions

The ubiquity and environmental sensitivity of the magnetic mineralogies present in soils, sediments, and dusts can provide a record of past and present environmental and climatic change and process. The speed and sensitivity of magnetic measurements, and their demonstrated range of environmental applications, has led to their application to a range of key environmental and climatic questions and problems, ranging from site-specific to global in scale. Environmental magnetism has thus become an established discipline, which continues to gain in strength from improved measurement capabilities, quantification, and interaction with other, complementary environmental analyses and proxies.

# ENVIRONMENTAL MAGNETISM, PALEOMAGNETIC APPLICATIONS

## Introduction

Environmental magnetism involves magnetic measurements of environmental materials, including sediments, soils, rocks, mineral dust, anthropogenic pollutants, and biological materials. The magnetic properties of these materials can be highly sensitive to a broad range of environmental processes, which makes mineral magnetic studies widely useful in the environmental sciences. More detailed treatments of the breadth of environmental magnetic research applications, and definitions of magnetic parameters and their interpretation, can be found in recent review articles and books (e.g., Verosub and Roberts, 1995; Maher and Thompson 1999; Evans and Heller 2003; see also Environmental magnetism). Most environmental magnetic studies aptly focus on environmental interpretations. Nevertheless, environmental magnetism, whether explicitly stated as such or not, routinely plays an important role in paleomagnetic studies, including tectonic, geochronological, and geomagnetic applications. It is the paleomagnetic applications of environmental magnetism that are in focus here, especially in relation to studies of sediments and sedimentary rocks. These paleomagnetic applications are discussed below following four broad themes:

- 1. Inter-core correlation and development of relative age models;
- 2. Development of astronomically calibrated age models;
- 3. Testing the hypothesis of orbital forcing of the geomagnetic field;
- 4. Determining the origin of the paleomagnetic signal.

# Inter-core correlation and development of relative age models

Sedimentary environments receive inputs of detrital magnetic minerals that vary with time and that are diluted by varying supply of lithogenic mineral components and production of biogenic mineral components, respectively. Stratigraphic variations in magnetic properties within sedimentary basins are usually spatially coherent on scales of tens of meters; in some cases, magnetic property variations can be traced over large portions of an ocean basin. Variations in magnetic properties, such as the low-field magnetic susceptibility, therefore, provide a fundamentally important physical parameter for stratigraphic correlation among cores from a coherent depositional environment. Variations in magnetic susceptibility are routinely used for inter-core correlation and provide the basis for development of relative age models in paleomagnetic studies of geomagnetic field behavior. For example, classic studies of paleosecular variation (see *Paleomagnetic secular variation*) recorded by postglacial lake sediments depended on intercore correlation based on magnetic susceptibility variations (Turner and Thompson, 1979). The resultant correlation provided independent confirmation that the same paleomagnetic variations were observed at the same time in the respective cores. This procedure yielded a coherent relative age model that was then transformed into a numerical age model by combined use of radiocarbon dating, correlation to historical secular variation measurements from the Greenwich observatory and correlation to archaeomagnetic secular variation data (Turner and Thompson, 1979).

Inter-core correlation, based on magnetic susceptibility variations, is widely performed in paleomagnetic studies of lacustrine and marine sediments. For example, thick marine sedimentary sequences are routinely cored by the Ocean Drilling Program (ODP), and its successor the integrated ODP (IODP), by taking successive  $\sim$ 10-m cores from a single hole. Modern high-resolution studies require acquisition of continuous records, which necessitates coring of multiple holes at the same site with slight depth offsets among cores from adjacent holes to ensure complete stratigraphic recovery. A continuous stratigraphic record is then "spliced" together by correlating high-resolution measurements of physical properties such as magnetic susceptibility from multiple cores (Hagelberg et al., 1992). This routine procedure of using magnetic susceptibility variations for stratigraphic correlation provides the basis for high-resolution paleomagnetic studies of sediment cores as well as for a wide range of other studies. An example of the type of high-resolution inter-core correlation that is possible using magnetic susceptibility variations is shown for two ODP holes from the North Pacific Ocean in Figure E37. The two holes are separated by 00°26' and were cored at water depths of 2385 m (Hole 883D) and 3826 m (Hole 884D), respectively, on the flanks of Detroit Seamount. The sediments from the two depositional environments have different carbonate and volcanic ash concentrations. The magnetic susceptibility variations for the two holes, measured at 1-cm intervals on u-channel samples, therefore have significant differences (Figure E37a,b). Regardless, the records can still be readily correlated and the depths of correlative horizons from one hole can be transferred into equivalent depths in the other hole (Figure E37c). The physical correlation between ODP holes 883D and 884D shown in Figure E37c enabled Roberts et al. (1997) to independently correlate relative geomagnetic paleointensity records for the two holes and to produce a stacked paleointensity record for the North Pacific Ocean for the last 200 ka. This approach to inter-core correlation can also help with analysis of finer details of geomagnetic field behavior. For example, the interval between 8.5 and 9.5 m below seafloor (mbsf) at ODP Site 884 contains a detailed record of a geomagnetic excursion (Roberts et al., 1997). By correlating whole-core magnetic susceptibility records from three holes cored at Site 884 (Figure E38a), in the same way as shown in Figure E37, it is possible to place detailed records of the excursion on the same relative depth scale (Figure E38b).

Inter-core correlation using environmental magnetic parameters that are independent of paleomagnetic variations (Figures E37 and E38) enable powerful direct comparison of details of geomagnetic field behavior in paleomagnetic analyses of the spectrum of geomagnetic field behavior, including studies of paleosecular variation, relative paleointensity of the geomagnetic field, excursions, and polarity transitions. It should be stressed that this technique of inter-core correlation simply provides a relative stratigraphic age model; development of numerical age models depends either on direct dating or on correlation of magnetic properties with an appropriate astronomical target curve, as described below.

## Development of astronomically calibrated age models

Stratigraphic variations in magnetic properties are climatically controlled in many depositional environments. This can occur, for

**Figure E37** Example of inter-core correlation using low-field magnetic susceptibility. (a) Magnetic susceptibility profile for ODP Hole 883D. (b) Magnetic susceptibility profile for ODP Hole 884D. (c) Correlation of magnetic susceptibility profiles (both for u-channel samples) for ODP holes 883D and 884D, with data from Hole 883D transformed onto the depth scale for Hole 884D (see Roberts *et al.*, 1997 for details). Such correlations based on environmental magnetic parameters provide an independent basis for detailed correlation of paleomagnetic features in cores.

example, as a result of climatic modulation of the supply of lithogenic mineral components eroded from a source rock or through dilution of a roughly constant lithogenic component by a climatically controlled biogenic mineral component. The result is an environmental magnetic record that responds coherently to orbitally forced variations in climate (e.g., Kent, 1982). In some cases, environmental magnetic parameters

provide such a good representation of an orbitally controlled forcing parameter (e.g., summer insolation) that the magnetic parameter can be used to directly date the sediment core (e.g., Larrasoaña *et al.*, 2003a). Paleomagnetic studies of relative geomagnetic paleointensity are often conducted on cores where the magnetic properties are climatically controlled. In such cases, age models are routinely developed

**Figure E38** Example of comparison of fine-scale paleomagnetic features based on inter-core correlation using low-field magnetic susceptibility. (a) Correlation of whole-core magnetic susceptibility profiles for ODP holes 884B, 884C, and 884D in the vicinity of a geomagnetic excursion (see Roberts *et al.*, 1997). (b) Paleomagnetic inclination records for the geomagnetic excursion for the characteristic remanent magnetization (ChRM) for discrete samples (holes 884B, C, and D) and for u-channel samples after alternating field demagnetization at 25 mT (Hole 884D). Susceptibility correlation provides a good independent first-order constraint for tying together different high-resolution paleomagnetic records of geomagnetic features.

by correlation of environmental magnetic parameters with astronomical target curves (e.g., Guyodo *et al.*, 1999; Dinarès-Turrell *et al.*, 2002). It is preferable to test such age models against, for example, oxygen isotope records for the same sediment core (e.g., Larrasoaña *et al.*, 2003a); however, age models are often developed solely by correlating environmental magnetic parameters with astronomical target curves.

Environmental magnetic parameters can be routinely used not only for constructing chronologies for individual cores but also for calibrating geological timescales. While development of the astronomical polarity timescale (APTS) (Hilgen, 1991; Langereis and Hilgen, 1991) has been independent of environmental magnetism, extension of the APTS beyond the Miocene-Pliocene boundary has in some cases relied on magnetic properties of sediments. For example, magnetic susceptibility variations have been used to astronomically calibrate the Oligocene and Miocene (Shackleton *et al.*, 1999) via correlation with calculated records of variations in Earth's orbital geometry (Laskar *et al.*, 1993) (see Figure E39).

The APTS was developed by identifying the positions of magnetic reversals in cyclically deposited marine sediments from the Mediterranean Sea, in which organic-rich sapropel deposits provide key tie points to astronomical target curves (Hilgen, 1991; Langereis and Hilgen, 1991). Magnetic minerals are highly sensitive to diagenetic alteration associated with degradation of sedimentary organic matter during early burial, and variations in the burial of organic carbon has produced cycles of nonsteady state diagenesis that has left a characteristic signature in the magnetic properties of these sediments (e.g., Larrasoaña *et al.*, 2003b). In many cases, sapropels that were originally present have been completely removed from the record by postdepositional oxidation, yet magnetic properties can preserve the

**Figure E39** Example of how an environmental magnetic parameter (low-field magnetic susceptibility) can be used to calibrate geological time. The example is from the Early Miocene in ODP Hole 929A from Ceara Rise (Shackleton *et al.*, 1999), with the astronomical target curve being the eccentricity-tilt-precession (ETP) parameter that was extended from the data of Laskar *et al.* (1993). Differences between the curves result from numerous factors (see Shackleton *et al.*, 1999).

characteristic signal associated with the former presence of sapropels (Larrasoaña *et al.*, 2003b). Environmental magnetic analysis of sediments that have undergone orbitally controlled variations of nonsteady state diagenesis can therefore enable development of astronomically calibrated timescales with age tie points in addition to those that are identifiable using standard lithological observations.

# Testing the hypothesis of orbital forcing of the geomagnetic field

Long, continuous records of vector variability of the geomagnetic field are needed to understand long-term field evolution and to constrain models of field generation. While it is straightforward to determine the horizontal and vertical components of the paleomagnetic vector in sediments, estimating the intensity of the ancient geomagnetic field has often proved problematical (see *Paleointensity, relative, in sediments*). The problem can be overcome in ideal sediments by normalizing the natural remanent magnetization (NRM) by an appropriate parameter that can remove the effects of variation in magnetic grain size and magnetic mineral concentration. Environmental magnetic parameters such as the low-field magnetic susceptibility, the anhysteretic remanent magnetization, and the isothermal remanent magnetization are routinely used to normalize the NRM to determine the relative geomagnetic paleointensity.

It is accepted that the geomagnetic field is generated by dynamo action within the Earth's electrically conducting fluid outer core (where buoyancy-driven convection generates a self-sustaining dynamo). Calculations indicate that any energization of the dynamo by external orbital forcing is insufficient (by at least an order of magnitude) to control the geomagnetic field (e.g., Rochester *et al.*, 1975). Nevertheless, recent recovery of long, continuous high-resolution vector paleomagnetic records has provided the type of geomagnetic time series needed for testing whether there is any relationship between the field and orbital forcing parameters. Surprisingly, several paleomagnetic records of both the intensity (e.g., Tauxe and Shackleton, 1994; Channell *et al.*, 1998) and direction (e.g., Yamazaki and Oda, 2002) of the field have resurrected the suggestion that orbital energy could drive the geodynamo.

In the case of orbital periodicities embedded within relative paleointensity records, periodograms of these records suggested that orbital periodicities were not present in the environmental magnetic parameters used for relative paleointensity normalization. This was taken to suggest that statistically significant signals at Earth orbital periods in the relative paleointensity records indicate orbital energization of the geomagnetic field (Channell et al., 1998). However, when Guyodo et al. (2000) performed wavelet analysis on both the relative paleointensity signals and on the magnetic parameters used for normalization, they found statistically significant periodicities in both the paleointensity estimate and in the normalization parameter during the same time intervals. Guyodo et al. (2000) concluded that, overall, there is a subtle climatic contamination of the magnetic parameters that was not removed in the normalization process. The claim of orbital modulation of the geomagnetic field by Channell et al. (1998) was therefore retracted.

In another intriguing case, Yamazaki and Oda (2002) reported a link between the paleomagnetic inclination and orbital parameters and explained it by using a model based on long-term regions of nondipole field behavior at the Earth's surface. Horng et al. (2003) studied a core that spanned the same age interval from the same region of nondipole field behavior and found no such relationship. Roberts et al. (2003) used the data of Yamazaki and Oda (2002), and, while they found the same spectral peaks, they demonstrated that these peaks were not statistically significant. Even when it is considered that sediments might record a forcing signal in a nonlinear manner, comparison of the spectral signal of Yamazaki and Oda (2002) with that of the orbital solution of Laskar et al. (1993) demonstrates a lack of coherence between these signals (Figure E40a). In contrast, a demonstrably orbitally controlled environmental magnetic signal (Larrasoaña et al., 2003a) is convincingly coherent with orbital parameters (Figure E40b). Roberts et al. (2003) therefore concluded that the hypothesis of (partial) orbital energization of the geomagnetic field remains undemonstrated. Environmental magnetic signals have played a fundamental role in the debate concerning this interesting paleomagnetic application.

**Figure E40** Example of a test of the hypothesis of orbital forcing of the geomagnetic field. (a) Coherency for the ETP parameter from the data of Laskar *et al.* (1993) and the inclination record of Yamazaki and Oda (2002). There is no statistically significant coherency at the 100-ka period (or at other Milankovitch periodicities). (b) Coherency for the ETP parameter from the data of Laskar *et al.* (1993) and the Saharan dust record of Larrasoaña *et al.* (2003a) for the last 3 million years. Orbital forcing of the dust record is clearly demonstrated, with statistically significant coherency with the orbital solutions at the 99% confidence level (see Roberts *et al.*, 2003 for details). This comparison suggests that the hypothesis of orbital forcing of the geomagnetic field is undemonstrated.

## Determining the origin of the paleomagnetic signal

Rock magnetic and environmental magnetic investigations constitute a fundamentally important component of most modern paleomagnetic studies. This is because the fidelity of a measured paleomagnetic signal is directly related to the magnetic mineral(s) and the magnetic grain size distribution of the magnetic mineral(s) within a rock. For example, it is generally expected that an assemblage of detrital single-domain or pseudosingle-domain magnetic field at or near the time of deposition. On the other hand, similar sediments that are magnetically dominated by multidomain grains would not be expected to faithfully record field information dating from the time of deposition. To complicate matters,

paleomagnetically important minerals can authigenically grow within some sediments. In such cases, constraining the time of magnetic mineral growth is crucially important for interpretation of paleomagnetic data. Two examples of authigenic iron sulfide minerals, greigite (Fe<sub>3</sub>S<sub>4</sub>) and monoclinic pyrrhotite (Fe<sub>7</sub>S<sub>8</sub>), are given here to illustrate the importance of rock magnetic and environmental magnetic studies in support of paleomagnetic studies (see *Iron sulfides*).

Greigite grows within anoxic sedimentary environments that support active bacterial sulfate reduction. Dissolved sulfide forms within pore waters (or within an anoxic water column), which then reacts with detrital iron-bearing minerals, causing their progressive dissolution, resulting in the authigenic formation of pyrite ( $FeS_2$ ). Pyrite is the end product of sulfidization reactions, with greigite forming as a precursor to pyrite. Greigite can survive in sediments for long periods of geological time and can retain a stable paleomagnetic signal. In early studies involving greigite, it was interpreted to have formed during early diagenesis within tens of centimeters of the sediment-water interface (e.g., Tric et al., 1991; Roberts and Turner, 1993). Subsequently, however, sedimentary greigite has been found to frequently carry a late diagenetic paleomagnetic signal that makes it a highly problematical mineral in many paleomagnetic applications, including magnetostratigraphy (e.g., Florindo and Sagnotti, 1995; Horng et al., 1998; Sagnotti et al., 2005) and tectonics (e.g., Rowan and Roberts, 2005). Paleomagnetic field tests, in particular the fold test, become extremely important for constraining the timing of magnetizations carried by greigite (e.g., Rowan and Roberts, 2005). The reversals test can be misleading and false polarity stratigraphies, resulting from patchy or variably timed remagnetizations (e.g., Florindo and Sagnotti, 1995; Horng et al., 1998; Rowan and Roberts, 2005; Sagnotti et al., 2005), can easily go unidentified if careful rock magnetic and environmental magnetic investigations are not conducted in support of paleomagnetic studies.

Similar to the case with greigite, it is often assumed in paleomagnetic studies that pyrrhotite forms during early diagenesis and that it can carry a stable syndepositional paleomagnetic signal. Geochemical literature, however, indicates that the formation of pyrrhotite is kinetically inhibited at ambient temperatures typical of early burial and that pyrrhotite cannot form during early diagenesis (e.g., Schoonen and Barnes, 1991; Lennie et al., 1995). This presents an apparent conundrum because Horng et al. (1998) reported that pyrrhotite carried an identical paleomagnetic signature to detrital magnetite in sedimentary rocks from Taiwan. Horng and Roberts (2006) carried out a source to sink study in southwestern Taiwan and demonstrated that the pyrrhotite in the studied sediments is detrital in origin and that it is sourced from metamorphic rocks in the Central Range of Taiwan. While it is now recognized that pyrrhotite can carry a detrital magnetization (Horng and Roberts, 2006), and while it can also carry late diagenetic remagnetizations (e.g., Jackson et al., 1993; Xu et al., 1998; Weaver et al., 2002), pyrrhotite clearly cannot carry an early diagenetic magnetization. Knowing which type of magnetization is being carried by monoclinic pyrrhotite grains within a sediment is of crucial importance in arriving at a correct paleomagnetic interpretation. These two examples involving different magnetic iron sulfide minerals demonstrate that the assumptions made in many paleomagnetic studies are incorrect. They also make clear the need for careful rock magnetic and environmental magnetic investigations in support of determining the origin, nature, and age of the magnetization in paleomagnetic studies.

## Summary

While most environmental magnetic studies appropriately focus on environmental interpretations, environmental magnetism routinely plays an important role in a wide range of paleomagnetic applications. These applications include correlation of paleomagnetic features in suites of sediment cores, development of astronomically calibrated age models, testing the hypothesis of orbital forcing of the geomagnetic field, and determining the origin of the paleomagnetic signal. The importance of environmental magnetism to this range of paleomagnetic applications therefore makes it fundamentally valuable to paleomagnetism.

## EQUILIBRATION OF MAGNETIC FIELD, WEAK- AND STRONG-FIELD DYNAMOS

# The necessity of equilibration of a growing magnetic field

It is enlightening to consider the theory of the Earth's dynamo as two separate constituents: kinematic and dynamic problems. The kinematic problem concerns conditions under which an electrically conducting flow can produce a growing magnetic field. Alternatively, the kinematic dynamo may be regarded as an instability problem where a purely hydrodynamic flow becomes unstable to infinitesimal disturbances of magnetic field. In contrast, the dynamic dynamo problem studies the equilibration of a kinematically growing magnetic field by considering the magnetic feedback on the flow (for example, Bassom and Gilbert, 1997).

In the kinematic dynamo problem, let  $\mathbf{u}$  denote the velocity of nonmagnetic convection in the Earth's fluid core at a given Rayleigh number *R*, while the magnetic field **B** is described by the dynamo equation

$$\frac{\partial}{\partial t}\mathbf{B} = \nabla \times (\mathbf{u} \times \mathbf{B}) + \lambda \nabla^2 \mathbf{B},$$
 (Eq. 1)

together with the condition

$$\nabla \cdot \mathbf{B} = 0. \tag{Eq. 2}$$

In Eq. (1),  $\lambda$  represents the magnetic diffusivity of the fluid. Equations (1) and (2) admit a solution with the generated magnetic field of the form

$$\mathbf{B}(\mathbf{r},t) = \mathbf{B}(\mathbf{r})\mathbf{e}^{\sigma t} \tag{Eq. 3}$$

together with an appropriate set of boundary conditions for **B** (Moffatt, 1978). When *U*, the typical speed of the convective flow **u**, is small, any initial magnetic field would decay to zero as  $t \to \infty(\text{Real}[\sigma] < 0)$ ; when *U* is sufficiently large,  $\text{Real}[\sigma] > 0$  and an initial magnetic field would grow without bound, i.e.,

$$|\mathbf{B}| \to \infty$$
, as  $t \to \infty$ . (Eq. 4)

The critical threshold at the onset of dynamo action takes place at some particular Rayleigh number,  $R_m$ , when  $\text{Real}[\sigma] = 0$  (for example, Zhang and Busse, 1989). Physically speaking, however, the kinematically growing magnetic field at  $R > R_m$  must be brought to an equilibrium, presumably by nonlinear effects.

#### Equilibration: subcritical and supercritical bifurcation

Mathematically speaking, the equilibration of a kinematically growing magnetic field is described by the momentum equation in a rotating fluid which may be written as

$$2\Omega \times \mathbf{u} = -\frac{1}{\rho} \nabla p + \frac{1}{\rho \mu} (\nabla \times \mathbf{B}) \times \mathbf{B} + \mathbf{f}, \qquad (\text{Eq. 5})$$

where *p* is the pressure,  $\mu$  is the magnetic permeability,  $\rho$  is the fluid density, **f** represents forces such as buoyancy, and  $\Omega$  is the angular velocity of the Earth. For an infinitesimal magnetic field, the magnetic (Lorentz) force  $(1/\rho\mu)(\nabla \times \mathbf{B}) \times \mathbf{B}$  is too weak to alter the convective flow **u** and two problems, one pertaining to nonmagnetic convection and the other to kinematic dynamo, are nearly decoupled. A growing magnetic field ultimately leads to a sufficiently large magnetic force which suppresses the convective flow and brings the generated magnetic field to an equilibration.

The equilibration of a kinematically growing magnetic field is associated with a bifurcation from the corresponding nonmagnetic convective state. There exist at least two different sequences of the bifurcation, which are sketched in Figure E41. In the first possible sequence, the linear convective instability occurs at  $R = R_c$ . When the system is driven harder at larger R, the typical amplitude U of nonmagnetic convection increases. Dynamo action takes place at  $R = R_m$  when convection is vigorous enough. The equilibration of the generated magnetic field is achieved when  $R > R_m$  as a supercritical bifurcation. In this case, larger values of the Rayleigh number R are required to power the convection-driven dynamo with extra magnetic dissipation.

The second possible sequence of bifurcation is subcritical (or backward), which is also shown in Figure E41. In comparison to a supercritical bifurcation, the nature of equilibration is quite different, which is perhaps more relevant to a rapidly rotating system like the Earth's core dynamo. When *R* is slightly smaller than  $R_m$ , the nonmagnetic convective system is linearly stable but is unstable to finite-amplitude perturbations of a magnetic field. In consequence, the backward branch of the bifurcation (the dashed curve for  $R < R_m$  in Figure E41) is unstable and cannot be physically realized. By implication, the Lorentz force resulting from dynamo action has a destabilizing effect which relaxes the inhibiting effect of rapid rotation on nonmagnetic convection. When *R* is close to  $R_m$ , the amplitude of the generated magnetic field suddenly jumps and the equilibrated magnetic field is characterized by a large amplitude. In this case, the usefulness of the kinematic study determining the onset of dynamo action is highly limited.

#### Equilibration: $\alpha$ -quenching in turbulent dynamos

The equilibration of magnetic field in turbulent dynamos can be modeled through a mechanism called  $\alpha$ -quenching. In this process we separate the generated magnetic field **B** into large-scale axisymmetric (**B**<sub>0</sub>) and small-scale nonaxisymmetric ( $\hat{\mathbf{B}}$ ) parts

$$\mathbf{B} = \mathbf{B}_0 + \mathbf{B},\tag{Eq. 6}$$

where  $\mathbf{B}_0$  is generated by an  $\alpha$ -effect in connection with interactions between small-scale turbulent flows and magnetic fields (Moffatt, 1978). The strength of the  $\alpha$ -effect would be suppressed when the back-reaction of the generated magnetic field on the flow is significantly strong. This reduced  $\alpha$  would prevent the unlimited growth of the mean magnetic field  $\mathbf{B}_0$  and bring it to an equilibration. This process is usually described by

**Figure E41** Conjectured structure of bifurcation diagram for the equilibration of convection-driven dynamos. Here  $R_c$  is the critical Rayleigh number for the onset of convection and  $R_m$  is the another critical Rayleigh number at which dynamo action takes place according to kinematic dynamo theory. Both supercritical (the solid line) and subcritical dynamo (the dashed line) bifurcations are shown.

$$\frac{\partial}{\partial t} \mathbf{B}_0 = \nabla \times \left[ \frac{\alpha \mathbf{B}_0}{\left( 1 + q |\mathbf{B}_0|^n \right)} \right] - \lambda_0 \nabla \times \nabla \times \mathbf{B}_0, \tag{Eq. 7}$$

where  $\lambda_0$  is a turbulent magnetic diffusivity, q > 0 and *n* often takes the value 2 (Jepps, 1975; Roberts and Soward, 1992). The  $\alpha$ -quenching formulation has been widely used in dynamo simulations and one of its major advantages is that it can simulate the equilibration of the generated magnetic field and the essential dynamo processes without reference to the difficult dynamics of strong nonlinear interaction between the flow and the Lorentz force described by the momentum equation (5). The corresponding bifurcation in the  $\alpha$ -quenching dynamo is typically supercritical because the dynamic effect of rotation is not taken into account.

## Weak- and strong-field dynamos

In rapidly rotating systems like the Earth's fluid core, magnetohydrodynamic dynamos may be divided into two different categories: weak-field dynamos and strong-field dynamos (for example, Gubbins and Roberts, 1987; Zhang and Schubert, 2000). They are usually defined on the basis of the relative importance of the Lorentz and Coriolis forces in a convection-driven dynamo. In the case of weak-field dynamos, the dynamic role of the Lorentz force plays an insignificant role and the viscous force must be sufficiently strong to offset the part of the Coriolis force that cannot be balanced by the pressure gradient. In the case of strong-field dynamos, the dynamic role of viscosity is taken over by the Lorentz force.

A widely used criterion for the distinction between weak-field and strong-field dynamos is associated with the Elsasser number  $\Lambda$  defined as

$$\Lambda \equiv \frac{B_0^2}{2|\Omega|\mu\rho\lambda},$$

where  $B_0$  is an average or a representative value of the amplitude of the magnetic field generated by a dynamo. Equations (1) and (5) yield an estimate for the relative importance of the Lorentz and Coriolis forces

$$\frac{|(\mu\rho)^{-1}(\nabla \times \mathbf{B}) \times \mathbf{B}|}{|2\Omega \times \mathbf{u}|} = O(\Lambda),$$
(Eq. 8)

where inertial and viscous terms are neglected. In estimating the value of the Elsasser number  $\Lambda$ , we often take  $B_0$  as a spatially or temporally averaged magnetic field. A strong-field dynamo is one in which  $\Lambda \geq O(1)$  while a weak-field dynamo is one in which  $\Lambda < O(1)$ . However, it should be pointed out that this definition is not entirely satisfactory because a large Elsasser number does not necessarily imply a strong interaction between the convective flow and the generated magnetic field.

An alternative criterion for the distinction between strong- and weak-field dynamos is based on the dynamic effect of the generated magnetic field. A strong-field dynamo is defined as one in which viscosity is dynamically unimportant so that the scale of convection is large as a direct consequence of the dynamic effect of the generated magnetic field. In other words, in a strong-field dynamo the structure and scale of the convective flow are highly sensitive to variations in the generated magnetic field. Similarly, we may define a weak-field dynamo as one in which the dynamic effect of the generated magnetic field can be treated as a perturbation. In other words, in a weak-field dynamo the structure and scale of the convective flow are controlled by the effects of viscosity and rotation and are insensitive to variations in the generated magnetic field. When one turns off dynamo action, convective motions remain largely unchanged for a weak-field dynamo but change almost completely for a strong-field dynamo.

## **EULER DECONVOLUTION**

## Introduction

Magnetic surveys are widely used in mineral and oil exploration to delineate geological structure and locate targets of interest (see *Magnetic anomalies for geology and resources*). They are also used in environmental work to locate buried metal objects such as unexploded ordnance, drums, pipework, and the like. In all of these applications, we need a quick means of turning magnetic field measurements into estimates of magnetic source body location and depth. Euler deconvolution is one such method. Others include Werner deconvolution (Werner, 1955; Hartman *et al.*, 1971) and the Naudy (1971) method.

The method may be applied to survey profile data or gridded data. It operates on a data subset extracted using a moving window. In each window, Euler's equation (see below) is solved for source body coordinates. The source body geometry is specified by a structural index (SI) ranging between 0 (contact of great depth extent) and 3 (dipole or sphere). Possible source bodies and their structural indices are tabulated below. Intermediate bodies have noninteger SIs and the Euler formulation is only approximate. The method does not require any assumptions about direction of exciting field, direction of magnetization, or the relative magnitudes of induced and remanent magnetization of the sources. But it appears to work best on data after *reduction to pole* (q.v.).

#### History

Hood (1963) proposed that Euler's equation might be used with vertical magnetic gradient survey measurements to determine source depth. Ruddock *et al.* (1966) were awarded a US patent describing a graphical method that exploited Euler's equation to determine source depth from magnetic gradient measurements. Thompson (1982) described a fully developed profile method (called EULDPH). It was widely used within the Gulf and Chevron Oil Companies and also by Durrheim (1983) and Corner and Wilsher (1989) to delineate the magnetic markers in the Witwatersrand Basin in the search for gold. Thompson also developed the theory for the case of gridded data. Reid *et al.* (1990)
implemented Thompson's method for gridded data and extended the theory to the case of zero structural index. They also coined the term "Euler deconvolution" by analogy with the established Werner deconvolution technique.

#### Theory

Strictly speaking, Euler deconvolution is only valid for homogeneous functions. A function  $f(\mathbf{v})$  of a set of variables  $\mathbf{v} = (v_1, v_2, ...)$  is homogeneous of degree *n*, if

$$f(t\mathbf{v}) = t^n f(\mathbf{v}) \tag{Eq. 1}$$

where *t* is a real number, and *n* is an integer. This is really a statement of the scaling properties of  $f(\mathbf{v})$ . If *f* has a differential at **v**, then

$$\mathbf{v}\nabla_{\mathbf{v}}f(\mathbf{v}) = nf(\mathbf{v}). \tag{Eq. 2}$$

This is Euler's equation, and Euler deconvolution solves it in appropriate cases.

If a field F can be expressed in the form

$$F = A/r^n \tag{Eq. 3}$$

F will be homogeneous of degree -n. For convenience we define the SI as N (= -n, i.e., the negative degree of homogeneity).

Thompson (1982) showed that Euler's equation could usefully be written in the form

$$(x - x_0)\partial T/\partial x + (y - y_0)\partial T/\partial y + (z - z_0)\partial T/\partial z = N(B - T),$$
(Eq. 4)

where  $(x_0, y_0, z_0)$  is the position of a magnetic source whose total field *T* is detected at (x, y, z). The total field has a regional value of *B*. *N* is the structural index.

Strictly speaking, Euler deconvolution is only valid for homogeneous fields. These are only obtained from particular idealized bodies (see Table E2) with integer structural index. The fields of most real bodies do not meet this strict criterion and the method is therefore an approximation in practice. Nevertheless, it has been found useful enough to be applied in a wide variety of cases.

#### Implementation

The process is implemented as follows.

 Interpolate line data to a constant spacing, or multiline or point data to a uniform grid. Use an interpolation interval which represents the data well but does not overinterpolate. The interval should be no more than the depth of the shallowest magnetic sources thought to exist in the area.

Table E2 Possible source bodies and their structural indic	es
--	----

Source body	Magnetic structural index
Dipole (sphere, small, compact body)	3
Thin pipe (vertical—kimberlite; horizontal—pipeline); thin bed fault	2
Thin sheet edge (dyke, sill) Contact with depth extent $\gg$ depth	1 0 (requires modified equation)

- 2. Calculate along line (x) and vertical (z) gradients for profile data and x, y, and z gradients for gridded data, using finite difference or Fourier methods. If measured gradient are available, interpolate them to the same pattern as the field data.
- 3. Choose a suitable subset size or "window." Grid windows are normally square. The window length should be greater than half the depth to the deepest magnetic sources sought. Since the method assumes that any window contains effects from only one source body, good resolution requires windows to be as small as possible. Typical grid windows might be  $7 \times 7$  to  $10 \times 10$  grid points. If necessary, for deep sources, it may be necessary to revisit 1 above, apply an anti-alias low-pass filter and desample the profile or grid.
- 4. Move the sample window through the profile or grid, using small overlapping steps. At each step, use all the data points in the current window to solve Eq. (4) above for  $x_0$ ,  $y_0$ ,  $z_0$ , and T for whatever values of structural index N seem relevant to the situation.

The method generates a solution for each window position, regardless of the presence (or lack) of any nearby magnetic source. In addition, the method effectively assumes that the effects of only one source are present in any window. Interference effects give rise to festoons of misleading solutions trailing away from valid solutions that cluster along source body edges. Various strategies have been devised to eliminate unhelpful solutions. They include:

- Eliminate solutions with high estimation uncertainties (often normalized by depth).
- 2. Eliminate solutions from poorly conditioned matrices.
- 3. Identify and select for clusters of solutions.
- 4. Only solve in windows showing positive field curvature (Fairhead *et al.*, 1994).
- 5. Eliminate solutions that fall beyond their data window.

#### Recent developments and ongoing research

Stavrev (1997) has applied differential similarity transforms to Euler deconvolution. This unconventional approach shows promise of progress in the area of multiple interfering sources. Barbosa *et al.* (1999) developed a means of determining the structural index for an isolated source body by correlating the observed field with the derived "background" field. Mushayandebvu *et al.* (2001, 2003) added rotational invariance to the scaling rule and found it possible to solve for strike, dip, and magnetization contrast or the magnetization-thickness product. Hansen and Suciu (2002) have developed a formulation for multiple sources. But all sources in one solution run must have the same structural index Nabighian and Hansen (2001) applied a Hilbert transform as well as rotational invariance and have found it possible to solve for structural index and dip. They also showed that this form of Euler deconvolution is equivalent to Werner deconvolution (see above).

The following problems are unsolved (this list is almost certainly incomplete):

- 1. Develop a reliable and robust means of solution selection.
- Pursue the application of seismic migration approaches to collapsing the festoon (spray) solutions onto their primary points.
- 3. Establish the bounds of applicability of the method to real data by working on realistic models based on the real Earth.
- Further explore the potential of differential similarity transforms as applied to Euler deconvolution. They appear to offer scope for advance in multiple-source analysis.

Magnetic Anomalies for Geology and Resources Reduction to Pole

# FIRST-ORDER REVERSAL CURVE (FORC) DIAGRAMS

#### Introduction

In many geomagnetic, geological, and environmental magnetic studies, it is important to have reliable methods of characterizing the composition and grain size distribution of magnetic minerals within samples. For example, identification of single domain (SD) magnetic grains is important in absolute paleointensity studies because SD grains produce the most reliable results, while larger multidomain (MD) grains yield the least meaningful results. In paleoclimatic studies, useful environmental information is often revealed by subtle changes in grain size distribution, as revealed by domain state, while the same grain size variations will complicate determination of relative paleointensity from the same sediment. It is therefore crucially important to have reliable methods for determining the magnetic grain size distribution in a wide range of geomagnetic, paleomagnetic, and environmental magnetic applications.

Determining the composition of magnetic minerals in a rock is relatively straightforward, however, identification of the domain state is more difficult. Conventional methods, such as measurement of magnetic hysteresis, can be powerful, but they can also yield ambiguous results because various combinations of mineral composition, grain size, internal stress, and magnetic interactions among the grains can produce the same magnetic behavior. This is particularly true for the commonly used Day plot (Day et al., 1977), which summarizes the bulk magnetic hysteresis properties by plotting ratios of  $M_{\rm rs}/M_{\rm s}$  versus  $H_{\rm cr}/H_{\rm c}$ , where  $M_{\rm rs}$  is the saturation remanent magnetization,  $M_{\rm s}$  is the saturation magnetization,  $H_{cr}$  is the coercivity of remanence, and  $H_{c}$  is the coercive force (see Rock magnetism, hysteresis measurements for a description of how these parameters are determined). For example, numerical studies have shown that magnetostatic interactions among ideal SD grains can cause the bulk hysteresis parameters of samples to plot within the MD region of the Day plot (Muxworthy et al., 2003).

In an attempt to remove some of the ambiguity inherent to conventional hysteresis measurements, Pike *et al.* (1999) and Roberts *et al.* (2000) developed a method of mineral and domain state discrimination using a type of hysteresis curve called a first-order reversal curve (FORC). Measurement of a suite of FORCs provides detailed information from within the major hysteresis loop, which enables determination of the distribution of switching fields and interaction fields for all of the particles that contribute to the hysteresis loop. The ability to measure sufficient FORCs to construct a FORC diagram has only recently become possible with rapid and sensitive vibrating sample magnetometers and alternating gradient magnetometers.

### Measuring and constructing FORC diagrams

A FORC is measured by progressively saturating a sample in a field  $H_{\text{SAT}}$  decreasing the field to a value  $H_A$ , reversing the field and sweeping it back to  $H_{\text{SAT}}$  in a series of regular field steps  $(H_B)$  (Figure F1a). This process is repeated for many values of  $H_A$ , which yields a series of FORCs, and the measured magnetization M at each step as a function of  $H_A$  and  $H_B$  gives  $M(H_A, H_B)$  (Figure F1b).  $M(H_A, H_B)$  can then be plotted as a function of  $H_A$  and  $H_B$  in field space (Figure F1c). The field steps are chosen such that  $H_A$  and  $H_B$  are regularly spaced, which means that  $M(H_A, H_B)$  can be plotted on a regular grid. The FORC distribution  $\rho(H_A, H_B)$  is defined as the mixed second derivative of the surface shown in Figure F1c:

$$\rho(H_{\rm A}, H_{\rm B}) \equiv -\partial^2 M(H_{\rm A}/H_{\rm B})\partial H_{\rm A}/\partial H_{\rm B}$$
(Eq. 1)

When  $\rho(H_A, H_B)$  is plotted as a contour plot (i.e., as a FORC diagram; Figure F1d), it is convenient to rotate the axes by changing coordinates from  $(H_A, H_B)$  to  $H_C = (H_B - H_A)/2$  and  $H_U = (H_B + H_A)/2$ .

As is standard when fitting functions to experimental data, reduction of the effect of noise on FORC distributions is achieved in a piecewise manner. That is, rather than fitting a function to the entire  $M(H_A, H_B)$  surface and then directly differentiating this surface to determine  $\rho(H_A, H_B)$ , the FORC distribution is determined at each point by fitting a mixed second-order polynomial of the form  $a_1$  +  $a_2H_A + a_3H_A^2 + a_4H_B + a_5H_B^2 + a_6H_AH_B$  to a local, moving grid.  $\rho(H_{\rm A}, H_{\rm B})$  is simply equal to the fitted parameter  $-a_6$ . As the polynomial is only of second order, it cannot accurately accommodate complex surfaces, however, this will not commonly be a problem for geological or environmental samples, which usually have relatively smooth FORC distributions. The size of the local area is determined by a user-defined smoothing factor (SF), where the size of the grid is simply  $(2SF+1)^2$ . SF normally takes values between 2 and 5, although ideally it should be 2. Taking the second derivative in Eq. (1) magnifies the noise that is inevitably present in the magnetization data. Increasing SF reduces the contribution of noise to the resulting FORC diagram, but it also removes measured data. Simple tests can be conducted to determine suitable smoothing factors for each sample. These tests determine when all of the noise that has been removed by smoothing; if SF is increased above this value, the effect will be only to remove data (Heslop and Muxworthy, 2005).

**Figure F1** Illustration of how FORC diagrams are constructed. (a) After applying a field at positive saturation ( $H_{SAT}$ ), the field is reversed to  $H_A$  and is then progressively increased at a range of  $H_B$  values in the direction of  $H_{SAT}$ . The magnetization is denoted by  $M(H_A, H_B)$ . The *dashed line* represents the major hysteresis loop and the *solid line* represents a single FORC. (b) A set of consecutive FORCs. (c) The  $M(H_A, H_B)$  surface plotted in nonrotated field space ( $H_A, H_B$ ). (d) The resulting FORC diagram for the data shown in (b) and (c) for SF = 4. The FORC data shown in (b) to (d) are for a numerical model of randomly orientated uniaxial SD grains.

A FORC diagram is well described by 100-140 raw FORCs. Recent improvements in system hardware have made it possible to measure 100 FORCs in approximately 1 h. The exact time depends on the field-step size, the aspect ratio of the FORC diagram,  $H_{\rm SAT}$ , and the averaging time. The effects of these measurement variables depend as follows:

- 1. The chosen field-step size depends ultimately on the mineralogy of the sample under investigation. For a simple SD-dominated sample as in Figure F1d, the main peak of the FORC diagram is directly related to the coercive force  $H_c$ . It is necessary to choose suitable boundary values for  $H_U$  and  $H_C$  to fully depict the FORC distribution. The field-step size will be larger for FORC diagrams with larger boundary values, which then increases the measurement time. That is, it will take longer to measure a FORC diagram dominated by high coercivity minerals such as hematite compared to low coercivity minerals such as magnetite.
- 2. The aspect ratio of the FORC diagram also affects the measurement time. The overall measurement time will decrease as the ratio of the length of the axes, i.e.,  $(H_U \text{ axis})/(H_C \text{ axis})$ , increases. A square FORC diagram therefore is optimal in terms of measurement time (but the characteristics of the measured sample should dictate the selected axis lengths). Also, in order to rigorously calculate a FORC diagram (depending on the value of SF). This will also (marginally) increase the measurement time.
- 3.  $H_{\text{SAT}}$  should be sufficient to magnetically saturate the sample. However, making  $H_{\text{SAT}}$  unnecessarily large will increase measurement time because of the finite time taken to sweep the magnet down from high values of  $H_{\text{SAT}}$ .

4. The averaging time is the amount of time taken to measure each data point, and is usually 0.1–0.25 s. Typically, the averaging time is set to 0.15 s. Increasing the averaging time increases the total measurement time, but improves signal to noise ratios. In systems that magnetically relax on the same time scale as the averaging time, the averaging time can be critical to the resulting FORC diagram. The averaging time should therefore always be stated in the accompanying text or figure caption.

#### FORC and Preisach diagrams

The FORC method originates in the phenomenological Preisach-Néel theory of hysteresis (Preisach, 1935; Néel, 1954). There has been much unnecessary confusion in the paleomagnetic community over the relationship between Preisach diagrams and FORC diagrams. Much of this confusion has arisen due to the lack of understanding as to what a Preisach diagram is. Put simply, there are many ways of measuring a Preisach diagram, of which the FORC method is one. FORC diagrams are essentially a new well-defined algorithm or method for rapidly generating a particular class of Preisach diagram.

# **Characteristic FORC diagrams**

#### Noninteracting SD behavior

To help in the understanding of FORC diagrams, consider a FORC diagram for a SD grain, with uniaxial anisotropy, that is aligned in the direction of the applied field. Such an ideal SD grain will have a perfect square hysteresis loop (Figure F2a). When plotting raw FORC

**Figure F2** (a) Schematic square hysteresis loop for an ideal noninteracting SD particle, with uniaxial anisotropy, aligned along the direction of the applied field ( $H_{SW}$  is the switching field). (b) The raw hysteresis data for a series of FORCs for the grain shown in (a) plotted in nonrotated field space ( $H_A$ ,  $H_B$ ). (c) FORC diagram for data shown in (a) and (b). The FORC distribution for this grain lies at  $H_c = H_{SW}$  and  $H_u = 0$ .

data for such a particle in nonrotated field space,  $M(H_A, H_B)$  can take one of two values, i.e.,  $+M_s$  or  $-M_s$  (Figure F2b). For  $H_A > -H_{SW}$ (where  $H_{SW}$  is the switching field),  $M(H_A, H_B)$  is  $+M_s$ , for  $H_A < -H_{SW}$ and  $H_B < +H_{SW}$ ,  $M(H_A, H_B)$  is  $-M_s$ , and for  $H_A < -H_{SW}$  and  $H_B > +H_{SW}$ ,  $M(H_A, H_B)$  is  $+M_s$ . On differentiating the surface with respect to  $H_A$  and  $H_B$ , only at  $H_A = H_B = H_{SW}$  is  $M(H_A, H_B)$  nonzero. That is, the FORC distribution should be a perfect delta function, normal to the FORC plane; however, due to the smoothing factor,  $\rho(H_A, H_B)$  will have finite width (Figure F2c). An ideal noninteracting uniaxial SD particle with field applied along the easy axis of magnetization will therefore have a FORC distribution that lies at  $H_c = H_{SW}$  and  $H_U = 0$ .

For assemblages of randomly orientated, noninteracting, identical, uniaxial SD grains, there are three main features in the FORC diagram (Figure F3): first, there is a central peak; second, the main peak displays an asymmetric "boomerang" shape; and third, there is a negative region near the bottom left-hand corner of the FORC diagram. The central peak is due to the switching of the magnetization at  $H_{SW}$ . From a more mathematical point of view, the positive peak is associated with the increase in  $\partial M/\partial H_{\rm B}$  with decreasing  $H_{\rm A}$  as highlighted in Figure F3. The lower left-hand arm of the boomerang is related to FORCs near the relatively abrupt positive switching field. The right-hand arm of the boomerang is related to more subtle contours, which are due to the FORCs having different return paths, as highlighted in Figure F3. The shape of the return paths is controlled by the orientation of the grains with respect to the applied field, which results from the fact that the orientation controls the coercivity. Initially, return curve behavior is dominated by grains oriented  $\sim 45^{\circ}$  to the field. As  $H_{\rm A}$  decreases, grains with orientations closer to 90° and 0° will start contributing to the hysteresis curve, so each time  $H_A$  is decreased the return path includes grains with slightly differently shaped hysteresis loops. The right-hand arm is therefore a result of moving from the return path for a 45° assemblage in the first instance, into the return path for a randomly orientated assemblage. This effect is particularly enhanced for an assemblage of identical grains. The origin of the negative region is related to sections of the FORCs where  $H_{\rm B} < 0$  (Newell, 2005). As illustrated in Figure F3,  $\partial M / \partial H_B$  decreases with decreasing  $H_A$  at  $H_{B1}$ , which gives rise to negative values for  $\rho(H_A, H_B)$ . The decrease in  $\partial M/\partial H_{\rm B}$  with  $H_{\rm A}$  is not as pronounced for  $H_{\rm B} < 0$ ; consequently the negative region is significantly smaller than the large central peak near  $H_{\rm B2}$ . If the SD grains have a distribution of switching fields, this causes the FORC diagram to stretch out in the  $H_C$  direction (Figure F4). A distribution of coercivities (e.g., Figure F4) is much more typical of natural samples than an assemblage of identical grains as depicted in Figure F3.

#### Interacting SD behavior

FORC distributions are highly sensitive to magnetostatic interactions. As a starting point to understanding the contribution of interactions to the FORC diagram, it is simplest to consider Néel's (1954) interpretation of the Preisach (1935) diagram. Néel (1954) showed that for interacting SD grains,  $H_{\rm C}$  corresponds to the coercive force of eachSD loop in the absence of interactions and that  $H_{\rm II}$  is the local interaction field  $H_{\rm I}$ . It follows in the Preisach-Néel interpretation that  $\rho(H_{\rm a}, H_{\rm b})$ is the product of two distributions: the coercivity distribution  $g(H_C)$ and the interaction field distribution  $f(H_U)$ . In a simple visualization, when the ideal SD grain in Figure F2a is affected by magnetic interactions,  $H_{\rm I}$  will shift the switching field (Figure F5a). This asymmetry between the forward and backward switching fields gives rise to spreading in the  $H_{\rm U}$  direction on a FORC diagram (Figure F5b). Micromagnetic models for FORC diagrams have shown that Néel's (1954) approximation is correct for moderately interacting systems, but that it breaks down when the grains are separated by less than a grain width (Muxworthy et al., 2004). Highly interacting systems produce FORC diagrams that appear to be essentially the same as those for MD grains (see below and compare Figure F5 with Pike et al., 2001a).

#### MD and pseudosingle domain grains

FORC diagrams for large MD grains (Pike *et al.*, 2001a) produce a series of contours that run parallel or nearly parallel to the  $H_{\rm U}$  axis (Figure F6a). This spreading of the FORC distribution is essentially the same as for interacting SD grains; instead of the spreading being due to inter-grain magnetostatic interaction fields, it is due to internal demagnetizing fields. Pseudo-single domain (PSD) grains display behavior intermediate between true MD and true SD behavior (Figure F6b). That is, they display both the closed peak structures observed for SD grains and the more open contours that become increasingly parallel to the  $H_{\rm U}$  axis with coarser grain sizes (Roberts *et al.*, 2000).

#### Superparamagnetic behavior

Superparamagnetic (SP) grains will only manifest themselves on the FORC diagram if their relaxation time is of the same order as the averaging time (Roberts *et al.*, 2000; Pike *et al.*, 2001b). If the grains have shorter relaxation times, i.e.,  $H_{\rm SW} \rightarrow 0$ , then  $\rho(H_{\rm A}, H_{\rm B}) = 0$  at all values. SP grains with relaxation times of ~0.1–0.25 s have FORC diagrams similar to those for MD grains, i.e.,  $\rho(H_{\rm A}, H_{\rm B})$  plots as a

**Figure F3** FORCs and FORC diagram for a numerical model of 1000 identical noninteracting SD grains with randomly distributed uniaxial anisotropy (modified after Muxworthy *et al.* (2004)). The origins of the negative and positive regions in the FORC diagram are highlighted (SF = 4). The negative region is due to a decrease in  $\partial M/\partial H_B$  with decreasing  $H_A$  for negative values of  $H_B$  ( $H_{B_1}$ ). The large positive peak is associated with the increase in  $\partial M/\partial H_B$  with decreasing  $H_A$  for positive values of  $H_B$ , near the switching field ( $H_{B_2}$ ). The different return paths give rise to the positive region of the FORC distribution to the right of the main peak as illustrated.

**Figure F4** FORC diagram (SF = 3; averaging time = 0.15 s) for an assemblage of noninteracting ideal SD grains for a tuff sample from Yucca Mountain, Nevada (from Roberts *et al.* (2000)).

**Figure F5** (a) Schematic diagram depicting the effect of a local interaction field  $H_1$  on a square hysteresis loop for an ideal SD particle, with uniaxial anisotropy, aligned along the direction of the applied field, as shown in Figure F2a. (b) Numerical simulation for an assemblage of 1000 evenly spaced, magnetite-like ideal SD grains with oriented uniaxial anisotropy. The distance between grain is 1.5 times the grains size.

series of contours running almost parallel to the  $H_U$  axis (Figure F6c). Although SP behavior may initially seem similar to MD behavior, the coercivity spectra of MD and SP samples and the shapes of the FORC distributions can be visually distinguished (Figure F6a,c). Cooling a sample by a few degrees can also easily enable identification of thermal relaxation. Due to the exponential nature of SD relaxation times, small temperature variations are sufficient to increase relaxation times, which effectively make the grains thermally stable on the time scale of a measurement. Upon cooling, the FORC diagram for a SP sample would then resemble that of a stable SD sample (cf. Figure F4). In contrast, FORC diagrams for MD samples would not display such variations with temperature.

#### Further features of FORC diagrams

#### The $H_{\cup}$ axis

Due to the use of the local grid when calculating a FORC diagram for any value of SF, it is necessary to fit the polynomial surface using points outside the plotted FORC diagram. For the upper, lower, and right-hand bounds of the FORC diagram, this is readily achievable by simply measuring extra data points. For the  $H_{\rm U}$  axis, however, this is not possible. This means that points on the  $H_{\rm U}$  axis are not directly

**Figure F6** (a) FORC diagram (SF = 4; averaging time = 0.2 s) for a MD magnetite sample (mean grain size of 76  $\mu$ m). (b) FORC diagram (SF = 3; averaging time = 0.15 s) for a PSD magnetite sample (mean grain size of 1.7  $\mu$ m). (c) FORC diagram (SF = 3; averaging time = 0.2 s) for tuff sample CS014 from Yucca Mountain, Nevada, containing SP magnetite (from Roberts *et al.* (2000)).

**Figure F7** Illustration of three methods for fitting a FORC diagram. (a) A "truncated" FORC diagram, with no extrapolation of data onto the  $H_{U}$  axis; (b) a "relaxed-fit" FORC diagram with extrapolation onto the  $H_{U}$  axis; and (c) "reversible-ridge" fitting (following Pike, 2003). The sample is a PSD magnetite (mean grain size of 0.3 µm; SF = 4; averaging time = 0.1s).

measured, and there will be a gap of size 2SF+1 multiplied by the field spacing between  $\rho(H_A, H_B)$  and the  $H_U$  axis on the FORC diagram. Three approaches have been made to deal with this problem.

- Do not plot the FORC distribution for the region where the polynomial cannot be rigorously calculated. This results in a "truncated" FORC diagram (Figure F7a).
- 2. Relax the calculation of  $\rho(H_A, H_B)$  back on to the  $H_U$  axis by reducing the smoothing near the  $H_U$  axis. Such "relaxed fit" diagrams (Figure F7b) will produce distortions, which can give misleading results if the field step size is too large, but they have the advantage that it is at least possible to observe low coercivity magnetization components. Such components are usually important in natural samples, so relaxing the fit is considered by some workers to be preferable to truncation.
- Reversible-ridge method (Figure F7c) (Pike, 2003). This approach, which has been developed from Preisach theory, accommodates the reversible component of the magnetization data in addition to

the irreversible part. With this approach, FORCs are extrapolated beyond  $H_A < 0$ , which enables rigorous calculation of  $\rho(H_A, H_B)$  back on to the  $H_U$  axis. For SD assemblages this approach can be successful, however, for natural samples containing PSD or MD material the reversible ridge can often swamp the signal from the irreversible component of magnetization.

#### Asymmetry of FORC diagrams

The FORC method is a highly asymmetric method of measuring a Preisach diagram. The asymmetry originates from the measurement method in which each FORC starts from a saturated state. In interacting SD and MD systems, this means that there is bias in the magnetostatic interaction and internal demagnetizing fields in the direction of  $H_{\text{SAT}}$ . The only FORCs that do not contain a history of the initial  $H_{\text{SAT}}$ state are those that start from a sufficiently large negative  $H_A$  value that saturates the sample in the opposite direction. Asymmetry is therefore inherent to FORC diagrams.

**Figure F8** (a) Major hysteresis loop and (b) FORC diagram for a sample containing PSD magnetite and PSD hematite in a ratio of 81:19. On the FORC diagram, the hematite is readily identified, but it is not evident in the major hysteresis loop (SF = 3; averaging time = 0.15 s).

#### Applications of the FORC diagram

FORC diagrams provide much more detailed information about magnetic assemblages than standard hysteresis measurements. Thermal relaxation, variations in domain state, and magnetostatic interactions all produce characteristic and distinct manifestations on a FORC diagram. Here we illustrate four applications of FORC diagrams in paleomagnetic and environmental magnetic studies.

- 1. Unraveling mixed magnetic assemblages. A key problem in many paleomagnetic and environmental studies is identifying and isolating specific minerals and/or grain size distributions within a sample. This can be difficult in mixed samples if the signal from one mineral is magnetically swamped by that of another mineral. FORC diagrams have been shown to be successful at identifying magnetic signals due to minerals with low intrinsic magnetizations when they are present along with more strongly magnetic minerals (Roberts et al., 2000; Muxworthy et al., 2005). For example, consider a mixture of PSD magnetite and PSD hematite. The hysteresis loop in Figure F8a provides no evidence for the presence of hematite, whereas in the FORC diagram the presence of hematite is clearly visible by the high-coercivity component that extends to high values of  $H_{\rm C}$  (Figure F8b). Although the FORC diagram is more successful than standard magnetic hysteresis measurements at identifying weaker magnetic phases in mixtures with more strongly magnetic phases, there are still concentration thresholds beyond which the magnetic signal of the strongly magnetic phase dominates and the weakly magnetic phase is no longer detectable in FORC diagrams (Muxworthy et al., 2005). In such cases, other magnetic methods may be more suitable than FORC analysis. For example, in mixtures of MD magnetite and hematite, low-temperature techniques can be more sensitive than FORC diagrams at identifying hematite in the presence of magnetite.
- 2. Source discrimination. Due to the detailed nature of FORC diagrams, they can be used to identify subtle differences between source materials that are not so readily observed using magnetic hysteresis data. For example, in a study of a loess/paleosol sequence from Moravia, two different source materials could be clearly distinguished and identified using FORC diagrams (van Oorschot *et al.*, 2002). There are many other apparent uses of FORC diagrams in environmental magnetic applications.
- Assessing leaching. Sequential leaching techniques are commonly used by soil chemists to remove iron oxides from samples to facilitate clay mineral analysis. FORC analysis has been shown to help in elucidation of the leaching process where magnetic hysteresis alone was less diagnostic (Roberts *et al.*, 2000).

4. Pre-selection for paleointensity studies. In absolute paleointensity studies, SD assemblages should provide reliable results, while samples with strong magnetostatic interactions and/or MD grains should yield unacceptable results. Domain state and magnetostatic interactions are both readily identifiable on a FORC diagram, which should make them useful for sample screening and selection for absolute paleointensity studies. Likewise, strict criteria apply to the mineralogy, domain state, and concentration of magnetic particles in sedimentary sequences in terms of their suitability for relative paleointensity studies. FORC diagrams therefore also have potential for screening sediments for relative paleointensity studies.

Rock Magnetism, Hysteresis Measurements

# FISHER STATISTICS

When describing the dispersion of paleomagnetic directions about some mean direction it is a standard practice within paleomagnetism to employ Fisher (1953) statistics. The theory of Fisher statistics assumes a mean direction, defined by a Cartesian unit vector  $\hat{\mathbf{x}}_{\mu}$ , and data, each defined by Cartesian unit vectors  $\hat{\mathbf{x}}$ . The off-axis angle  $\theta$ between the mean direction and a datum is defined by

$$\cos\theta = \hat{\mathbf{x}} \cdot \hat{\mathbf{x}}_{\mu}. \tag{Eq. 1}$$

With this, then, the Fisher distribution gives the probability that a particular directional datum  $\hat{\mathbf{x}}$  falls between  $\theta$  and  $\theta + d\theta$  as

$$P_f(\theta|\kappa) = \int_{\theta}^{\theta+d\theta} p_f(\theta'|\kappa) d\theta', \qquad (Eq. 2)$$

where the probability-density function is

$$p_f(\theta|\kappa) = \frac{\kappa}{2\sinh\kappa} \sin\theta \,\exp(\kappa\cos\theta), \qquad (\text{Eq. 3})$$

and where  $\kappa$  is a parameter that measures the directional dispersion of the data about the mean direction. If one considers the dispersion of directions over the unit sphere, then the probability of particular a datum falling onto a unit differential area

$$dA = \sin\theta d\theta d\phi, \tag{Eq. 4}$$

where  $\phi$  is the azimuthal angle symmetrically-distributed about  $\hat{x}_{\mu}$ , is just

$$P_f(A|\kappa) = \int_{\phi}^{\phi+d\phi} \int_{\theta}^{\theta+d\theta} p_f(A'|\kappa) \sin \theta' d\theta' d\phi', \qquad (Eq. 5)$$

where the corresponding density function is

$$p_f(A|\kappa) = \frac{\kappa}{4\pi\sinh\kappa} \exp(\kappa\cos\theta).$$
 (Eq. 6)

As with all probability-density functions, that a particular datum is realized is certain, we are, after all, describing data that exist, and therefore

$$\int_0^{\pi} p_f(\theta'|\kappa) \mathrm{d}\theta' = \int_0^{2\pi} \int_0^{\pi} p_f(A'|\kappa) \sin \theta' \mathrm{d}\theta' \mathrm{d}\phi' = 1. \quad \text{(Eq. 7)}$$

In Figure F9 we show examples of the Fisher density function.

# Application

Let us consider now a set of paleomagnetic data, with the *i*th paleomagnetic direction  $\hat{\mathbf{x}}_i$  defined by an inclination-declination pair  $(I_i, D_i)$ , such that the Cartesian components are

$$x_i = \cos I_i \cos D_i, \quad y_i = \cos I_i \sin D_i, \quad z_i = \sin I_i.$$
 (Eq. 8)

The mean unit direction  $\bar{\mathbf{x}}$  given by N data is

$$\bar{x} = \frac{1}{R} \sum_{i=1}^{N} x_i, \quad \bar{y} = \frac{1}{R} \sum_{i=1}^{N} y_i, \quad \bar{z} = \frac{1}{R} \sum_{i=1}^{N} z_i,$$
 (Eq. 9)

where

$$R^{2} = \left(\sum_{i=1}^{N} x_{i}\right)^{2} + \left(\sum_{i=1}^{N} y_{i}\right)^{2} + \left(\sum_{i=1}^{N} z_{i}\right)^{2}.$$
 (Eq. 10)

The mean vector  $\bar{\mathbf{x}}$  is an estimate of the true mean  $\hat{\mathbf{x}}_{\mu}$  corresponding to the underlying distribution  $p_{f_2}$  and with this estimated mean direction we can measure the off-axis angle  $\theta_i$  of each datum, where

$$\cos \theta_i = \bar{\mathbf{x}} \cdot \hat{\mathbf{x}}_i. \tag{Eq. 11}$$

**Figure F9** Examples of the Fisher probability-density function  $p_f(\theta)$  for a variety of  $\kappa$  dispersion parameters: 1, 4, 16, 64. Note that as  $\kappa$  is increased the dispersion decreases.

**Figure F10** Comparison of a Fisher distribution fit to a histogram of Réunion data recording secular variation during the Brunhes.

The precision parameter  $\kappa$  is given approximately by (McFadden, 1980):

$$\kappa = \frac{N-1}{N-R},\tag{Eq. 12}$$

As  $R \to N$  the precision parameter  $\kappa$  increases, and the distribution of directions becomes more tightly clustered about the mean direction.

As an example of a fit of the Fisher distribution to real data, in Figure F10 we show a histogram of off-axis angles corresponding to a compilation of Brunhes-age paleomagnetic data collected at or near the island of Réunion (Love and Constable, 2003). Note that the Fisher distribution fitted using the procedure outlined here captures most of the actual distribution of the data, but that the fit is also not perfect. Indeed, although the Fisher distribution is often used in paleomagnetism, only rarely does paleaomagnetic data actually show a strict Fisher distribution. Both the secular variation of the geomagnetic field and the process by which rocks obtain their paleomagnetic signatures are extremely complicated, and it is, therefore, not too surprising that there is some misfit to a Fisher distribution. Although the Fisher distribution does arise from first principles in the context of the Langevin theory of paramagnetism, more generally, there often is very little reason to expect a set of paleomagnetic data to exhibit perfect Fisher statistics. The real utility of the Fisher distribution comes as a benchmark for comparison, the deviation from its relatively simple mathematical form that is of interest. Further review material on Fisher statistics can be found in the books by Butler (1992) and Tauxe (1998).

Magnetization, Natural Remanent (NRM) Paleomagnetic Secular Variation Statistical Methods for Paleovector Analysis

# FLEMING, JOHN ADAM (1877–1956)

Few individuals influenced geophysics in the 20th century more profoundly than John A. Fleming (Figure F11): geophysicist, engineer, scientific organizer, and administrator. He devoted his life to promoting the study of geomagnetism and building its professional organizations, and played a leading role in organizing magnetic and electric surveys of the Earth during the first half of the 20th century. Yet, as *Sydney Chapman* (q.v.) wrote of him, "He was so self-effacing that only those who knew and worked with him can properly assess... what he did for geophysics in USA and in the world at large" (Chapman, 1957).

Fleming was born in Cincinnati, Ohio on January 28, 1877. Educated as a civil engineer at the University of Cincinnati (1895–1899), he worked briefly in construction after receiving his B.S. degree, then joined the U.S. Coast and Geodetic Survey's Division of Terrestrial Magnetism. He advanced steadily at the Survey from 1899 to 1903 and was involved with the planning and construction of magnetic observatories in Alaska, Hawaii, and Maryland. In 1904, he was appointed "Chief Magnetician" at the newly established *Department of Terrestrial Magnetism* (DTM, q.v.) of the Carnegie Institution of Washington. He would be associated with the Institution for the next 50 years.

Figure F11 John Adam Fleming (*photograph:* Carnegie Institution, Department of Terrestrial Magnetism).

Working under the direction of DTM's founder, *Louis A. Bauer* (q.v.) (with whom he had previously worked at the Coast and Geodetic Survey), Fleming proved himself an able manager of DTM's world magnetic survey—a far-flung enterprise of overland magnetic expeditions and ocean research vessels. He developed new and improved magnetic instruments for use on land and at sea, and made important contributions to establishing and maintaining the world's magnetic standards. He designed the department's geophysical observatories at Huancayo, Peru and Watheroo, Australia. Appointed acting director in 1929, he ran the department for several years during Bauer's incapacitation and after his death. In 1935, bolstered by honorary degrees from the University of Cincinnati (D.Sc., 1933) and Dartmouth College (D.Sc., 1934), Fleming was finally named director of DTM.

Fleming substantially broadened DTM's focus to include studies of the ionosphere, cosmic rays, Earth currents, physical oceanography, marine biology, and atomic physics. He was instrumental in initiating in 1935 the highly productive Washington Conferences on Theoretical Physics. In 1941, in conjunction with the University of Alaska, he established a cooperative research facility for arctic geophysics (College Observatory) in Fairbanks—then later helped lobby successfully for creation of the Geophysical Institute there. During World War II, Fleming oversaw all of DTM's defense contracts, ranging from radio propagation predictions for the armed forces to the development of magnetic compasses and odographs.

E.H. Vestine observed that Fleming possessed "a most unusual gift in judging the future possibilities and capabilities of the young men he brought to DTM" (Vestine, 1956, p. 532). Among these were staff members Merle Tuve, Lloyd Berkner, and Scott Forbush; research associates Julius Bartels and Sydney Chapman; and the department's first postdoctoral fellows, among them James Van Allen.

In addition to authoring more than 130 papers, primarily on magnetic surveys and secular variation, Fleming was a dedicated editor. (A bibliography of Fleming's work was published by Tuve in 1967.) He edited and published the journal Terrestrial Magnetism and Atmospheric Electricity-the forerunner of the Journal of Geophysical Researchfor two decades (1928-1948). He contributed to, and edited, an encyclopedic volume on Terrestrial Magnetism and Electricity (1939) in the National Research Council's landmark "Physics of the Earth" series. But Fleming's most enduring legacy was probably as an organizer and administrator of geophysics. In the 1890s Bauer had begun a crusade to professionalize the study of geomagnetism and to set it on an equal footing with established disciplines such as astronomy and meteorology (Good, 1994). Fleming shared Bauer's zeal, and as General Secretary of the American Geophysical Union (AGU) from 1925 to 1947 he devoted himself tirelessly to fostering the community of geophysicists. In the days before AGU had paid administrative staff, Fleming contributed long hours in correspondence, organizing meetings, and editing thousands of pages of the AGU Transactions, with only a clerical assistant or two.

In 1941 he was awarded the William Bowie Medal, AGU's highest honor, and when he stepped down as general secretary he was elected "honorary president" (a title created for him) for life. Other noteworthy leadership positions of Fleming's included the presidency of the Association of Terrestrial Magnetism and Electricity (now the *International Association of Geomagnetism and Aeronomy*, *q.v.*) of the International Union of Geodesy and Geophysics (1930–1948), and of the International Council of Scientific Unions (1946–1949). He was a member of the National Academy of Sciences as well as numerous foreign academies and learned societies. In 1945 the Physical Society (London) honored him with its Charles Chree Medal and Prize.

In 1946 Fleming retired from DTM, but continued to serve the Carnegie Institution as Adviser in International Scientific Relations until 1954. His last major project consisted of chronicling the origin and development of the AGU in characteristically detailed and quantitative fashion.

Fleming died in San Mateo, California on July 29, 1956. The AGU posthumously established the John Adam Fleming Medal in his honor.

The medal recognizes original research and technical leadership in geomagnetism, atmospheric electricity, aeronomy, space physics, and related sciences. Fleming's colleagues considered him modest, supportive, and scientifically broad-minded, but also demanding, strict, and strong-willed —"a man of enormous energy with a most notable capacity for getting things done. His work was his life and his hobby, but above all he enjoyed companionship and discussions with his many friends and colleagues" (Vestine, 1956, p. 532).

# FLUID DYNAMICS EXPERIMENTS

Over the last half century, fluid dynamics experiments have provided researchers with a means of simulating processes relevant to planetary cores. These experiments utilize actual fluids, such as water and liquid metals, to replicate various aspects of core flows, including rotating convection, rotating magnetoconvection, precession, and dynamo generation (Nataf, 2003). In comparison to numerical simulations, laboratory experiments can presently simulate conditions that are closer to those in planetary cores. In addition, experiments can contain smallscale flow structures that are not resolved in numerical models. Thus, experimental studies supply results that are essential for improving our understanding of planetary core dynamics and dynamo action.

In a planetary dynamo, kinetic energy of iron-rich core fluid motions is converted into large-scale magnetic field energy. On the basis of the assumption that buoyancy driven motions dominate precessionally driven motions in Earth's core (see *Precession and core dynamics*), the majority of investigations have focused on understanding how core convection can generate dynamo action. Thus, most laboratory research has recently followed two main tacks: buoyancydriven convection experiments and mechanically driven dynamo experiments. These approaches provide distinct but complementary ways of studying core processes. The mechanically driven dynamo experiments impose a strong velocity field in order to produce dynamo-generated magnetic fields (see *Dynamos, experimental*). These mechanically forced flows, which are typically driven by pumps or rapidly rotating impellers, may not be realistic analogs to flows in planetary cores. Yet in successful experiments where dynamo generation occurs, the results provide an excellent opportunity to study flows that generate dynamo action and the process by which dynamo-generated magnetic fields equilibrate (see *Dynamo, Gailitis*).

In contrast, buoyancy-driven experiments study the fundamental dynamics and characteristics of core-type flows. Because the laboratory convective flows are far less energetic than flows in the mechanically-driven experiments, the magnetic Reynolds number, which is the ratio of magnetic induction to diffusion, is small. Thus, convection-driven induction processes are weak, and dynamo action cannot be achieved in such experiments. However, these experiments are critical for simulating the details of planetary *core convection* (q.v.).

In addition to buoyancy forces, core flows are also strongly affected by Coriolis forces, due to planetary rotation, and Lorentz forces, due to planetary magnetic fields. The Elsasser number,  $\Lambda$ , is the ratio of Lorentz and Coriolis forces. In cases where  $\Lambda \ll 1$ , Coriolis forces dominate the Lorentz forces and the rotationally constrained fluid motions tend to become two-dimensional along the direction of the rotation axis (see Proudman-Taylor theorem). From planetary magnetic field observations, including that of the Earth,  $\Lambda$  is estimated to be O(1) (see Dynamos, planetary and satellite). However, numerical simulations of magnetoconvection and dynamo action have found that fluid motions still tend to remain nearly two-dimensional and aligned along the rotation axis for even relatively large Elsasser numbers, i.e.,  $\Lambda \lesssim 10$  (see *Magnetoconvection*). Thus, both rotating convection experiments, in which Lorentz forces are not present, and rotating magnetoconvection experiments in the  $\Lambda \sim 1$  regime can yield critical insights into the dynamics of planetary cores.

#### **Rotating convection experiments**

Rotating convection experiments study fluid motions within a spherical shell that mimics the geometry of the Earth's outer core. In the majority of these devices the outer spherical shell, which simulates the Earth's core-mantle boundary, is made of a transparent plastic such as polycarbonate and has a typical radius measuring between 5 and 15 cm. This allows for visualization studies of the convection pattern in transparent fluids like water. By rapidly rotating the shell, a centrifugal acceleration is produced that acts as an effective gravity within the fluid. This centrifugal gravity varies linearly with cylindrical radius, similarly to gravity within a planetary core. However, it points outward, opposite to the direction of a planet's gravity. In order to account for this reversal in gravity's direction, the inner spherical shell, which represents the Earth's inner core boundary, must be held at a lower temperature than the outer shell for thermal convection to occur. Because the direction of gravity and the sign of the temperature difference across the shell are both reversed, the buoyancy forces in the experiment act in the same way as in a planetary core.

The first such experiments studied flows near the onset of nonmagnetic rotating convection (q.v.) in spherical shells (Busse and Carrigan, 1976). These studies showed that convective motions first manifest as thin cylindrical columns aligned parallel to the axis of rotation (Figure F12a). The two-dimensionality of the flow demonstrates the applicability of the Proudman-Taylor theorem. Further experiments studied stronger convection occurring at higher rotation rates (Cardin and Olson, 1994). In such studies, it was found that strong thermal or compositional buoyancy forces drive fluid motions on columnar structures that fill the entire volume of the spherical shell (Figure F12b). It was also determined that the typical width of the convection columns decreases with the shell's rate of rotation. Sumita and Olson (2000) carried out rotating convection experiments using even stronger thermal buoyancy forces, and found that the convective motions occurred on thin two-dimensional sheets that stretch between the inner and outer spherical boundaries (Figure F12c). Retrograde azimuthal zonal flows were also found to develop in the vast majority of these studies (Aubert et al., 2001; Aurnou et al., 2003; Shew and Lathrop, 2005). Numerical simulations (q.v.) verify that

**Figure F12** (a) Sideview of the onset of rotating spherical shell convection. Adapted from Busse and Carrigan (1976). (b) Sideview of moderately supercritical rotating spherical shell convection showing convection columns filling the entire shell volume. Adapted from Cardin and Olson (1992). the well-organized columnar motions and the large-scale zonal flows that are inherent in rotating convection are important components in generating dynamo action.

Recent rotating convection experiments have employed ultrasonic Doppler velocimetry techniques to make precise, quantitative flow velocity measurements (Aubert *et al.*, 2001). They have produced velocity scaling laws as a function of thermal forcing and shell rotation rate, using water and low viscosity liquid gallium as working fluids. Using the same experimental device, Brito *et al.* (2004) have been able to measure changes in water's effective viscosity in a set of turbulent rotating convection experiments. These studies demonstrate how improved experimental diagnostics allow characterizations of the detailed flow properties that are crucial for parametrization and better understanding of core processes. 276

#### **Rotating magnetohydrodynamics experiments**

Rotating magnetoconvection experiments more accurately simulate planetary core physics than rotating convection experiments because they include Lorentz forces, in addition to buoyancy and Coriolis forces. These experiments use liquid metals, such as liquid sodium, liquid gallium, or mercury, as their working fluids in order to simulate the physical properties of the metallic alloys in planetary cores. Until recently, diagnostic techniques were unable to determine flow fields in the opaque liquid metals. Indeed, the paucity of meaningful diagnostics has led to few experimental studies of flows in liquid metals.

Rotating magnetoconvection experiments were first made by Y. Nakagawa (1957, 1958). His experiments studied the onset of thermal convection in a cylindrical, plane layer of liquid mercury subject to a vertical magnetic field and rotation around a vertical rotation axis. These experiments showed that for large rotation rates and magnetic field strengths, thermal convection is facilitated in the  $\Lambda \sim 1$  regime, in agreement with the linear stability analysis of S. Chandrasekhar (1961). In experiments with the top lid removed from the convection tank, Nakagawa (1957; 1958) determined the characteristic length scale of the convective motions by observing the motions of sand particles on the surface of the mercury. These observations showed an increase in convective length scale in the  $\Lambda \sim 1$  regime, which roughly agree with the predictions of linear stability analysis.

More recently, Aurnou and Olson (2001) studied supercritical heat transfer in rotating magnetoconvection experiments in the  $\Lambda \sim 1$  regime but with weaker magnetic fields and rotation rates than in Nakagawa's experiments. For the less extreme parameter values that they investigated, thermal turbulence marked the onset of convection in all their experiments, while no increase in convective heat transfer was measured in the  $\Lambda \sim 1$  regime. The difference between their results and Nakagawa's can be explained by the fact that convection is only facilitated in the  $\Lambda \sim 1$  regime for sufficiently large magnetic field strengths and rotation rates.

The next generation of rotating *magnetoconvection* and *magnetohy-drodynamics* (*q.v.*) experiments will employ the acoustic Doppler techniques that have proven so successful in the studies of Aubert *et al.* (2001) and Brito *et al.* (2004). Such experiments will allow investigators to determine flow patterns, scaling laws and small-scale flow characteristics for convection in liquid metals subject to strong rotational and magnetic forces, as occurs within planetary cores. With experimental information regarding the behavior of small-scale flows (see *Core turbulence*), it may soon be possible for laboratory studies to provide detailed parametrizations of subgrid-scale motions for future numerical models of planetary dynamos.

# GALVANIC DISTORTION

The electrical conductivity of Earth materials affects two physical processes: electromagnetic induction which is utilized with *magneto-tellurics* (MT) (q.v.), and electrical conduction. If electromagnetic induction in media which are heterogeneous with respect to their electrical conductivity is considered, then both processes take place simultaneously: Due to Faraday's law, a variational electric field is induced in the Earth, and due to the conductivity of the subsoil an electric current flows as a consequence of the electric field. The current component normal to boundaries within the heterogeneous structure passes these boundaries continously according to

$$\sigma_1 E_1 = \sigma_2 E_2$$

where the subscripts 1 and 2 indicate the boundary values of conductivity and electric field in regions 1 and 2, respectively. Therefore the amplitude and the direction of the electric field are changed in the vicinity of the boundaries (Figure G1). In electromagnetic induction studies, the totality of these changes in comparison with the electric field distribution in homogeneous media is referred to as galvanic distortion.

The electrical conductivity of Earth materials spans 13 orders of magnitude (e.g., dry crystalline rocks can have conductivities of less than  $10^{-6}$  S m<sup>-1</sup>, while ores can have conductivities exceeding  $10^{6}$  S m<sup>-1</sup>). Therefore, MT has a potential for producing well constrained models of the Earth's electrical conductivity structure, but almost all field studies are affected by the phenomenon of galvanic distortion, and sophisticated techniques have been developed for dealing with it (Simpson and Bahr, 2005).

#### Electric field amplitude changes and static shift

A change in an electric field amplitude causes a frequency-independent offset in *apparent resistivity* curves so that they plot parallel to their true level, but are scaled by a real factor. Because this shift can be regarded as spatial undersampling or "aliasing," the scaling factor or *static shift factor* cannot be determined directly from MT data recorded at a single site. If MT data are interpreted via onedimensional modeling without correcting for static shift, the depth to a conductive body will be shifted by the square root of the factor by which the apparent resistivities are shifted.

Static shift corrections may be classified into three broad groups:

 Short period corrections relying on active near-surface measurements such as transient electromagnetic sounding (TEM) (e.g., Meju, 1996).

- Averaging (statistical) techniques. As an example, electromagnetic array profiling is an adaptation of the magnetotelluric technique that involves sampling lateral variations in the electric field continuously, and spatial low pass filtering can be used to suppress static shift effects (Torres-Verdin and Bostick, 1992).
- 3. Long period corrections relying on assumed deep structure (e.g., a resistivity drop at the mid-mantle transition zones) or long-period magnetic *transfer functions* (Schmucker, 1973). An equivalence relationship exists between the magnetotelluric impedance Z and Schmucker's *C*-response:

$$C = \frac{Z}{\mathrm{i}\omega\mu_0},$$

which can be determined from the magnetic fields alone, thereby providing an *inductive scale length* that is independent of the distorted electric field. Magnetic *transfer functions* can, for example, be derived from the magnetic daily variation.

The appropriate method for correcting static shift often depends on the target depth, because there can be a continuum of distortion at all scales. As an example, in complex three-dimensional environments near-surface correction techniques may be inadequate if the conductivity of the mantle is considered, because electrical heterogeneity in the deep crust creates additional galvanic distortion at a larger-scale, which is not resolved with near-surface measurements (e.g., Simpson and Bahr, 2005).

# Changes in the direction of electric fields and mixing of polarizations

In some target areas of the MT method the conductivity distribution is two-dimensional (e.g., in the case of *electrical anisotropy* (q.v.)) and the induction process can be described by two decoupled polarizations of the electromagnetic field (e.g., Simpson and Bahr, 2005). Then, the changes in the direction of electric fields that are associated with galvanic distortion can result in mixing of these two polarizations. The recovery of the undistorted electromagnetic field is referred to as magnetotelluric tensor decomposition (e.g., Bahr, 1988, Groom and Bailey, 1989).

#### Current channeling and the "magnetic" distortion

In the case of extreme conductivity contrasts the electrical current can be channeled in such way that it is surrounded by a magnetic

**Figure G1** Amplitude and direction of the electric field outside and inside a conductivity anomaly with a conductivity contrast  $\sigma_1 : \sigma_2 = 10$  between the anomaly and the host medium.

variational field that has, opposite to the assumptions made in the *geomagnetic deep sounding* (q.v.) method, no phase lag with respect to the electric field. The occurrence of such magnetic fields in field data has been shown by Zhang *et al.* (1993) and Ritter and Banks (1998). An example of a magnetotelluric tensor decomposition that includes magnetic distortion has been presented by Chave and Smith (1994).

# GAUSS' DETERMINATION OF ABSOLUTE INTENSITY

The concept of magnetic intensity was known as early as 1600 in *De Magnete* (see *Gilbert, William*). The *relative* intensity of the geomagnetic field in different locations could be measured with some precision from the rate of oscillation of a dip needle—a method used by *Humboldt, Alexander von* (q.v.) in South America in 1798. But it was not until Gauss became interested in a universal system of units that the idea of measuring *absolute* intensity, in terms of units of mass, length, and time, was considered. It is now difficult to imagine how revolutionary was the idea that something as subtle as magnetism could be measured in such mundane units.

On 18 February 1832, *Gauss, Carl Friedrich (q.v.)* wrote to the German astronomer Olbers:

"I occupy myself now with the Earth's magnetism, particularly with an *absolute* determination of its intensity. Friend Weber" (Wilhelm Weber, Professor of Physics at the University of Göttingen) "conducts the experiments on my instructions. As, for example, a clear concept of velocity can be given only through statements on time *and* space, so in my opinion, the complete determination of the intensity of the Earth's magnetism requires to specify (1) a weight = p, (2) a length = r, and then the Earth's magnetism can be expressed by  $\sqrt{p/r}$ ."

After minor adjustment to the units, the experiment was completed in May 1832, when the horizontal intensity (*H*) at Göttingen was found to be  $1.7820 \text{ mg}^{1/2} \text{ mm}^{-1/2} \text{ s}^{-1}$  (17820 nT).

### The experiment

The experiment was in two parts. In the vibration experiment (Figure G2) magnet A was set oscillating in a horizontal plane by deflecting it from magnetic north. The period of oscillations was determined at different small amplitudes, and from these the period  $t_0$  of infinite-simal oscillations was deduced. This gave a measure of *MH*, where *M* denotes the magnetic moment of magnet A:

 $MH = 4\pi^2 I/t_0^2$ 

The moment of inertia, *I*, of the oscillating part is difficult to determine directly, so Gauss used the ingenious idea of conducting the

**Figure G2** The vibration experiment. Magnet A is suspended from a silk fiber F It is set swinging horizontally and the period of an oscillation is obtained by timing an integral number of swings with clock C, using telescope T to observe the scale S reflected in mirror M. The moment of inertia of the oscillating part can be changed by a known amount by hanging weights W from the rod R.

**Figure G3** The deflection experiment. Suspended magnet B is deflected from magnetic north by placing magnet A east or west (magnetic) of it at a known distance *d*. The angle of deflection  $\theta$  is measured by using telescope T to observe the scale S reflected in mirror M.

experiment for *I* and then  $I + \Delta I$ , where  $\Delta I$  is a known increment obtained by hanging weights at a known distance from the suspension. From several measures of  $t_0$  with different values of  $\Delta I$ , *I* was determined by the method of least squares (another of Gauss's original methods).

In the deflection experiment, magnet A was removed from the suspension and replaced with magnet B. The ratio M/H was measured by the deflection of magnet B from magnetic north,  $\theta$ , produced by magnet A when placed in the same horizontal plane as B at distance d magnetic east (or west) of the suspension (Figure G3). This required knowledge of the magnetic intensity due to a bar magnet. Gauss deduced that the intensity at distance d on the axis of a dipole is inversely proportional to  $d^3$ , but that just one additional term is required to allow for the finite length of the magnet, giving  $2M (1 + k/d^2)/d^3$ , where k denotes a small constant. Then

$$M/H = 1/2 d^3 (1 - k/d^2) \tan \theta.$$

The value of k was determined, again by the method of least squares, from the results of a number of measures of  $\theta$  at different d.

From MH and M/H both M and, as required by Gauss, H could readily be deduced.

#### **Present methods**

With remarkably little modification, Gauss's experiment was developed into the Kew magnetometer, which remained the standard means of determining absolute H until electrical methods were introduced in the 1920s. At some observatories, Kew magnetometers were still in use in the 1980s. Nowadays absolute intensity can be measured in seconds with a proton magnetometer and without the considerable time and experimental skill required by Gauss's method.

Gauss, Carl Friedrich (1777–1855) Geomagnetism, History of Gilbert, William (1544–1603) Humboldt, Alexander von (1759–1859) Instrumentation, History of

# GAUSS, CARL FRIEDRICH (1777–1855)

Amongst the 19th century scientists working in the field of geomagnetism, Carl Friedrich Gauss was certainly one of the most outstanding contributors, who also made very fundamental contributions to the fields of mathematics, astronomy, and geodetics. Born in April 30, 1777 in Braunschweig (Germany) as the son of a gardener, street butcher, and mason Johann Friderich Carl, as he was named in the certificate of baptism, already in primary school at the age of nine perplexed his teacher J.G. Büttner by his innovative way to sum up the numbers from 1 to 100. Later Gauss used to claim that he learned manipulating numbers earlier than being able to speak. In 1788, Gauss became a pupil at the Catharineum in Braunschweig, where M.C. Bartels (1769–1836) recognized his outstanding mathematical abilities and introduced Gauss to more advanced problems of mathematics. Gauss proved to be an exceptional pupil catching the attention of Duke Carl Wilhelm Ferdinand of Braunschweig who provided Gauss with the necessary financial support to attend the Collegium Carolinum (now the Technical University of Braunschweig) from 1792 to 1795.

From 1795 to 1798 Gauss studied at the University of Göttingen, where his number theoretical studies allowed him to prove in 1796, that the regular 17-gon can be constructed using a pair of compasses and a ruler only. In 1799, he received his doctors degree from the University of Helmstedt (close to Braunschweig; closed 1809 by Napoleon) without any oral examination and *in absentia*. His mentor in Helmstedt was J.F. Pfaff (1765–1825). The thesis submitted was a complete proof of the fundamental theorem of algebra. His studies on number theory published in Latin language as *Disquitiones arithimeticae* in 1801 made Carl Friedrich Gauss immediately one of the leading mathematicians in Europe. Gauss also made further pioneering contributions to complex number theory, elliptical functions, function theory, and noneuclidian geometry. Many of his thoughts have not been published in regular books but can be read in his more than 7000 letters to friends and colleagues.

But Gauss was not only interested in mathematics. On January 1, 1801 the Italian astronomer G. Piazzi (1746–1820) for the first time detected the asteroid Ceres, but lost him again a couple of weeks later. Based on completely new numerical methods, Gauss determined the orbit of Ceres in November 1801, which allowed F.X. von Zach (1754–1832) to redetect Ceres on December 7, 1801. This prediction made Gauss famous next to his mathematical findings.

In 1805, Gauss got married to Johanna Osthoff (1780–1809), who gave birth to two sons, Joseph and Louis, and a daughter, Wilhelmina. In 1810, Gauss married his second wife, Minna Waldeck (1788–1815). They had three more children together, Eugen, Wilhelm, and Therese. Eugen Gauss later became the founder and first president of the First National Bank of St. Charles, Missouri.

Carl Friedrich Gauss' interest in the Earth magnetic field is evident in a letter to his friend Wilhelm Olbers (1781–1862) as early as 1803, when he told Olbers that geomagnetism is a field where still many mathematical studies can be done. He became more engaged in geomagnetism after a meeting with A. von Humboldt (1769–1859) and W.E. Weber (1804–1891) in Berlin in 1828 where von Humboldt pointed out to Gauss the large number of unsolved problems in geomagnetism. When Weber became a professor of physics at the University of Göttingen in 1831, one of the most productive periods in the 280

field of geomagnetism started. In 1832, Gauss and Weber introduced the well-known Gauss system according to which the magnetic field unit was based on the centimeter, the gram, and the second. The Magnetic Observatory of Göttingen was finished in 1833 and its construction became the prototype for many other observatories all over Europe. Gauss and Weber furthermore developed and improved instruments to measure the magnetic field, such as the unifilar and bifilar magnetometer.

Inspired by A. von Humboldt, Gauss and Weber realized that magnetic field measurements need to be done globally with standardized instruments and at agreed times. This led to the foundation of the *Göttinger Magnetische Verein* in 1836, an organization without any formal structure, only devoted to organize magnetic field measurements all over the world. The results of this organization have been published in six volumes as the *Resultate aus den Beobachtungen des Magnetischen Vereins*. The issue of 1838 contains the pioneering work *Allgemeine Theorie des Erdmagnetismus* where Gauss introduced the concept of the spherical harmonic analysis and applied this new tool to magnetic field measurements. His general theory of geomagnetism also allowed to separate the magnetic field into its externally and its internally caused parts. As the external contributions are nowadays interpreted as current systems in the ionosphere and magnetosphere Gauss can also be named the founder of magnetospheric research.

Publication of the *Resultate* ceased in 1843. W.E. Weber together with such eminent professors of the University of Göttingen as Jacob Grimm (1785–1863) and Wilhelm Grimm (1786–1859) had formed the political group *Göttingen Seven* protesting against constitutional violations of King Ernst August of Hannover. As a consequence of these political activities, Weber and his colleagues were dismissed. Though Gauss tried everything to bring back Weber in his position he did not succeed and Weber finally decided to accept a chair at the University of Leipzig in 1843. This finished a most fruitful and remarkable cooperation between two of the most outstanding contributors to geomagnetism in the 19th century. Their heritage was not only the invention of the first telegraph station in 1833, but especially the network of 36 globally operating magnetic observatories.

In his later years Gauss considered to either enter the field of botanics or to learn another language. He decided for the language and started to study Russian, already being in his seventies. At that time he was the only person in Göttingen speaking that language fluently. Furthermore, he was asked by the Senate of the University of Göttingen to reorganize their widow's pension system. This work made him one of the founders of insurance mathematics. In his final years Gauss became fascinated by the newly built railway lines and supported their development using the telegraph idea invented by Weber and himself.

Carl Friedrich Gauss died on February 23, 1855 as a most respected citizen of his town Göttingen. He was a real genius who was named *Princeps mathematicorum* already during his life time, but was also praised for his practical abilities.

# GELLIBRAND, HENRY (1597–1636)

Henry Gellibrand was the eldest son of a physician, also Henry, and was born on 17 November 1597 in the parish of St. Botolph, Aldersgate, London. In 1615, he became a commoner at Trinity College, Oxford, and obtained a BA in 1619 and an MA in 1621. After taking Holy Orders he became curate at Chiddingstone, Kent, but the lectures of Sir Henry Savile inspired him to become a full-time mathematician. He settled in Oxford, where he became friends with Henry Briggs, famed for introducing logarithms to the base 10. It was on Briggs' recommendation that, on the death of Edmund Gunter, Gellibrand succeeded him as Gresham Professor of Astronomy in 1627—a post he held until his death from a fever on 16 February 1636. He was buried at St. Peter the Poor, Broad Street, London (now demolished).

Gellibrand's principal publications were concerned with mathematics (notably the completion of Briggs' *Trigonometrica Britannica* after Briggs died in 1630) and navigation. But he is included here because he is credited with the discovery of geomagnetic secular variation. The events leading to this discovery are as follows (for further details see Malin and Bullard, 1981).

The sequence starts with an observation of magnetic declination made by William Borough, a merchant seaman who rose to "captain general" on the Russian trade route before becoming comptroller of the Queen's Navy. The magnetic observation (Borough, 1581, 1596) was made on 16 October 1580 at Limehouse, London, where he observed the magnetic azimuth of the sun as it rose through seven fixed altitudes in the morning and as it descended through the same altitude gives a measure of magnetic declination, *D*, the mean of which is  $11^{\circ}19' \text{ E} \pm 5'$  rms. Despite the small scatter, the value could have been biased by site or compass errors.

Some 40 years later, Edmund Gunter, distinguished mathematician, Gresham Professor of Astronomy and inventor of the slide rule, found D to be "only 6 gr 15 m" ( $6^{\circ}15'$  E) "as I have sometimes found it of late" (Gunter, 1624, 66). The exact date (ca. 1622) and location (probably Deptford) of the observation are not stated, but it alerted Gunter to the discrepancy with Borough's measurement. To investigate further, Gunter "enquired after the place where Mr. Borough observed, and went to Limehouse with ... a quadrant of three foot Semidiameter, and two Needles, the one above 6 inches, and the other 10 inches long ... towards the night the 13 of June 1622, I made observation in several parts of the ground" (Gunter, 1624, 66). These observations, with a mean of 5°56' E  $\pm$  12' rms, confirmed that D in 1622 was significantly less than had been measured by Borough in 1580. But was this an error in the earlier measure, or, unlikely as it then seemed, was D changing? Unfortunately Gunter died in 1626, before making any further measurements.

When Gellibrand succeeded Gunter as Gresham Professor, all he required to do to confirm a major scientific discovery was to wait a few years and then repeat the Limehouse observation. But he chose instead to go to the site of Gunter's earlier observation in Deptford, where, in June 1633, Gellibrand found *D* to be "much less than 5°" (Gellibrand, 1635, 16). He made a further measurement of *D* on the same site on June 12, 1634 and "found it not much to exceed 4°" (Gellibrand, 1635, 7), the published data giving 4° 5'  $E \pm 4'$  rms. His observation of *D* at Paul's Cray on July 4, 1634 adds little, because it is a new site. On the strength of these observations, he announced his discovery of secular variation (Gellibrand, 1635, 7 and 19), but the reader may decide how much of the credit should go to Gunter.

# **GEOCENTRIC AXIAL DIPOLE HYPOTHESIS**

#### The time-averaged paleomagnetic field

Paleomagnetic studies provide measurements of the direction of the ancient geomagnetic field on the geological timescale. Samples are generally collected at a number of sites, where each site is defined as a single point in time. In most cases the time relationship between the sites is not known, moreover when samples are collected from a stratigraphic sequence the time interval between the levels is also not known. In order to deal with such data, the concept of the timeaveraged paleomagnetic field is used. Hospers (1954) first introduced the geocentric axial dipole hypothesis (GAD) as a means of defining this time-averaged field and as a method for the analysis of paleomagnetic results. The hypothesis states that the paleomagnetic field, when averaged over a sufficient time interval, will conform with the field expected from a geocentric axial dipole. Hospers presumed that a time interval of several thousand years would be sufficient for the purpose of averaging, but many studies now suggest that tens or hundreds of thousand years are generally required to produce a good time-average.

The GAD model is a simple one (Figure G4) in which the geomagnetic and geographic axes and equators coincide. Thus at any point on the surface of the Earth, the time-averaged paleomagnetic latitude  $\lambda$  is equal to the geographic latitude. If *m* is the magnetic moment of this time-averaged geocentric axial dipole and *a* is the radius of the Earth, the horizontal (*H*) and vertical (*Z*) components of the magnetic field at latitude  $\lambda$  are given by

$$H = \frac{\mu_0 m \cos \lambda}{4\pi a^2}, \quad Z = \frac{2\mu_0 m \sin \lambda}{4\pi a^2}, \tag{Eq. 1}$$

and the total field F is given by

$$F = (H^2 + Z^2)^{1/2} = \frac{\mu_0 m}{4\pi a^2} (1 + 3\sin^2 \lambda)^{1/2}.$$
 (Eq. 2)

Since the tangent of the magnetic inclination I is Z/H, then

$$\tan I = 2\tan\lambda,\tag{Eq. 3}$$

and by definition, the declination D is given by

$$D = 0^{\circ}.$$
 (Eq. 4)

The colatitude p (90° minus the latitude) can be obtained from

$$\tan I = 2 \cot p (0 \le p \le 180^{\circ}).$$
 (Eq. 5)

The relationship given in Eq. (3) is fundamental to paleomagnetism and is a direct consequence of the GAD hypothesis. When applied to results from different geologic periods, it enables the paleomagnetic latitude to be derived from the mean inclination. This relationship between latitude and inclination is shown in Figure G5.

Figure G4 The field of a geocentric axial dipole.

**Figure G5** Variation of inclination with latitude for a geocentric dipole.

#### **Paleomagnetic poles**

The position where the time-averaged dipole axis cuts the surface of the Earth is called the *paleomagnetic pole* and is defined on the present latitude-longitude grid. Paleomagnetic poles make it possible to compare results from different observing localities, since such poles should represent the best estimate of the position of the geographic pole. These poles are the most useful parameter derived from the GAD hypothesis. If the paleomagnetic mean direction  $(D_m, I_m)$  is known at some sampling locality S, with latitude and longitude  $(\lambda_s, \phi_s)$ , the coordinates of the paleomagnetic pole P  $(\lambda_p, \phi_p)$  can be calculated from the following equations by reference to Figure G6.

$$\sin \lambda_{\rm p} = \sin \lambda_{\rm s} \cos p + \cos \lambda_{\rm s} \sin p \cos D_{\rm m} \ (-90^{\circ} \le \lambda_{\rm p} \le +90^{\circ})$$
(Eq. 6)

$$\phi_p = \phi_s + \beta$$
, when  $\cos p \le \sin \lambda_s \sin \lambda_p$ 

or

$$b_{\rm p} = \phi_s + 180 - \beta$$
, when  $\cos p \le \sin \lambda_{\rm s} \sin \lambda_{\rm p}$  (Eq. 7)

where

$$\sin\beta = \sin p \sin D_{\rm m} / \cos \lambda_{\rm p}. \tag{Eq. 8}$$

The paleocolatitude *p* is determined from Eq. (5). The paleomagnetic pole  $(\lambda_p, \phi_p)$  calculated in this way implies that "sufficient" time averaging has been carried out. What "sufficient" time is defined as is a subject of much debate and it is always difficult to estimate the time covered by the rocks being sampled. Any instantaneous paleofield direction (representing only a single point in time) may also be converted to a pole position using Eqs. (7) and (8). In this case the pole is termed a *virtual geomagnetic pole* (VGP). A VGP can be regarded as the paleomagnetic nalog of the geomagnetic poles of the present field. The paleomagnetic pole may then also be calculated by finding the average of many VGPs, corresponding to many paleodirections.

Of course, given a paleomagnetic pole position with coordinates  $(\lambda_p, \phi_p)$ , the expected mean direction of magnetization  $(D_m, I_m)$  at any site location  $(\lambda_s, \phi_s)$  may be also calculated (Figure G6). The paleocolatitude *p* is given by

$$\cos p = \sin \lambda_{\rm s} \sin \lambda_{\rm p} + \cos \lambda_{\rm s} \cos \lambda_{\rm p} \cos(\phi_{\rm p} - \phi_{\rm s}), \qquad (\text{Eq. 9})$$

**Figure G6** Calculation of the position P ( $\lambda_p$ ,  $\phi_p$ ) of the paleomagnetic pole relative to the sampling site S ( $\lambda_s$ ,  $\phi_s$ ) with mean magnetic direction ( $D_m$ ,  $I_m$ ).

and the inclination  $I_{\rm m}$  may then be calculated from Eq. (5). The corresponding declination  $D_{\rm m}$  is given by

$$\cos D_{\rm m} = \frac{\sin \lambda_{\rm p} - \sin \lambda_{\rm s} \cos p}{\cos \lambda_{\rm s} \sin p},$$
(Eq. 10)

where

$$D^{\circ} \le D_{\rm m} \le 180^{\circ}$$
 for  $0^{\circ} \le (\phi_{\rm p} - \phi_{\rm s}) \le 180^{\circ}$ 

and

$$180^{\circ} < D_{\rm m} < 360^{\circ}$$
 for  $180^{\circ} < (\phi_{\rm p} - \phi_{\rm s}) < 360^{\circ}$ .

The declination is indeterminate (that is any value may be chosen) if the site and the pole position coincide. If  $\lambda_s = \pm 90^\circ$  then  $D_m$  is defined as being equal to  $\phi_p$ , the longitude of the paleomagnetic pole.

#### Testing the GAD hypothesis

#### Timescale 0-5 Ma

On the timescale 0–5 Ma, little or no continental drift will have occurred, so it was originally thought that the observation that worldwide paleomagnetic poles for this time span plotted around the present geographic indicated support for the GAD hypothesis (Cox and Doell, 1960; Irving, 1964; McElhinny, 1973). However, any set of axial multipoles ( $g_1^0, g_2^0, g_3^0$ , etc.) will also produce paleomagnetic poles that center around the geographic pole. Indeed, careful analysis of the paleomagnetic data in this time interval has enabled the determination of any second-order multipole terms in the time-averaged field (see below for more detailed discussion of these departures from the GAD hypothesis).

The first important test of the GAD hypothesis for the interval 0-5 Ma was carried out by Opdyke and Henry (1969), who plotted the mean inclinations observed in deep-sea sediment cores as a function of latitude, showing that these observations conformed with the GAD hypothesis as predicted by Eq. (3) and plotted in Figure G5.

#### Testing the axial nature of the time-averaged field

On the geological timescale it is observed that paleomagnetic poles for any geological period from a single continent or block are closely grouped indicating the dipole hypothesis is true at least to first-order. However, this observation by itself does not prove the axial nature of the dipole field. This can be tested through the use of paleoclimatic indicators (see McElhinny and McFadden, 2000 for a general discussion). Paleoclimatologists use a simple model based on the fact that the net solar flux reaching the surface of the Earth has a maximum at the equator and a minimum at the poles. The global temperature may thus be expected to have the same variation. The density distribution of many climatic indicators (climatically sensitive sediments) at the present time shows a maximum at the equator and either a minimum at the poles or a high-latitude zone from which the indicator is absent (e.g., coral reefs, evaporates, and carbonates). A less common distribution is that of glacial deposits and some deciduous trees, which have a maximum in polar and intermediate latitudes. It has been shown that the distributions of paleoclimatic indicators can be related to the present-day climatic zones that are roughly parallel with latitude.

Irving (1956) first suggested that comparisons between paleomagnetic results and geological evidence of past climates could provide a test for the GAD hypothesis over geological time. The essential point regarding such a test is that both paleomagnetic and paleoclimatic data provide independent evidence of past latitudes, since the factors controlling climate are quite independent of the Earth's magnetic field. The most useful approach is to compile the paleolatitude values for a particular occurrence in the form of equal angle or equal area

**Figure G7** Equal angle latitude histogram for Phanerozoic phosphate deposits. (a) Present latitudes of deposits. (b) Paleolatitudes of those deposits where paleomagnetic data are available. Updated from Cook and McElhinny (1979).

histograms and compare these with the present-day distribution (see Briden and Irving, 1964 for several examples). A more recent example involves the occurrence of phosphate deposits. In this case the distribution of land and sea plays a critical part in their formation. For a phosphate deposit to form, the coastal part of a continent must drift into a low-latitude zone. Thus, the formation of phosphorites is not uniform as a function of time. Cook and McElhinny (1979) have examined the paleolatitudes of Phanerozoic phosphate deposits and have shown that they occur mainly within 40° of the equator as is observed for young phosphorites (Figure G7).

#### A direct test of the GAD field

If a large continent or block covered a wide latitude range in the past, then the GAD hypothesis can be tested directly by noting the difference in paleolatitude between two sites lying on the same paleomeridian. During the Mesozoic the paleolatitude of Africa covered a range of nearly 60°. Following McElhinny and Brock (1978), McElhinny and McFadden (2000) calculated mean poles for northern Africa and southern Africa. The mean locations for these subsets lie close to a paleomeridian with mean declinations of 340.8° and 338.7° (Figure G8). The present angular difference between these two locations is 50.3° and their paleolatitude difference is 47.4°  $\pm$  4.3°. Therefore these data are consistent with the GAD hypothesis during part of the Mesozoic.

# Departures from the GAD hypothesis

#### The far-sided effect

Wilson (1970, 1971) noted that the paleomagnetic poles from Europe and Asia tended to plot too far away from the observation site along the great circle joining the site to the geographic pole (Figure G9). He referred to this as the *far-sided effect* and modeled the effect as originating from a dipole source that is displaced northward along the axis of rotation. Such modeling of the sources of the geomagnetic field is nonunique as there are many possible sources that could equally satisfy the data. It is thus always more useful to use spherical harmonics.

# Determining spherical harmonic terms

The potential V (in units of amperes) of the geomagnetic field of internal origin at the surface of the Earth at colatitude  $\theta$  and longitude  $\phi$ can be represented as a series of spherical harmonics in the form

$$V = \frac{a}{\mu_0} \sum_{l=1}^{\infty} \sum_{m=0}^{l} P_l^m(\cos\theta) (g_l^m \cos m\phi + h_l^m \sin m\phi), \quad (\text{Eq. 11})$$

**Figure G8** Test of the geocentric axial dipole field during the Mesozoic. Mean values of the paleomagnetic field for northern and southern Africa are shown as calculated by McElhinny and McFadden (2000). The mean sites lie on the same paleomeridian as indicated by the closeness of the mean declinations observed.

where *a* is the radius of the Earth and  $P_l^m$  is the Schmidt quasinormalized form of the associated Legendre function  $P_{l,m}$  of degree *l* and order *m*. The coefficients  $g_l^m$  and  $h_l^m$  are the Gauss coefficients. When averaged over long periods of time such as is required to obtain the time-averaged field when calculating paleomagnetic poles, it might be supposed that the nonzonal components of the magnetic potential will be eliminated leaving only the zonal terms (m = 0). Equation (11) then reduces to

$$V = \frac{a}{\mu_0} \sum_{l=1}^{\infty} g_l^0 P_l^0(\cos \theta).$$
 (Eq. 12)

**Figure G9** Analysis of global paleomagnetic results for 0–5 Ma from McElhinny *et al.* (1996). Pole positions are averaged over 45° longitude sectors for (a) normal and (b) reverse magnetized data. The paleomagnetic poles tend to plot on the farside of the geographic pole when viewed from each sector. The number of spot readings of the field is indicated for each average. Polar stereographic projection at 76°N.

On the basis of Eq. (12), Merrill and McElhinny (1977) analyzed data for the past 5 Ma by looking at the departure  $\Delta I$  of the observed inclination I from that expected from a GAD field as a function of latitude. Using a least-squares analysis, they were able to find the best fitting  $g_2^0$  and  $g_3^0$  terms. The most recent least-squares analysis is that of McElhinny et al. (1996) in which it was shown that, with present data, only the  $g_2^0$  term is significant and that there are no differences between the normal and reverse field. When the data are restricted to lava flows for the past 5 Ma, several authors have attempted full spherical harmonic analyses. Unlike the least-squares approach, which assumes that nonzonal harmonics are zero, these spherical harmonic analyses are carried out so as to minimize the non-GAD terms (e.g., Johnson and Constable, 1997; Kelly and Gubbins, 1997; Carlut and Courtillot, 1998). It is often claimed in these analyses that significant nonzonal terms are present, but careful analysis of the errors shows that any terms greater than or equal to degree three are not significant (Carlut and Courtillot, 1998). Furthermore, McElhinny and McFadden (1997) and McElhinny (2004) have shown that the data quality is presently not robust enough to determine terms beyond  $g_2^0$ , because most of the data were derived during the 1970s when demagnetization techniques were not as robust as those developed during the 1980s. At the present time, the only significant term beyond the GAD field for the interval 0-5 Ma is a persistent geocentric axial quadrupole  $(g_2^0)$  of about 4% of the GAD field. Table G1 gives an historical view of the values determined for  $g_2^0$  by various methods over the past 25 years.

#### Time-averaged field initiative

A program to obtain high-quality data from lava flows in the time interval 0-5 Ma is currently under way and is referred to as the *time-averaged field initiative*. It arose directly as a result of the criticisms put forward by McElhinny and McFadden (1997). New data have been obtained from the Azores (Johnson *et al.*, 1998), Sicily (Zanella, 1998), Hawaii (Laj *et al.*, 1999; Herrero-Bervera and Valet, 2002), the Carribean (Carlut *et al.*, 2000), the Canary Islands (Tauxe *et al.*, 2000), Japan (Morinaga *et al.*, 2000), Possession Island in the southern Indian Ocean (Camps *et al.*, 2001), Easter Island (Miki *et al.*, 1998; Brown, 2002), western Canada (Mejia *et al.*, 2002), southwestern USA (Tauxe *et al.*, 2003), southern Australia (Opdyke and Musgrave, 2004), and Patagonia (Mejia *et al.*, 2004). A significant observation from all of these new data is that the time-averaged field appears to be much simpler than was previously thought. The results

**Table G1** Values of  $G_2 = g_2^0/g_1^0$  for the time-averaged field 0–5 Ma as determined by successive authors based on directional data alone. 95% confidence limits are shown where available. The method used is indicated as least squares (LS) or spherical harmonics (SH)

appear to indicate that the time-averaged field for 0-5 Ma is very close to that predicted by the GAD hypothesis.

#### 5 Ma",5,0,3,0,105pt,105pt,0,0>Times > 5 Ma

For times older than 5 Ma, it has been proposed that significant octupole ( $g_3^0$  terms) are present in the time-averaged paleomagnetic field. Axial octupole terms can arise in a variety of ways as a result of poor data quality or data artifacts. A full discussion of these effects is given by McElhinny *et al.* (1996) and McElhinny (2004). When the

observed paleomagnetic inclinations appear to be consistently shallower worldwide than those predicted by the GAD field, spherical harmonic analyses interpret this as an axial octupole term. Such inclination shallowing can arise in the following ways:

- 1. Inclination errors in sediments arising from detrital remanent magnetization (DRM) processes (King and Rees, 1966), or compaction effects (Blow and Hamilton, 1978).
- 2. Inclination errors in lavas arising from the bulk demagnetizing effect (shape anisotropy) (Coe, 1979). This is unlikely to be a significant effect except in very thin lavas.
- 3. Creer (1983) has shown that the use of unit vectors in paleomagnetism can cause an artificial shallowing of the observed inclinations.
- 4. McElhinny *et al.* (1996) have shown that the incomplete magnetic cleaning (demagnetization) of Brunhes-age overprints in reversely magnetized rocks can also create an artificial axial octupole term. Viscous components that would average to the axial dipole field during the Brunhes epoch would have longer relaxation times and would require more careful cleaning procedures.
- 5. In the least-squares method, the mapping of the inclination anomaly curve  $\Delta I$  leads to nonorthogonality of the spherical harmonic terms such that the estimates of the coefficients are not entirely independent. However, for small values of the quadrupole and octupole terms, the effect is small.
- 6. Poor data distribution can cause aliazing between the various axial multipole terms. This problem is exacerbated in the least-squares method where an infinite spherical harmonic representation is truncated to a finite series with only 1, 2, or 3 zonal harmonics. Full spherical harmonic analyses helps overcome this problem, but in this case the individual coefficient estimates should not be overinterpreted as they could arise purely from the poor quality of the data.

# Random paleogeography test

The random paleogeography test proposed by Evans (1976) has been much used in recent times (e.g., Kent and Smethurst, 1998), purporting to show that significant axial octupole terms were present in the time-averaged field in pre-Cenozoic times. McElhinny and McFadden (2000) surmised that the basic assumption of random paleogeographic sampling required by the Evans (1976) test has not been fulfilled. Meert *et al.* (2003) and McFadden (2004) have both demonstrated that this is indeed the case. On a GAD Earth, sampling over 600 Ma will produce a GAD-like distribution of inclinations as required by the Evans (1976) test only 30% of the time. Inadequate sampling can produce false quadrupole and octupole effects. With the present global paleomagnetic data set, it now appears unlikely that the GAD hypothesis can be tested in this way even using data covering the age of the Earth (McFadden, 2004).

#### Paleointensities and the GAD hypothesis

The intensity (F) of the GAD field has twice the value at the poles as it does at the equator and varies with latitude ( $\lambda$ ) according to the relation

$$F = F_0 (1 + 3\sin^2 \lambda)^{1/2},$$
 (Eq. 13)

where  $F_0$  is the intensity of the GAD field at the equator. Tanaka *et al.* (1995) and Perrin and Shcherbakov (1997) have summarized global paleointensity values for the time intervals 0–10 Ma and 0–400 Ma, respectively and calculated mean values over 20° latitude bands. These values should conform with the expected variation in Eq. (13) from the GAD hypothesis. Figure G10 shows these mean values plotted as a function of paleomagnetic latitude and the best-fit curves for a GAD field are drawn through each data set. A chi-square test indicates that the data are consistent with the latitude variation expected for a

**Figure G10** Global paleointensities plotted as a function of paleomagnetic latitude using the mean values averaged over 20° latitude bands calculated by Tanaka *et al.* (1995) for 0–10 Ma (dashed curve) and Perrin and Shcherbakov (1997) for 0–400 Ma (solid curve). The number of units used in each average is indicated with 95% confidence limits for each mean (crosses with dashed error bars for 0–10 Ma, solid circles with solid error bars for 0–400 Ma). The curves represent the best fits for a geocentric axial dipole field.

GAD field. This provides further confirmation that the GAD model is valid, at least to first-order, for the past 400 Ma.

#### Conclusions

At the present time, the GAD model is a reasonable first-order approximation for the time-averaged field at least for the past 400 Ma and probably for the whole of geological time. A persistent geocentric axial quadrupole term of about 4% of the axial dipole term is present for the interval 0-5 Ma and, with possible variations, can be expected to be a permanent feature of the time-averaged field through time. More precise evaluation of the time-averaged field for 0-5 Ma will become possible when results from the time-averaged field initiative become available and are fully analyzed. Previous analyses were based on poor quality data and new results from the acquisition of new high-quality data worldwide appear to indicate that the time-averaged field is much simpler than was previously thought.

Geocentric Axial Dipole Hypothesis Pole, Paleomagnetic Time-averaged Paleomagnetic Field

# GEODYNAMO

#### Introduction

The discovery of the magnetic *compass* (q.v.) by the Chinese dates back at least to the A.D. 1st century A.D., and it was known in Europe during the A.D. 12th century. An early idea was that the magnetic needle was attracted to the pole star, but by the year 1600, *William Gilbert* (q.v.) had realized that the source of the Earth's magnetic field came from within the Earth rather than outside it. Final confirmation of this was not made until 1838, when *Carl Friedrich Gauss* (q.v.) used a *spherical harmonic* (q.v.) decomposition of the geomagnetic field to establish that the main field is internal. The important discovery that the field changes with time was made in 1634 by *Henry Gellibrand* (q.v.). This showed that the Earth's field cannot be a permanent magnet, as William Gilbert had envisaged. *Edmond Halley* (q.v.) investigated the changes in the Earth's field and showed that some magnetic features were drifting westward, and on this basis suggested that the interior of the Earth might be liquid.

Evidence from the study of rock magnetism shows that the Earth's magnetic field is certainly not static, but varies dramatically over long periods of time. Indeed, the Earth has undergone many complete magnetic reversals throughout its history. The most widely accepted theory is that the magnetic field is continually being created and destroyed by fluid motions in the interior of the Earth, as suggested by *Joseph Larmor* (q.v.) (1919). Since electricity and magnetism are commonly generated by means of dynamos, the mechanism by which the Earth's magnetic field is created is known as the geodynamo. Permanent magnetism does occur in the *crustal magnetic field* (q.v.) of the Earth, and contributes a small and relatively static contribution to the main internally generated magnetic field, the core field.

There are also external components of the magnetic field measured at the Earth's surface. They can be distinguished from the internal core field partly because they increase upward rather than decrease upward, but also because they vary on a much shorter timescale. The origin of these external fields is in the Earth's *ionosphere* (q,v), where charged particles in the solar wind interact with the upper atmosphere. Since solar magnetic activity changes on a timescale of a few days, short bursts of activity known as *magnetic storms and substorms* (q,v) can be detected in magnetic observatories. The external components of the geomagnetic field will not be discussed further here as they are not part of the geodynamo.

#### Magnetic fields on other planets and stars

The Earth is by no means the only planet to have a strong internal magnetic field. Jupiter has a surface field 10 times larger than the geomagnetic field, and Saturn, Uranus, and Neptune have surface fields at least as strong. Internal fields exist on Mercury (though this field is quite weak) and on Ganymede, one of Jupiter's moons. There are *planetary and satellite dynamos* (q.v.) as well as a dynamo in the

Earth. Planetary magnetic fields have been reviewed by Stevenson (1982, 2003) and Jones (2003).

Not all the planetary magnetic fields are dominated by an axial dipole, as is the Earth. Uranus and Neptune have more complex fields. Our moon, and the planet Mars, have *crustal magnetic fields* (q.v.) which are very likely to have been created by internal dynamos, which operated early in their history, but have now ceased to function. The issue of whether a planet or satellite has an internally generated magnetic field depends on the physical conditions in the *interiors of the planets and satellites* (q.v.). The *magnetic field of Sun* (q.v.) is much stronger than the geomagnetic field, and some stars have fields that are stronger still. The solar magnetic field is believed to be generated by dynamo processes occurring in the Sun's deep interior, (see the *Solar dynamo*).

#### The dynamo process

According to dynamo theory, the magnetic field in the Earth is maintained by a system of electrical currents flowing through its liquid metal core. There are four key laws from electromagnetic theory that describe how the magnetic field and the currents behave in terms of concepts from elementary vector calculus. These are discussed in detail in books on *magnetohydrodynamics* (q.v.), or MHD for short, such as Roberts (1967), Moffatt (1978), and Davidson (2001). The first is Ampere's law, which can be written

$$\nabla \times \mathbf{B} = \mu \mathbf{j},\tag{Eq. 1}$$

where **B** is the magnetic field, **j** is the current density (the current flowing through a wire is **j** times its cross-sectional area), and  $\mu$  is the permeability of free space (the high core temperature makes the free space value  $4\pi \times 10^{-7}$  Tm A<sup>-1</sup> appropriate). Maxwell showed that a displacement current term should be added to this equation, but for the Earth's core this extra term can be ignored, so Eq. (1) is sometimes called the pre-Maxwell equation. The second equation is Faraday's law of electromagnetic induction, which is

$$\frac{\partial \mathbf{B}}{\partial t} = -\nabla \times \mathbf{E},\tag{Eq. 2}$$

and says that if a magnetic field is varied in time, an electric field  $\mathbf{E}$  is created. The third result from electromagnetic theory is Ohm's law in a moving conductor, which can be written

$$\mathbf{j} = \sigma(\mathbf{E} + \mathbf{u} \times \mathbf{B}). \tag{Eq. 3}$$

Here the conductor (which may be fluid or solid) is moving with velocity **u**.  $\sigma$  is the *electrical conductivity of the core* (*q.v.*), a physical quantity of fundamental importance for the geodynamo. It is estimated to be around  $5 \times 10^5$  S m<sup>-1</sup>. Dividing by  $\sigma$  and taking the curl of Eq. (3) allows us to eliminate the electric field **E**, and dividing Eq. (1) by  $\mu$  and taking the curl allows us to eliminate **j**. The fourth law is simply

$$\nabla \cdot \mathbf{B} = 0, \tag{Eq. 4}$$

which is equivalent to saying there are no magnetic monopoles. If  $\mu$  and  $\sigma$  are constants, we obtain (using the vector identity curl curl = grad div  $-\nabla^2$ ) the induction equation

$$\frac{\partial \mathbf{B}}{\partial t} = \nabla \times (\mathbf{u} \times \mathbf{B}) + \eta \nabla^2 \mathbf{B}, \tag{Eq. 5}$$

where  $\eta = 1/\mu\sigma$  is called the magnetic diffusivity, and its typical value in the core is  $\eta \sim 2 \text{ m}^2 \text{ s}^{-1}$ . The last diffusive term in Eq. (5) arises because all metals have some electrical resistance. Seismology has shown that the Earth consists of a solid inner core, the inner core radius being approximately 1100 km (see *Core properties, physical*), surrounded by a fluid outer core of radius approximately 3500 km, surrounded in turn by the mantle. The electrical conductivity of the mantle is very low compared with that of the outer core, so the liquid metal outer core is the most natural seat of the geodynamo.

We first consider what happens if there is no motion,  $\mathbf{u} = 0$ , so that Eq. (5) becomes the diffusion equation. When the power flowing into a laboratory electromagnet is switched off, the magnetic field usually collapses quite quickly, but the Earth's core is very large and this slows down the decay. Equation (5) with  $\mathbf{u} = 0$  can be solved for a spherical conducting core surrounded by an insulating mantle (see e.g., Moffatt, 1978), and the field is found to decay in time as  $\exp(-\pi^2 \eta t/a^2)$ , where a is the core radius. Putting in the estimates given above, the field reduces by a factor e (the e-folding time) in 20 ka. The core of the Earth is so large that even if the source of the driving were suddenly removed, the field would decay only on this very long timescale. However, the age of the Earth is around  $4.5 \times 10^9$  y, and paleomagnetic studies show that the Earth's magnetic field has existed for at least  $3 \times 10^9$  y. This is much longer than the 20 ka magnetic decay time, so an energy source for the geodynamo (q.v.) is required to maintain the field.

The generation mechanism for the geodynamo is that the field is maintained by *core motions* (q.v.) inside the liquid metal outer core of the Earth, so **u** is nonzero and the electromagnetic induction term in Eq. (5),  $\nabla \times (\mathbf{u} \times \mathbf{B})$ , is important. This mechanism has now been demonstrated to work in laboratory *experimental dynamos* (q.v.). The same process is used in power stations to generate virtually all our electricity, though there the conducting material is an array of copper wires rather than a core of liquid metal.

The velocity required to generate the magnetic field can be estimated from the size of the induction term relative to the diffusion term. This ratio is approximately  $U_*a/\eta = R_{\rm m}$ , the magnetic Reynolds number, where  $U_*$  is a typical value of the velocity of the fluid inside the core relative to the frame rotating with the mantle. This can be estimated by observing the westward drift (q.v.) velocity of the magnetic field itself. Since the inhomogeneities in the field are to a large extent carried along by the fluid motion in the core, this provides a rough estimate of approximately  $U_* \sim 2 \times 10^{-4} \text{ m s}^{-1}$  for the core flow, giving  $R_{\rm m} \sim 300$  (note though that in some places in the core the velocity can be as much as  $8 \times 10^{-4}$  m s<sup>-1</sup>, Bloxham and Jackson, 1991). Unfortunately, it is not possible to get a complete picture of the flow below the core-mantle boundary (CMB), but core-based inversions (q.v.) can extract much useful information about core velocities. Since  $R_{\rm m}$  is significantly larger than unity, this ensures that the induction term, which generates the magnetic field, makes good the losses arising from magnetic diffusion. This large value of  $R_{\rm m}$  arising from these natural estimates provides strong support for the dynamo hypothesis in the Earth's core. It is of interest to seek the minimum value of  $R_{\rm m}$ required to overcome diffusion. A number of bounding theorems have been proved to answer this question.

The actual flow  $\mathbf{u}$  inside the core that is driving the dynamo will be time-dependent and have a complex structure. However, some idea of the type of flow inside the core suggested by the theory of the dynamics of the core (see section below on "Core dynamics") is shown in Figure G11.

#### Nondynamo generation mechanisms

Although the dynamo theory is a very reasonable hypothesis, it is necessary to consider the other *nondynamo theories* (q.v.) which have been suggested for driving the Earth's magnetic field. Most of these are capable of generating some magnetic field, but are not up to the task of generating the rather strong magnetic field observed. Permanent magnets are demagnetized when raised to temperatures above the Curie point temperature, which for the materials which constitute

**Figure G11** A possible configuration for the fluid flow and the field inside the core (after Bloxham and Gubbins, 1989).

the core is well below any reasonable estimate of core temperature. Admittedly, the Curie point might be affected by the high pressure in the Earth's core (see *Depth to the Curie temperature*). The strong variability of the geomagnetic field is the best argument against a permanent magnetism explanation. Thermoelectric effects can create currents and hence magnetic fields; indeed Stevenson (1987) has proposed this mechanism for Mercury's field, but it cannot produce enough field to explain geomagnetism. Other possible mechanisms, with references, are listed by Merrill *et al.* (1996), but none has gained any widespread acceptance.

#### How is the geodynamo driven?

A more controversial issue is the energy source of the fluid flow inside the core. The diffusion of the magnetic field is accompanied by ohmic heating, sometimes called Joule dissipation. This loss of energy requires a source to replace it. *Core convection* (q.v.) is the mostly widely accepted source, and the two most developed driving mechanisms are thermal convection and compositional convection. Other possibilities are precession and tidal interaction. For a more detailed discussion on these mechanisms (see *Energy source for the geodynamo*).

The fundamental source of energy for precession and tidal interactions is the rotational energy of the Earth. If these contribute to driving the geodynamo, they would lead to a slowing down of the Earth's rotation, i.e., to a lengthening of the day (see *Decadal length of day variations*). Earth tides and oceanic tides are also slowing down the rotation rate of the Earth, so a precession-driven dynamo would give additional slowing.

Thermal convection derives its energy from the cooling down of the Earth, although if there is radioactive heating in the core, this could contribute too. The issue of whether there is radioactivity in the core has a long history and remains highly controversial (see *Radioactive isotopes and their decay*). There is no doubt that radioactivity is important in the mantle, but whether radioactive elements were carried into the core during formation is a very challenging problem for geochemists. The primordial heating of the Earth occurred as part of the core formation process through gravitational collapse, so the thermal energy of the core may be thought of as originating from gravitational energy.

Another source of energy for driving the dynamo is compositional or *chemical convection* (q.v.) (Braginsky, 1963; *J. Verhoogen* (q.v.), 1961). The solid inner core of the Earth contains a higher fraction of iron than the fluid outer core (see *Inner core composition*), and so is more dense than the fluid outer core. As the inner core grows, due to core cooling, iron is deposited on the inner core, and light material is released at the moment of freezing. This light material rises due to buoyancy, and stirs up the outer core. Since the net effect of this process is to move heavier material toward the center, gravitational energy is liberated. It is slightly surprising that the core first freezes near the center of the Earth, where the temperature is highest. This happens because the melting temperature of iron in the core increases strongly with pressure.

The question of whether tidal forcing or precessional forcing (see Precession and core dynamics) is large enough to drive the geodynamo has been discussed by Malkus (1994). The typical height of an Earth tide inside the core is expected to be about  $h \sim 0.15$  m, and precession gives a similar displacement. The typical radial velocity is then  $\Omega h \sim 10^{-5}$  m s<sup>-1</sup>. The azimuthal velocity might be a little larger, so a value not that far off the convective velocity  $U_*$  might be achieved. There is a difficulty because this velocity is fluctuating on a timescale of a day, whereas a flow varying only on a much longer timescale (a 1 ka) is needed to sustain a dynamo. Some mechanism for converting oscillatory flows into steady flows is required, and some suggestions for overcoming this difficulty have been proposed (Kerswell, 2002; Aldridge, 2003). A recent example of a precessiondriven dynamo has been given by Tilgner (2005), though the conditions under which these dynamos operate are still very far from Earth-like.

#### Energy balance for a convective dynamo

This naturally leads on to the question of how efficient the geodynamo actually is. In the *solar dynamo* (q.v.), only a tiny fraction of the heat energy pouring out of the Sun is converted into the solar magnetic energy: is the Earth more efficient in this respect? To investigate this we need to examine the overall energy and entropy budget in the Earth's core, and to do this we need a model for the *Core temperature* of the Earth (q.v.).

Since we believe the fluid outer core is stirred it is reasonable to assume it is approximately adiabatically stratified, so the temperature gradient is given by the *adiabatic gradient in the core* (q.v.). This is dependent on a quantity called the *Grüneisen parameter* (q.v.) which itself varies somewhat between the inner core boundary (ICB) and the Core-Mantle boundary but if we adopt the currently accepted estimates, we find that the temperature drop from the ICB to the CMB is about 1100 K (Braginsky and Roberts, 1995; Roberts et al., 2003). In principle, the melting temperature of iron at high pressure (see *melting* temperature of iron in the core), should determine the ICB temperature, but unfortunately, the impurities expected in the core significantly depress the melting temperature, so this is somewhat uncertain. A reasonable guess at the present time (Roberts et al., 2003) is  $T_{\rm ICB} = 5100$  K, giving  $T_{\rm CMB} = 4000$  K. An important issue is the amount of thermal conduction in the core (q.v.). Again there is uncertainty due to the difficulty of the very high core pressures but if we take  $\sim\!40~W~m^{-1}~K^{-1}$  as our estimate, the conducted flux down the adiabat near the CMB is  $Q_{cond} \sim 6$  TW, and only  $\sim 0.25$  TW near the ICB. There are two reasons for the big difference; first the adiabatic temperature gradient decreases somewhat with depth, so the conducted heat flux per square meter decreases with depth, but secondly the geometry of the much larger surface area near the CMB means that a much larger number of terawatts is conducted there. The critical question is whether the actual heat flux out of the core is greater or less than this conducted flux. If the actual flux exceeds the conducted flux  $Q_{\text{cond}}$  at any point in the fluid outer core, the excess flux is carried by convection. If however the actual heat flux is less than  $Q_{cond}$  then there will be a region where there is a subadiabatic temperature gradient. This is most likely to occur just below the CMB. Here there is either

a nonadiabatic stably stratified region where the temperature gradient is significantly subadiabatic, thus reducing the conducted flux, or if compositional convection stirs this subadiabatic region the heat flux produced by compositional stirring is negative (back into the interior). A further possibility is that light material released at the ICB as the inner core forms accumulates just below the CMB. This possibility has been called by Braginsky (1993) the "inverted ocean," since it would consist of a sea of relatively light material floating up against the CMB.

Unfortunately, our knowledge of the *heat flow across the* Core-Mantle Boundary is imprecise, and we cannot yet be certain whether an inverted ocean exists or not. We know that at the present time there are 44 TW of heat coming through the Earth's surface, and that most of that originates in the mantle. Estimates of the CMB heat flux range from 3 TW (Sleep, 1990) to 15 TW (Roberts *et al.*, 2003), and are highly dependent on whether there is core radioactivity or not. In principle, mantle convection simulations could tell us the heat flux across the CMB, since this is one of the bottom boundary conditions to such simulations, and so will affect the structure of mantle convection. However, to date the uncertainties surrounding mantle convection modeling (see e.g., Schubert *et al.*, 2001) preclude this possibility. *Numerical simulations of the geodynamo* (*q.v.*), such as those of Glatzmaier and Roberts (1995, 1997), have typically adopted a compromise value of around 7 TW for the CMB heat flux, which just makes the core fully convective.

The overall energy balance in the core, ignoring any contributions from precession or tides, can be written

$$\mathcal{Q}^{S} = \mathcal{Q}_{CMB} - \mathcal{Q}_{ICB} - \mathcal{Q}^{L} - \mathcal{Q}^{G}(-\mathcal{Q}^{R}).$$
 (Eq. 6)

where  $Q^{S}$  is the rate of cooling,  $Q_{CMB}$  is the heat flux passing through the CMB,  $Q_{ICB}$  is the heat flux passing through the ICB,  $Q^{L}$  is the latent heat released by the freezing process on the inner core, Verhoogen (q.v.), 1961  $Q^G$  is the gravitational energy released by the same process, and  $Q^{R}$  is the heat produced by radioactivity (if any). For the sake of definiteness, we give reasonable estimates for each of these quantities (see e.g., Braginsky and Roberts, 1995; Roberts et al., 2003), but it cannot be emphasized too strongly that all of these estimates are uncertain, and it would be very surprising if improvements in our understanding of high pressure physics did not lead to radical revision of these estimates over the next decades. Discussions of some of the physics that goes into these estimates can be found in the articles on *core composition* (q.v.), core density (q.v.), and core properties, physical (q.v.). With this proviso, we take the cooling rate of the core to be  $Q^{S} \sim 2.3$  TW, the latent heat released at the ICB to be  $Q^{L} \sim 4.0$  TW, the gravitational energy released at the ICB  $Q^{G} \sim 0.5$  TW, and  $Q_{ICB} \sim 0.25$  TW. This gives  $Q_{\rm CMB} \sim 7$  TW, the value used by Glatzmaier and Roberts (1997).  $Q^{\rm R}$ , the heat released by core radioactivity is extremely uncertain, as mentioned above. Perhaps the best hope is that an improved understanding of the geodynamo might enable us to constrain  $Q^R$ , as might a better understanding of the thermal history of planetary interiors.

It might seem surprising that the ohmic dissipation generated by the magnetic field does not appear in the energy balance. This is because it is balanced by the work done by buoyant convection. Some of the heat energy flowing through the core is extracted to drive the fluid motions, only to be returned in full by the ohmic and viscous dissipation.

#### Entropy balance in the core

To get an estimate which involves the magnetic field we need to consider the rate of entropy production (Hewitt *et al.*, 1975; Gubbins, 1977; Gubbins *et al.*, 1979; Braginsky and Roberts, 1995; Roberts *et al.*, 2003). As magnetic field diffuses, it generates heat through ohmic dissipation,

$$Q^{\rm D} = \mu \eta \int \mathbf{j}^2 \mathrm{d}\nu \tag{Eq. 7}$$

Viscous dissipation is believed to be negligible in comparison with ohmic dissipation, because the magnetic energy is much larger than the kinetic energy in the core, and we obtain (Roberts *et al.*, 2003)

$$\mathcal{Q}^{\mathrm{D}} = \frac{T_{\mathrm{D}}}{T_{\mathrm{CMB}}} \left[ \left( \mathcal{Q}_{\mathrm{ICB}} + \mathcal{Q}^{\mathrm{L}} \right) \left( 1 - \frac{T_{\mathrm{CMB}}}{T_{\mathrm{ICB}}} \right) + \left( \mathcal{Q}^{\mathrm{S}} + \mathcal{Q}^{\mathrm{R}} \right) \\ \left( 1 - \frac{T_{\mathrm{CMB}}}{T_{\mathrm{M}}} \right) \mathcal{Q}^{\mathrm{G}} - \sum T_{C\mathrm{MB}} \right]$$
(Eq. 8)

where  $T_{\rm D}$  is the average temperature where dissipation occurs, and  $T_{\rm M}$  is the average temperature of the fluid outer core. As in a Carnot heat engine, there are "efficiency factors" which mean that thermal convection cannot extract more than  $(1 - T_{\rm CMB}/T_{\rm ICB}) \sim 20\%$  of the heat flux passing through the core, and for sources which are distributed throughout the core, such as cooling and radioactivity, the efficiency factor may be as low as 10%. Using the estimates above, we find that in the absence of radioactivity the dissipation is around 1 TW, with about 0.5 TW being from compositional convection  $Q^G$ , and 0.5 TW being from thermal convection (see also Christensen and Tilgner, 2004).

Most current *numerical simulations of the geodynamo* (q.v.) have an ohmic dissipation that is less than 1 TW, but this is most probably because they are not yet in the right parameter regime for the geodynamo. Roberts and Glatzmaier (2000) have shown that as the resolution is increased the dissipation rises (see also Kono and Roberts, 2002). Again some geodynamo simulations show a viscous dissipation rate as large as the ohmic dissipation rate, but this again is likely to be a consequence of the numerical difficulties in achieving the right parameter regime.

#### Kinematic dynamo models

A major difficulty in constructing geodynamo models was noted by Cowling (1934). He showed that it is impossible to maintain an axisymmetric magnetic field by means of dynamo action, a result now known as Cowling's theorem (q.v.). This was the first of a class of antidynamo theorems (q.v.) showing that fields with too much symmetry cannot be created by dynamo action. The earliest geodynamo models based on electromagnetic induction appeared in the 1950s (Bullard (q.v.) and Gellman, 1954), thus showing that although Cowling's theorem (q.v.)is a mathematical inconvenience (because symmetric solutions of partial differential equations are much easier to find) it is not a fatal objection to the dynamo idea. These models only considered the induction equation (5), the velocity field of the fluid flow being imposed. This is known as the kinematic dynamo problem, the significance of the word kinematic being that the velocity field is simply prescribed, rather than taking the flow to be a solution of an equation of motion. In practice fairly simple flows are chosen, but despite the induction equation (5) being linear in **B**, the nonaxisymmetric three-dimensional nature of the solutions makes it hard to solve, even with today's fast computers. Because of the linearity, the induction equation (5) has either exponentially growing or decaying solutions. We say that a flow is a kinematic dynamo if the solutions grow rather than decay. Fast dynamos, that is dynamos whose growth rate remains finite in the limit of small magnetic diffusion  $(R_{\rm m} \rightarrow \infty)$  are usually studied in the kinematic dynamo approximation.

It was noticed early on in the study of kinematic dynamos that quadrupolar dynamos, that is dynamos with a dominant quadrupole field (see symmetry and the geodynamo) rather than a dipole field can also be obtained, depending on the chosen flow. The issue of what makes some flows give dipolar dynamos and others quadrupolar dynamos is not yet fully resolved, so we cannot yet give a definite answer to the question why is the Earth dipole dominated rather than quadrupole dominated. *Numerical simulations of the geodynamo* (q.v.) usually, but not always, give dipolar fields.

Another issue to arise out of kinematic dynamo studies was the role of meridional circulation, which is the axisymmetric component of flow in the radial and latitudinal direction. (The axisymmetric component of flow in the longitudinal direction is called the azimuthal flow.) The time dependence of a kinematic dynamo is proportional to  $\exp(\sigma t)$ , and  $\sigma$  is in general complex. If  $\sigma$  happens to real, we say that the dynamo is steady, but if  $\sigma$  has an imaginary part we say it is oscillatory. The *solar dynamo* (*q.v.*) reverses continually in an approximately periodic 22-year cycle, and is therefore naturally modeled as an oscillatory dynamo, but the geodynamo is comparatively steady, although it does reverse (irregularly) occasionally (see *Reversals, theory*). Kinematic dynamo calculations (Roberts, 1972) showed that meridional circulation helps to make a dynamo steady, indicating that meridional circulation could play an important role in the geodynamo. Recent work on kinematic dynamos relevant to the Earth can be found in e.g., Gubbins *et al.* (2000a,b) and Sarson (2003).

#### Mean field dynamo models

In the 1960s, *mean field dynamos* (q.v.) were developed (Steenbeck *et al.*, 1966) see also Moffatt (1978). The basic idea is that small-scale *core turbulence* (q.v.) could help to generate the large-scale field. If the magnetic field is **B** + **b**, and the velocity is **U** + **u** where **b** and **u** are the small-scale turbulent parts, and **B** and **U** are the mean parts averaged over the small scales, then the induction equation averaged over the small scales becomes

$$\frac{\partial \mathbf{B}}{\partial t} = \nabla \times (\mathbf{U} \times \mathbf{B}) + \nabla \times (\overline{\mathbf{u} \times \mathbf{b}}) + \nabla^2 \mathbf{B}.$$
 (Eq. 9)

Provided certain criteria are satisfied the new term can be written

$$\nabla \times (\mathbf{\overline{u} \times b}) = \nabla \times \alpha \mathbf{B} \tag{Eq. 10}$$

where  $\alpha$  is in general a function of position in the core. More generally,  $\alpha$  is a tensor, but it is usually taken to be isotropic so that the comparatively simple form of Eq. (10) can be used. This term in the induction equation is known as the  $\alpha$ -effect. The types of turbulent flow which give a nonzero  $\alpha$  are those with nonzero mean helicity. The helicity of a flow is  $\mathbf{u} \cdot \boldsymbol{\omega}$  where  $\boldsymbol{\omega} = \nabla \times \mathbf{u}$  is the vorticity. Flows with a "screw-type" motion have helicity. Parker (1955) pointed out that a blob of hot fluid, rising because of its buoyancy, would twist as it rises due to the action of Coriolis force in a rotating body like the Earth or the Sun. This gives a natural source of helicity. The great advantage of mean field models is that axisymmetric mean fields are now possible solutions of Eqs. (9) and (10). The nonaxisymmetric components of the field which must be there because of Cowling's theorem (q.v.), do not need to be calculated explicitly. This simplification made it feasible to include dynamics into dynamo models, to obtain what are now known as intermediate dynamo models (see section below on "Intermediate dynamo models").

Mean field models have been extensively used in the *solar dynamo* (q.v.) problem, because they give rise to *dynamo waves* (q.v.), which can explain many features of the *solar dynamo* (q.v.). The main disadvantage of mean field models is that the distribution of  $\alpha$  over the core depends on the form of the turbulence in the Earth's core. This cannot be observed, and indeed it is not even known whether such turbulence satisfies the criteria required for a mean field dynamo to be valid. If it were the case that the spatial form of  $\alpha$  was not critical, this would be less important, but unfortunately numerical calculations indicated that the  $\alpha$ -distribution can make a very big difference to the types of dynamo generated (Hollerbach *et al.*, 1992).

#### Core dynamics

Some of the most interesting properties of the geodynamo are concerned with the dynamics that is the force balance in the core. This is described by the Navier-Stokes equation with additional forces which are important in the geodynamo. A simplification that is often used is the Boussinesq approximation (see the article on *Boussinesq* and anelastic approximations), in which density variations are ignored except where they are multiplied by g, so that buoyancy forces can be included. This approximation is not strictly valid in the core, as density variations of order 20% can occur, but it is nevertheless a use-ful simplification of equations which are difficult to solve, and we adopt it here.

The equation of motion for a rotating fluid in which Lorentz (magnetic) forces, buoyancy, and viscosity act can be written

$$\rho \left[ \frac{\mathbf{D}\mathbf{u}}{\mathbf{D}t} + 2\mathbf{\Omega} \times \mathbf{u} \right] = -\nabla p + \mathbf{j} \times \mathbf{B} + \rho v \nabla^2 \mathbf{u} + \rho g \alpha T \hat{\mathbf{r}}.$$
(Eq. 11)

Here  $\rho$  is the density (assumed constant), **u** is the velocity, *p* is the pressure, **j** is the current density, **B** is the magnetic field, *v* is the kinematic viscosity, *g* is gravity,  $\alpha$  is the coefficient of expansion, *T* is the temperature, and  $\hat{\mathbf{r}}$  is the unit vector in the direction of gravity, the radial direction. Not surprisingly, such a complex equation with so many different forces leads to many different physical effects. Note that the Coriolis acceleration,  $2\mathbf{\Omega} \times \mathbf{u}$  is often thought of as a force (when multiplied by  $\rho$ ) in a rotating frame. D/D*t* is the convective derivative,  $\partial/\partial t + \mathbf{u} \cdot \nabla$ .

Since the temperature occurs in this equation, another equation determining T is needed,

$$\frac{\partial T}{\partial t} = \kappa \nabla^2 T - \mathbf{u} \cdot \nabla T + Q. \tag{Eq. 12}$$

Here Q is the heat source and  $\kappa$  is the thermal diffusivity.

A number of dimensionless parameters can be formed from these equations. The Ekman number,  $E = v/2\Omega d^2$ , measures the relative importance of the viscous force to the Coriolis force. To estimate this we need to know the *core viscosity* (*q.v.*), but *E* is certainly very small, probably of order  $10^{-15}$  in the core. There are two diffusion coefficients, *v* and  $\kappa$ , and a third,  $\eta$ , occurs in the induction equation (5), so we have two dimensionless ratios,  $Pr = v/\kappa$ , known as the Prandtl number, and  $Pm = v/\eta$  known as the magnetic Frandtl number. Another useful combination involving the magnetic field is the *Elsasser* (*q.v.*) number  $\Lambda = B_0^2/2\Omega\mu\rho\eta$ , where  $B_0$  is a typical value of the magnetic field. The Elsasser number at the CMB, where the field is typically 0.5 mT, is about 0.25, but inside the core the field is likely to be stronger, and the Elsasser number is believed to be of order unity or a little more.

#### Rapidly rotating convection

Much of our understanding of convection in rapidly rotating systems comes from the problem of thermally driven *nonmagnetic rotating convection* (q.v.), and the problem of convection in an imposed magnetic field (usually either a uniform magnetic field or one with a simple geometry) which is called *magnetoconvection* (q.v.). The articles on these topics give a more detailed discussion, but there is a very large literature on both these topics, and some understanding is essential for an appreciation of the geodynamo. Our knowledge has been enhanced by *fluid dynamic experiments* (q.v.) and *experimental dynamos* (q.v.). It turns out that magnetic field affects the convection considerably, but at least the nonmagnetic case gives us a framework on which to build understanding of the magnetic case.

The onset of instability in a rapidly rotating sphere is now fairly well understood (Roberts, 1968; Busse, 1970; Jones *et al.*, 2000). Rapid rotation means the Ekman number,  $E = v/2\Omega d^2$  is small, and in this case convection occurs in a columnar form, somewhat as illustrated in Figure G11. However, in nonmagnetic convection the columns are tall but very thin, so that instead of the three columns shown in Figure G11, a much larger number of order  $E^{-1/3}$  fit into the sphere. These columns are known as Busse columns (Busse, 1970;

Busse and Carrigan, 1976), and their basic structure can be understood in terms of the Proudman-Taylor theorem (q.v.). The onset of convection in a uniformly heated sphere with stress-free boundaries in the absence of rotation occurs when the Rayleigh number  $Ra = g\alpha\beta r_a^6/\kappa v$  exceeds Ra<sub>crit</sub> = 1 546 (Chandrasekhar, 1961), where  $\beta = Q/3\kappa$ , so the static gradient is  $\beta r$ . Gravity is taken to be -gr, as in a uniform sphere gravity increases linearly from the center. In the small Ekman number limit, i.e., in rapid rotation, the critical Rayleigh number for the onset of convection approaches  $4.117E^{-4/3}$  at Prandtl number Pr = 1 (Jones *et al.*, 2000), which gets very large at small E. Although the onset of instability is strongly delayed by the rotation as the Rayleigh number is increased above critical, once the critical value for convection is achieved the flow becomes time-dependent, and then aperiodic, rather quickly. Abdulrahman et al. (2000) showed that the bifurcations to chaotic convection occur in a relatively small window in Rayleigh number space  $\operatorname{Ra}_{\operatorname{crit}} < \operatorname{Ra} < R_{\operatorname{crit}} + O(E^{-2/3}).$ 

Convection continues to occur in tall thin columns in the fully nonlinear regime provided the Rossby number  $\text{Ro} = U_*/a\Omega$  remains small, although the thickness of the columns does increase somewhat over its very thin linear value, and the columns tend to become rather transient, and occur fairly randomly throughout the sphere. Experiments suggest that in the nonlinear regime, inertial effects take over from viscous effects, and the leading order balance is between inertia, Coriolis force, and buoyancy (for details see Aubert *et al.*, 2001).

When a magnetic field is applied, the *Proudman-Taylor theorem* (q.v.) no longer controls the pattern of convection, as the Lorentz force becomes important. An important effect of magnetic field is to increase the thickness of the Busse columns (see e.g., Jones *et al.*, 2003), which occurs even at small Elsasser number  $\Lambda \sim O(E^{1/3})$  field strengths. If the Elsasser number is further increased to O(1) values, the columns are still visible, but the number fitting into the sphere is much reduced. Because magnetic field can break the Proudman-Taylor constraint, the critical Rayleigh number is reduced in the presence of a  $\Lambda \sim O(1)$  field, so magnetic field can help the system convect, see e.g., Fearn *et al.* (1988).

#### Dynamical regime in the core

In the magnetic case it is not unreasonable as a first approximation to assume that the large-scale flows and fields have dominant length scales of the size of the core radius. It is then possible to do a useful scale analysis of the dynamics of the Earth's core using Eq. (11) (see e.g., Braginsky and Roberts, 1995; Starchenko and Jones, 2002), although we must keep in mind this can only give order of magnitude estimates, and more exact results require that the geometry of the convection and the spherical domain be taken properly into account.

Some of the physical quantities in the core are quite accurately known, others somewhat less so, but here we only need order of magnitude estimates, to see which terms are large and which small in Eq. (11). We take as a typical value for the velocity in the core  $U_* = 2 \times 10^{-4}$  m s<sup>-1</sup>, see section "The dynamo process." For D/Dt we take 1/300 years, or  $10^{-10}$  s<sup>-1</sup>. Significant changes to the field occur on this timescale, though a full reversal of the field might take ten times as long. The density  $\rho \sim 10^4$  kg m<sup>-3</sup> in the core. The Earth's angular velocity  $\Omega = 7 \times 10^{-5}$ , and already we can see that the magnitude of the inertial term  $|D\mathbf{u}/Dt|$  is very small compared to the Coriolis term  $|2\mathbf{\Omega} \times \mathbf{u}|$ .

We turn next to the Lorentz force term,  $\mathbf{j} \times \mathbf{B}$ . The field at the CMB is about  $5 \times 10^{-4}$  T. The current is  $\nabla \times \mathbf{B}/\mu$ , and since the curl is a space derivative, we crudely estimate it at  $|\mathbf{B}\pi/a\mu|$  where *a* is the core radius,  $3.5 \times 10^6$  m. The Coriolis term  $|2\rho \mathbf{\Omega} \times \mathbf{u}| \sim 3 \times 10^{-4}$  N m<sup>-3</sup> while the Lorentz term  $|\mathbf{j} \times \mathbf{B}|$  has magnitude  $2.5 \times 10^{-7}$  N m<sup>-3</sup>. This is smaller than the Coriolis term, but it is generally believed that the invisible field inside the core is at least 10 times larger than the visible field, which leaves the core, increasing the magnitude of the Lorentz term. Furthermore, the magnetic field pattern at the CMB suggests that it varies on a shorter length scale than the core radius, which will

enhance **j**. It is therefore likely that the Lorentz force will be comparable to the other forces at least in some places. The main argument for a significant Lorentz force is that the induction equation (5) is linear in **B** and therefore cannot determine the field strength. This must be limited by the Lorentz force term, so  $\mathbf{j} \times \mathbf{B}$  must be significant at least somewhere in the core, and most dynamo models suggest that equilibration of the magnetic field takes place when the Lorentz and Coriolis forces are comparable.

One of the difficulties of numerical simulations is that they require a substantial amount of dissipation, in particular viscous dissipation, for numerical stability. Thus the balance in the models is often between Coriolis force and viscosity, with the Lorentz force playing only a small role in limiting the field strength without greatly affecting the flow. This is known as the weak field regime, in contrast to the strong field regime in which the Lorentz force is comparable to the other large forces in the equation of motion. This is the essential difference between the strong and weak field dynamo regimes. We address this issue further in the section "Taylor's constraint."

The buoyancy force drives the flow, and so we would expect this force to be comparable to the Coriolis and Lorentz force terms. If we estimate g at  $10 \text{ ms}^{-2}$ , and the coefficient of expansion  $\alpha$  at  $10^{-5} \text{ K}^{-1}$ , we find that the typical temperature fluctuation is in the range  $10^{-3}-10^{-4}$  K. It is rather remarkable that such tiny temperature fluctuations in the core are driving the whole dynamo process, but we should remember that core flows are very slow; even a lethargic snail could go faster! We also have a consistency check here, because the convective heat flux

$$Q_{\rm conv} = \rho c_{\rm p} \int_{S} u_{\rm r} T {\rm d}S, \qquad ({\rm Eq.~13})$$

can be estimated, and when we remember that *T* here is the very small superadiabatic temperature, which is  $10^{-3}-10^{-4}$  K only, we reassuringly discover that this flux is comparable to that suggested by the energy arguments of the section above "Energy balance for a convective dynamo."

The viscous term in the equation of motion turns out to be very small, and so is not in the primary force balance, except in thin *boundary layers in the core* (q.v.). It is however necessary to include the viscous term in the force balance when doing numerical simulations, to ensure numerical stability. Pressure forces are always important in convecting fluids; when buoyant fluid rises, the pressure forces push the ambient fluid aside to make room for the hot rising fluid.

The main balance of forces in the core is therefore between Lorentz force, Coriolis force, buoyancy force, and pressure force. This is known as MAC balance, M standing for magnetic, A for Archimedean force (Buoyancy), and C for Coriolis force (Braginsky, 1967). The word "magnetostrophic" is sometimes used as a synonym for MAC balance, though more commonly magnetostrophic balance refers to situations where buoyancy is absent. Pressure can usually be eliminated by taking the curl of the equation of motion, which converts it into a vorticity equation.

If compositional convection is present, an additional equation of similar form to the temperature equation (12) is required for  $\xi$ , the fraction of light material, and the resulting buoyancy must be included in the equation of motion (see e.g., Braginsky and Roberts, 1995). Equations (5), (11), and (12) can be solved numerically in dynamo simulations, but an important issue is whether laminar or turbulent values should be used for the diffusivities. Laminar values of  $\kappa$  and v are so small it is hard to believe they can be relevant to the core. Turbulent values are therefore generally used, and this raises the interesting question of the nature of turbulence in the Earth's core. The inertial terms, which are responsible for cascading energy down to small scales in "normal" fluids are only effective on tiny length scales in the core, so core turbulence may be quite different from normal turbulence. In particular, the diffusion processes may be quite anisotropic, as suggested by Braginsky and Meytlis (1990).

#### Waves and instabilities

Calculating how the field and the flow evolves in the core can only be done using sophisticated numerical dynamo models. However, insight can be obtained into the rather complicated nature of the dynamics of the core by considering simple equilibrium flows and fields, and analyzing the magnetohydrodynamic waves (q.v.) and instabilities that these simple equilibria undergo when they are slightly perturbed. This leads to linear problems which can be investigated mathematically. Perhaps the most fundamental problem is the case of a uniform magnetic field with fluid at rest (or in uniform motion) with a uniform temperature gradient imposed. Linearizing Eqs. (5), (11), and (12) about a uniform magnetic field  $\mathbf{B}_0$  and constant temperature gradient  $\beta$ , so that  $\mathbf{B} = \mathbf{B}_0 + \mathbf{b}'$ , the velocity is  $\mathbf{u}'$  and the temperature is  $T = \beta z + T'$ . The primed quantities are assumed small so that squares and products of primed quantities are neglected, and then wave solutions with  $\mathbf{u}', \mathbf{b}'$ , and T' proportional to  $\exp(\mathbf{k} \cdot \mathbf{x} - \omega t)$  can be found. Equations (5), (11), and (12) then give the dispersion relation between **k** and  $\omega$ . If the temperature gradient is stabilizing (subadiabatic) then real values of  $\omega$  are found if diffusion is neglected. If diffusion is retained,  $\omega$  is complex with a negative imaginary part corresponding to damped oscillations. If the temperature gradient is superadiabatic, growing waves (instabilities) are found provided the diffusion is not too large.

The dispersion relation is actually very complicated, but it can be simplified when as in the Earth's core, different types of waves have very different frequencies (Fearn et al., 1988). The fastest waves are inertial waves (see the article on gravity-inertio waves and inertial oscillations), which balance the Coriolis and inertial accelerations, and the inertial wave frequency is given by  $\omega_{\rm C} = 2(\mathbf{\Omega} \cdot \mathbf{k})/|\mathbf{k}|$ . The typical period is therefore of the order of a day. These waves have not yet been observed in the core, but they are expected to be driven by tidal forcing. Alfvén waves (q.v.) result from a balance of inertia and Lorentz force in the equation of motion, when combined with the induction equation. These waves have frequency  $\omega_{\rm M} = ({\bf B}_0 \cdot {\bf k})/(\mu \rho)^{1/2}$ and travel at the Alfvén speed,  $\mathbf{B}_0/(\mu\rho)^{1/2}$ , which for a moderate 1 mT core field is around  $10^{-2}$  m s<sup>-1</sup>, giving around 60 years for the wave to travel round the core. An important class of Alfvén waves are those corresponding to azimuthal motion constant on cylinders, which are called *torsional oscillations* (q.v.). These are believed to be important in the core; see "Taylor's constraint" below.

Another timescale comes from the temperature gradient, from the balance of buoyancy and inertia in the equation of motion, combined with the temperature equation (12). The frequency of internal gravity waves is  $\omega_{\rm A} = (g\alpha\beta)^{1/2}k_{\rm H}/{\bf k}|$ , where  $\beta$  is the subadiabatic temperature gradient, and  $k_{\rm H}$  is the component of  ${\bf k}$  perpendicular to gravity. In a convectively unstable region, the temperature gradient is superadiabatic and  $\beta$  is negative. Then  $\omega_{\rm A}$  is imaginary, which corresponds to an exponentially growing unstable mode, with  $|\omega_{\rm A}|$  being the growth rate. With the estimate of  $10^{-4}$  K for a typical superadiabatic temperature fluctuation,  $\beta \sim 10^{-4}/a$ , giving a typical growth rate of about 1 year.

When all the terms in the equation of motion are present, the dispersion relation gives a fast inertial wave and a slow wave in which only the time-derivative terms in the induction and temperature equations are important, inertia being negligible. These slow waves are known as MAC waves and have frequency

$$\omega_{\text{MAC}} = \omega_{\text{MC}} (1 + \omega_{\text{A}}^2 / \omega_{\text{M}}^2)^{1/2}, \text{ where } \omega_{\text{MC}} = \omega_{\text{M}}^2 / \omega_{\text{C}}.$$
(Eq. 14)

When  $|\omega_A| > |\omega_M|$ ,  $\omega_{MAC}$  is imaginary, corresponding to a growing convective mode. The rate of growth is slow, since  $\tau_{MC} = 2\pi/\omega_{MC}$  is of the order of some thousands of years. It is comparable to the magnetic diffusion time, since the ratio  $\tau_{diff}/\tau_{MC} = B_0^2/2\mu\rho\Omega\eta = \Lambda$  and the Elsasser number  $\Lambda$  has a value of O(1) in the core. The MAC growth rate will be a little larger than  $1/\tau_{MC}$  because  $|\omega_A| > \omega_M$ , but these slow growth times are consistent with the time taken for the typical convective velocity to take fluid across the core,  $\tau_{conv} \sim \! 10^{10}$  s, so the dynamical picture does seem to be self-consistent. The main role of the Coriolis acceleration and the Lorentz force is to constrain the convection and slow it down from an unimpeded growth rate of about a year down to  $\tau_{conv}$ .

There are, however, some difficulties. Although for general wave vectors **k** the MAC wave timescale is slow, it is much faster if **k** and  $\Omega$  are perpendicular. This is the case for motions which are independent of *z*, the coordinate parallel to the rotation axis. Then  $\omega_{MC}$  is infinite, which means we have to restore inertia, and we then get the much faster torsional wave frequency. It is also possible for **k** to be perpendicular to both  $\Omega$  and **B**<sub>0</sub>. Such waves have motion only along "plates," planes containing the rotation vector and the magnetic field vector. For these waves Eq. (14) is degenerate, with both  $\omega_{M}$  and  $\omega_{C}$  zero. Such motions are unaffected by the field and the rotation and so will grow on the much shorter  $\omega_{A}$  timescale. We therefore expect these modes to dominate small scale convection in the core (Braginsky and Meytlis, 1990).

The above analysis assumes uniform magnetic fields. Actually the field inside the core is likely to have a complicated structure. Such fields often become unstable, and allow magnetic energy to be converted into kinetic energy. In the Sun, this can happen on a very short timescale, and solar flares are the result. Nothing quite as dramatic is expected in the Earth's core, because magnetic diffusion is much more important there. Nevertheless magnetic instabilities could be important in driving shorter timescale motions and in controlling the strength of the magnetic field. Magnetic instabilities generally become important when the Elsasser number is O(1) (Fearn, 1998), (see also *Core magnetic instabilities*) so this may well be an important mechanism in the core.

#### Taylor's constraint

One interesting consequence of the MAC balance in the core pointed out by J.B. Taylor (1963) was that the geomagnetic field must satisfy a special condition, known as *Taylor's condition* (q.v.). Azimuthal flows that are constant on cylinders coaxial with the rotation axis play a rather special role in rotating flows, because the Coriolis acceleration can be balanced entirely by the pressure force. Such flows are called geostrophic flows. The special feature of the cylinders is that a column of fluid moving along such a cylinder has constant height, so no vortex stretching occurs. J.B. Taylor noted that if we integrate the net azimuthal force over a cylinder, the contribution from the Coriolis term is zero, as is the pressure term, and since buoyancy acts radially, not azimuthally, the only force left is Lorentz force. It follows that

$$\int_{S} (\mathbf{j} \times \mathbf{B})_{\phi} \, \mathrm{d}s = 0, \tag{Eq. 15}$$

where *S* is any cylindrical surface not intersecting the inner core. This is known as Taylor's constraint, and provided viscosity is negligible it must be satisfied in the core. Since the current is related to the field by Ampere's law, (1), Taylor's condition is a constraint on the magnetic field. An interesting question is what happens if we solve an initial value problem in which Taylor's constraint is not initially satisfied? We must then restore part of the inertial term,  $\rho \partial \mathbf{u}/\partial t$ , and the system responds with a fast *torsional oscillation* (*q.v.*), in which Lorentz forces directly accelerate the fluid. These oscillations have a period of some tens of years, and there is evidence that they occur in the core, as they may explain the *decadal variations of the length of day* (*q.v.*) (Jault *et al.*, 1988; Jackson, 1997; Jault, 2003), and possibly shorter period elements of the *geomagnetic secular variation* (*q.v.*), such as the so-called *geomagnetic jerks* (*q.v.*). On the much longer dynamo timescale, these oscillations would then decay away, restoring a field satisfying Taylor's condition. We can view the MAC balance state satisfying Taylor's constraint as a slowly evolving equilibrium state, with the magnetic field slowly changing as the convection moves the core fluid, on a timescale of hundreds of years. Short-term variations of the field on small length scales can be explained by convection, as variations on a short length-scale  $\ell$  would occur on short timescale  $\ell/U_*$ , but the short-term variations on long length scales, such as give rise to the decadal variations of the length of day, could be explained if torsional oscillations were continually being excited, so that the core is always vibrating around its equilibrium MAC state. How these torsional oscillations are excited is not yet understood.

#### Intermediate dynamo models

The full time-dependent three-dimensional equations (5), (11), and (12) are difficult to solve numerically, so it is only recently that computers have become fast enough to make it feasible to study them. Numerical simulations can also be hard to interpret. A compromise position has been to still retain the  $\alpha$ -effect, thus allowing axisymmetric solutions to be found, but to include some dynamics, normally the meridional circulation and the azimuthal flow driven by the magnetic field.

Intermediate dynamo models have often been used to investigate how Taylor's constraint could be met. It was suggested by Malkus and Proctor (1974) that the magnetic field would drive flows of exactly the right type to generate fields satisfying Taylor's constraint. Soward and Jones (1983) looked at an intermediate plane layer model which did indeed lead to solutions satisfying Taylor's constraint, in accord with the Malkus-Proctor scenario. With values of a close to critical, the magnetic field did not satisfy Taylor's constraint. The azimuthal force balance was therefore between the Lorentz force and the Ekman friction in the boundary layer which is  $O(E^{1/2})$ , so that the magnetic field was limited to a value with Elsasser number  $O(E^{1/2})$ . This balance is known as an Ekman state. However, as  $\alpha$ was increased, a value was reached at which the field did satisfy Eq. (15), and at that point the field dramatically increased, leaving the Ekman state and having a strength with Elsasser number O(1). However, Braginsky (1976, 1994) proposed an almost axisymmetric model-Z dynamo (q.v.) in which the Taylor constraint was met in an unusual way. In an axisymmetric configuration, Eq. (15) can be written

$$\frac{\mathrm{d}}{\mathrm{d}s}\left(s^2\int BB_{\mathrm{s}}\mathrm{d}z\right) = 0,\tag{Eq. 16}$$

where  $B_s$  is the component of magnetic field pointing away from the rotation axis. Taylor's constraint could be satisfied if the meridional part of **B** was purely in the *z*-direction, so  $B_s = 0$ , hence the name model *Z* dynamo. Braginsky proposed a specific distribution of  $\alpha$  concentrated near the equatorial region and the CMB, which led to a steady rather than an oscillatory dynamo, as part of the model *Z* scenario. A more detailed analysis by Jault (1995) suggested however that if the viscosity is reduced to very low values, "Taylorization" (that is the approach to a state in which Eq. (15) holds) occurs in the conventional Malkus-Proctor way, with  $B_s$  being small but finite.

Fully three-dimensional simulations usually have to be run with a viscosity too large to achieve "Taylorization" in order to maintain numerical stability. However, Rotvig and Jones (2002) have run fully three-dimensional simulations in plane geometry, which is less demanding computationally, and allows smaller E to be reached. They found that "Taylorization" did occur at the lowest values of E they could reach.

Another way of simplifying the full three-dimensional problem, is the so-called " $2\frac{1}{2}$ -dimensional" approach. Here full resolution is used in the *r* and  $\theta$  directions, but in the azimuthal  $\phi$ direction a severe truncation is imposed; in the most draconian approximation only the axisymmetric and one nonaxisymmetric exp(*im* $\phi$ ) modes are retained (e.g., Jones *et al.*, 1995). This still allows nonaxisymmetric convection to occur, so no  $\alpha$ -mechanism is needed, and the results are generally qualitatively similar to those obtained from fully three-dimensional simulations, but at much reduced cost. The disadvantage is that unless results are checked by fully three-dimensional simulations, one cannot be certain that the truncation is not affecting the behavior; nevertheless " $2\frac{1}{2}$ -dimensional" models are very useful for testing out new ideas in dynamo theory.

#### Role of the inner core

As mentioned in the energy balance section, the inner core makes an important contribution to the driving of convection in the core. It also significantly affects the dynamics of core convection. The importance of geostrophic motions in rapidly rotating fluids suggests that the solid inner core could play an important role in the dynamics of the Earth's interior. The cylinder, which just touches the inner core, is called the *inner core tangent cylinder* (q.v.). Whereas the volume of the inner core, the fraction inside the tangent cylinder is much larger.

The flow outside the tangent cylinder can convect heat out in tall thin columns, which although not exactly geostrophic, because some vortex stretching occurs as the columns rotate due to the sloping boundaries, nevertheless minimizes the effect of rotation. Inside the tangent cylinder the convection needs to get the heat out in a direction almost parallel to the rotation axis, and tall thin columns run into the inner core, causing additional friction. In consequence, most models show that convection is more efficient outside the tangent cylinder than inside it. This difference produces a latitudinal temperature gradient, with the poles being slightly hotter than the equator on a sphere of constant radius. Neglecting magnetic forces, the azimuthal component of the curl of Eq. (11), then gives the *thermal wind* (q.v.) equation,

$$2\Omega \frac{\partial u_{\phi}}{\partial z} = \frac{g\alpha}{r} \frac{\partial T}{\partial \theta}$$
(Eq. 17)

where z is the coordinate parallel to the rotation axis and  $\theta$  is the meridional direction in spherical polars  $(r, \theta, \phi)$ . This shows that  $u_{\phi}$ decreases with z in the northern hemisphere. A similar effect drives the jet stream in the Earth's atmosphere, though the sign is different (the jet stream velocities increase with height, because the pole is colder than the equator, and so the jet stream goes from west to east relative to the surface) and of course temperature gradients and velocities are much smaller in the core. Nevertheless, the thermal wind is sufficient to give a rotation of the inner core (q.v.) relative to the mantle. The strength of the thermal wind can also be affected by magnetic torques. It has been suggested (Buffett and Glatzmaier, 2000) that the acceleration produced by the thermal wind may be counteracted by a gravitational coupling of the inner core to the mantle, which may be expected if there are slight departures from axisymmetry in the figure of the mantle and the inner core. The rotation of the inner core relative to the mantle can in principle be measured by seismologists, but the actual value of the inner core rotation rate is still controversial (e.g., Collier and Helffrich, 2001).

# **Reversals and field morphology**

Two obvious questions about the geodynamo are (i) why is the field dominated by an axial dipole component? (ii) why does the field periodically reverse its polarity? Our lack of a full understanding of the geodynamo is perhaps highlighted by the fact that neither of these questions can be answered unambiguously. The majority of dynamo simulations do show a dipole dominated field, but by no means all do (e.g., Christensen *et al.*, 1999; Busse, 2002), and the Karlsruhe experimental dynamo was dominated by an equatorial rather than an axial dipole. Quadrupolar dynamos, equatorial dipoles, and axial dipoles can all be produced from flows, which are apparently not that dissimilar. A number of trends are apparent from the simulations; for example, a strong azimuthal flow makes an equatorial dipole less likely, as the shearing motion associated with differential rotation tends to disrupt an equatorial dipole field. Dipolar fields tend to be more common when the convection is driven by a flux of heat from the inner core, whereas quadrupolar dynamos are more common in uniformly heated models, and there is a tendency (Busse, 2002) for dipoles to be preferred over quadrupoles at higher Rayleigh number. However, all these observations are model dependent, and it should not be forgotten that it is not currently possible to run geodynamo models in the correct parameter regime.

A large number of papers have addressed the issue of the *theory of* reversals (q.v.) (see e.g., Sarson, 2000). One simple point is that the dynamo equations are invariant under a reversal of the field direction, so if a solution with "normal" polarity exists, an exactly similar one with reversed polarity also exists. To see this note that the transformation  $\mathbf{B} \to -\mathbf{B}$  changes the sign of both  $\mathbf{B}$  and  $\mathbf{j}$ , so the Lorentz force  $\mathbf{j} \times \mathbf{B}$  is unchanged, and the induction equation is linear in  $\mathbf{B}$  so reversing the sign of  $\mathbf{B}$  leaves this equation unchanged. This observation shows that it is reasonable to expect the geodynamo to reverse occasionally, but it doesn't explain why reversals are comparatively infrequent (there are only a few reversals per million years on average) and why they happen relatively quickly (around 5 ka or less) when they occur.

The magnetic field is continually fluctuating, and reversals appear to be part of this process. Magnetic excursions, events where the axis of the dipolar component moves rapidly away from the geographic poles occur much more frequently than full reversals, so it is possible that excursions are in some sense failed reversals, where the fluctuation is large but not large enough to cross a threshold leading to full reversal. Hollerbach and Jones (1993, 1995) suggested that the threshold necessary was that the field in the solid inner core had to be reversed. Since this can only occur by magnetic diffusion, rather than on the somewhat more rapid convective turnover time, only the larger, longer, excursions would allow the inner core field to reverse, and hence establish a full reversal. Numerical simulations of the geodynamo also suggest that the core is in a continually fluctuating state, and that some of these fluctuations occasionally lead to reversals. Glatzmaier et al. (1999) found that a spatially inhomogeneous heat flux at the core-mantle boundary could affect reversal frequency (see also Inhomogeneous boundary conditions and the dynamo). This is an interesting possibility, as mantle convection models suggest that such inhomogeneities are likely, and indeed seismic measurements of the CMB region also suggest there is such inhomogeneity. This would provide a link between mantle convection and the dynamo, and since mantle convection evolves on a very long million year timescale, this could explain why reversals are very infrequent compared to excursions. For example, on this picture during the 60-million-year Cretaceous superchron, during which there were no significant reversals, mantle convection was in a pattern, which affected the core flow in such a way as to make reversals unlikely. Sarson and Jones (1999) suggested that this might be connected with the meridional circulation, which would be associated with an inhomogeneous CMB heat flux, as in their model the strength of the meridional circulation played an important role in the reversal process.

There is much that we do not yet understand about the dynamics of the Earth's core and the reversal process, but progress is being made on a number of different fronts: better numerical simulations, and deeper understanding of the processes involved; more detailed and more accurate paleomagnetic studies giving information about the past behavior of the geomagnetic field; new results from seismology, probing the structure of the Earth's deep interior ever more thoroughly; a new and better understanding of the physical properties of matter at very high pressure. With all these stimuli, our understanding of the geodynamo will surely radically improve over the coming decades.

# GEODYNAMO, DIMENSIONAL ANALYSIS AND TIMESCALES

It is common to put the equations governing a complex physical system like the geodynamo into dimensionless form. This clarifies the importance of each term in the equations and can reduce the number of input parameters to a minimum. Consider the very simple example of the *kinematic dynamo* (q.v.), which is governed by a single partial differential equation, the induction equation:

$$\frac{\partial \boldsymbol{B}}{\partial t} = \nabla \times (\boldsymbol{\nu} \times \boldsymbol{B}) + \frac{1}{\mu_0 \sigma} \nabla^2 \boldsymbol{B}.$$
 (Eq. 1)

The fluid velocity is specified within a sphere and the induction equation solved for a growing magnetic field. It depends on just three input parameters: the amplitude of the velocity V, the radius of the sphere c, and the electrical conductivity  $\sigma$ . In dimensionless form this reduces to just one input parameter, the magnetic Reynolds number  $R_m = \mu_0 \sigma V c$ , where  $\mu_0$  is the permeability of free space (see Tables G2 and G3). Kinematic dynamo behavior therefore depends on the product of the three dimensional input parameter but not on all three independently. This is a great help in exploring the behavior of the system as a function of the input parameters. Incidentally, it means that scaling the Earth down to a laboratory-sized experiment would require a great increase in fluid velocity to compensate for the reduction in

 Table G2 Illustrative numerical values of core parameters used

Property	Symbol	Molecular	Turbulent
Density	ρ	10 <sup>4</sup> kg m <sup>-3</sup>	
Gravity	g	$0-10 \text{ m s}^{-2}$	
Core radius	c	3484 km	
Inner core radius	$r_i$	1215 km	
Outer core depth	$d = c - r_i$	2269 km	
Angular velocity	Ω	$7.272 \times 10^{-5}$	
Kinematic viscosity	v	$10^{-6} \text{ m}^2 \text{ s}^{-1}$	1 at room temperature
Electrical conductivity	σ	$5\times 10^5~S~m^{-1}$	
Thermal conductivity	k	$50 \text{ W m}^{-1} \text{ K}^{-1}$	
Specific heat	$C_{\rm p}$	$700 \text{ J kg}^{-1} \text{ K}^{-1}$	
Magnetic diffusivity	$\eta = (\mu_0 \sigma)^{-1}$	$1.6 \text{ m}^2 \text{ s}^{-1}$	$1.6 \text{ m}^2 \text{ s}^{-1}$
Thermal diffusivity	$\kappa = k(\rho C_{\rm p})^{-1}$	$7  imes 10^{-7} \text{ m}^2 \text{ s}^{-1}$	$1.6 \text{ m}^2 \text{ s}^{-1}$
Molecular diffusion	D	$10^{-6} \text{ m}^2 \text{ s}^{-1}$	$1.6 \text{ m}^2 \text{ s}^{-1}$
Thermal expansion	α	$5  imes 10^{-6} \ { m K}^{-1}$	
Typical core velocity	V	$10^{-4} \text{ m}^{-1}$	
Typical magnetic field	В	1 mT	
Adiabatic gradient	$T'_{-}$	$0.1 \text{ K km}^{-1}$	
Core heat flux	O	5 T W	
Temperature gradient	$\tilde{T}'$	$0.5 \text{ K km}^{-1}$	

length scale (increasing the conductivity is impossible since there are no materials at room temperature with electrical conductivity significantly higher than that of iron in the core).

Nondimensionalization is by no means a unique process: there are many ways in which to scale the dimensional variables, each giving different versions of the same equations. Consider once again the kinematic dynamo problem. The usual approach is to scale length with the radius *c* and time with the magnetic diffusion time,  $\mu_0 \sigma c^2$ . This leads to the form

$$\frac{\partial \boldsymbol{B}}{\partial t} = R_{\rm m} \nabla \times (\boldsymbol{\nu} \times \boldsymbol{B}) + \nabla^2 \boldsymbol{B}. \tag{Eq. 2}$$

so that  $R_{\rm m}$  can be regarded as a dimensionless measure of the fluid velocity. A second way to nondimensionalize the induction equation is to scale time with the overturn, or advection, time c/V, the time it takes for fluid to cross the sphere. This leads to the form

$$\frac{\partial \boldsymbol{B}}{\partial t} = \nabla \times (\boldsymbol{\nu} \times \boldsymbol{B}) + R_{\rm m}^{-1} \nabla^2 \boldsymbol{B}.$$
 (Eq. 3)

Now the inverse magnetic Reynolds number is a dimensionless measure of magnetic diffusion. At first sight, Eqs. (2) and (3) appear to contradict each other; the difference arises from the definition of time, t.

In this article, I shall consider the fairly general case of a geodynamo driven by a combination of heat and compositional buoyancy, governed by the equations of momentum, induction, heat, and mass transfer. The full geodynamo problem is usually put into a nondimensional form that leaves just four independent input parameters, the Rayleigh number  $R_a$ , Ekman number E, the Prandtl number  $P_r$ , and the magnetic Prandtl number  $P_m$ . These are defined and estimated in Table G3. Other nondimensional numbers are calculated from the solution of the equation, although they can also be independent input parameters for subproblems. Two examples are the magnetic Reynolds number, which depends on the fluid velocity and is therefore calculated from the convective flow from the full dynamo problem but is

Table G3 Dimensionless numbers

Name	Definition	Molecular	Turbulent
Rayleigh	$R_{\rm a} = g\Delta \rho' d^3 / \kappa v$	10 <sup>30</sup>	$7 \times 10^{17}$
Modified Rayleigh	$R_{\rm a}^{\rm m} = R_{\rm a}E = g\Delta\rho'd/\kappa\Omega$	$10^{15}$	$8 imes 10^8$
Buoyancy	$R_{a}^{B} = g\Delta\rho'/\Omega^{2}d$	3	3
Ekman	$E = v/\Omega c^2$	$10^{-15}$	$10^{-9}$
Prandtl	$P_{\rm r} = v/\kappa$	1.4	1

Mass Peclet	$P_{\rm D} = Vc/D$	$3  imes 10^8$	200

Those above the line are measured directly; those below the line are inferred from putative core composition, temperature, and pressure T' is the excess temperature gradient over the adiabat  $T'_a$ , as defined in Eq. (4). Current dynamo models usually assume some form of turbulence that brings the small diffusivities of heat, momentum (viscosity), and mass up to the larger value of the electrical diffusivity. For illustration I have taken these values equal to 1.6 when calculating turbulent values in Tables G3 and G4.

Those above the line appear explicitly in formulations of the geodynamo equations; those below are derived from solutions to the geodynamo problem; those in column 4 are for nominal turbulent values of the diffusivities,  $\kappa = v = D = \eta = 1.6 \text{ m}^2 \text{ s}^{-1}$ . Rayleigh and buoyancy numbers are calculated for thermal convection by replacing  $\Delta \rho'$  with  $\alpha \Delta T$ , where  $\rho'$  is the departure from the adiabatic density gradient, and  $\Delta T$  is the temperature difference from the adiabat. Values for compositional convection are likely to be higher.  $Q_a$  is the heat conducted down the adiabat.

the sole input parameter for the kinematic dynamo as already mentioned; and the Elsasser number (see below), which depends on the magnetic field strength but is the main input parameter to the magnetoconvection problem, in which a magnetic field is imposed rather than being self-generated.

The nondimensional numbers represent ratios of terms appearing in the governing equations: they are ratios of forces in the momentum equation, of magnetic induction in the induction equation, of heat transfer in the heat equation, and of mass transfer in the material diffusion equation. Further physical insight may be obtained by expressing them as ratios of timescales. The Earth's magnetic field varies on an enormous range of timescales, from less than a year for geomagnetic *jerks* (q.v.) to a million years between reversals, and its age is comparable with that of the Earth. Timescales contained within the geodynamo equations span an even wider spectrum, from a single day, the timescale of the Coriolis force, to the molecular viscous and heat diffusion times, which exceed the age of the Earth itself (Table G4). This enormous disparity of timescales makes numerical simulation of the geodynamo very difficult, more so than the range of length scales involved, because the computer must resolve details on the shortest timescale, then integrate the equations for sufficient time to demonstrate dynamo generation in order to follow the evolution. The very long viscous and thermal diffusion times are impossible to simulate and are usually shortened by assumed turbulent enhancement of the diffusivities (see Core turbulence), often by simply equalizing the diffusivities to the largest, electrical, diffusivity.

A summary of relevant timescales is given in Table G4. Diffusion times are quoted by the formula shown; true diffusion times in a sphere for magnetic, viscous, thermal, and compositional diffusion contain the factor  $\pi^2$  to give the time taken for a dipole field to fall by a factor of *e*. Geometrical factors and wavenumbers have been omitted from the formulae for dimensionless numbers in Table G5. The periods of MAC waves depend on the wavenumber and are considerably shorter than the time quoted in the table. Each group of nondimensional parameters is now discussed in turn.

# Rayleigh, modified Rayleigh, buoyancy numbers buoyancy: dissipation

The Rayleigh number multiplies the buoyancy force in the dimensionless equation of motion and as such measures the driving force of the convective dynamo. This discussion is restricted to thermal convection but the same remarks apply to compositional convection with concentration replacing temperature, D replacing  $\kappa$ , and a compositional expansion coefficient replacing  $\alpha$ . I do not discuss complications involving both thermal and compositional buoyancy since there has been very little discussion of it in the literature to date, and no direct observations.

 $R_{\rm a}$  is a complicated combination of dimensional parameters and is very difficult to estimate numerically. For free convection heated from below, a critical value of the Rayleigh number must be exceeded before convection starts. This is because motion is opposed by viscous forces and heat, the source of the buoyancy, can dissipate away by conduction. Consider the balance of buoyancy and viscous forces for a rising, hot, light blob:  $\rho \alpha \Delta Tg = \rho v V_S/d^2$ . The blob falls with terminal (Stokes) velocity when buoyancy equals viscous drag, of order  $V_{\rm S} = \alpha g \Delta T d^2 / v$ . The time to rise through the core is  $\tau_{\rm B} = d/V_{\rm S} = v/\alpha \Delta Tg d$ . Buoyancy is lost by diffusion of heat into the surrounding fluid, restricting the power of the convection. The Rayleigh number is the ratio of the thermal diffusion time  $\tau_{\kappa} = d^2/\kappa$ to the viscous buoyant rise time:  $R_{\rm a} = g \alpha \Delta T d^3 / \kappa v$ . Vigor of convection is measured by the speed with which fluid rises compared to the speed with which heat is lost by conduction.

There are two major difficulties with estimating  $R_a$  in the core. First, it is virtually impossible to estimate the temperature difference  $\Delta T$  driving the convection. The correct boundary condition for core

 Table G4 Timescales for the Earth's core, definition, and numerical estimates in years

Time	Definition	Molecular	Turbulent
Magnetic diffusion (core)	$ au_\eta = c^2/\eta\pi^2$	25000	25000
Magnetic diffusion (inner core)	$\tau_i = r_i^2 / \eta \pi^2$	3000

Rossby	$\tau/\tau_v$
Thermal Péclet	$\tau_{ m V}/\tau_{\kappa}$
Mass Péclet	$ au_{ m V}/ au_D$

convection is constant heat flux imposed by the convecting and cooling mantle. This gives the temperature gradient at the core surface, from which we must subtract the adiabatic gradient, which would hold in the absence of any convection:

$$T' = \frac{Q}{4\pi c^2 k} - T'_a. \tag{Eq. 4}$$

We could then take  $\Delta T$  to be the product of the temperature gradient T' and the outer core depth d. The problem is that Q is very uncertain and  $T'_a$  poorly known. We do know, however, that the core must convect in order to produce a dynamo, and that T' must exceed the adiabat by enough to power the dynamo. Gubbins (2001) estimates  $R_a$  in this way to be about 1000 times the critical value for nonmagnetic convection. Jones (2000) gives an independent argument based on the speed of the flow in the core and arrives at a similar value. The critical Rayleigh number depends strongly on both rotation, which increases it, and magnetic field, which in combination with rotation decreases it;  $R_a$  in the core seems to be close to the critical value in the absence of any magnetic field (Gubbins, 2001). The Rayleigh number for compositional convection could be much higher.

Studies of magnetoconvection have shown that, at high rotation rates, the critical Rayleigh number varies as  $E^{-1}$ , prompting some authors to use the modified Rayleigh number  $R_aE$ . This takes account, to some extent, the effect of rotation on the stability of convection.  $R_aE$ 

contains only the thermal diffusivity and not the fluid viscosity, which plays a negligible role in resisting the flow compared to the magnetic force. The presumed force balance is between Coriolis and buoyancy forces, leading to the scaling  $g\alpha\Delta T \sim \Omega V$ ; the relevant timescale is then

$$\tau_{\Omega} = c/V = \frac{c\Omega}{g\alpha\Delta T}.$$

The modified Rayleigh number is then seen as the ratio of thermal diffusion time to Coriolis rise time  $\tau_{\kappa}/\tau_{\Omega}$ . Others have used a buoyancy parameter that involves no diffusivity. This is the ratio of the day to the Coriolis rise time. Further details may be found in, for example, Gubbins and Roberts (1987).

#### Nusselt number-convected heat: conducted heat

The Nusselt number is a different dimensionless measure of the heat driving the convection. It is usually quoted as the ratio of convected heat flux to conducted heat flux for convection between boundaries with fixed temperatures. The situation in the Earth's outer core is somewhat different. First, the boundary conditions are fixed temperature at the bottom (melting temperature) and fixed heat flux at the top (as dictated by mantle convection). The Nusselt number is therefore, in some sense, an input parameter for the geodynamo problem. Second, the conduction profile includes the adiabatic gradient, which is steep and responsible for conduction of a large amount of heat in the context of the Earth's thermal history. It is not really an estimate of the vigor of the convection, which depends on the superadiabatic temperature gradient rather than the absolute value. Estimates of  $N_u$  in the core are inevitably restricted to low values, from 1 to 10, because of limits on the heat coming from the core.

#### Ekman number-viscous force: Coriolis force

*E* is tiny, whether we use molecular or turbulent values of the viscosity, reflecting the enormous disparity between the viscous and diurnal timescales. Smallness of *E* causes the greatest difficulty in numerical simulations of the geodynamo, even when turbulent diffusivities are used. The smallest values of *E* achieved in numerical simulations so far are  $10^{-5}-10^{-7}$ , compared with  $E = 10^{-9}$  for the Earth's core assuming a turbulent viscosity.

#### Rossby number-inertial: Coriolis force

 $R_{\rm o}$  is a measure of the importance of inertial forces Dv/Dt in the equation of motion. It is small in the core and many studies have dropped the inertial terms altogether. This may not be appropriate, since inertial terms may play a role in restoring the balance between magnetic, buoyancy, and rotational forces. Inertia also plays an essential role in *torsional oscillations* (*q.v.*).

#### Prandtl numbers

The Prandtl number measures the ratio of viscous to thermal diffusion. Liquid metals generally have small Prandtl numbers of order 0.1, and many studies have focused on this. Others have taken  $P_r = 1$ , consistent with the assumption of turbulence equalizing the diffusivities.  $P_m$  and  $P_q$  also have extremely low values that cause problems. Similar remarks apply to compositional diffusion.

# Magnetic Reynolds number—induction: magnetic diffusion

 $R_{\rm m}$  is a dimensionless measure of the fluid velocity, the input parameter for kinematic dynamos, and is the ratio of the overturn and magnetic diffusion times. It must exceed a critical value for dynamo action, for which there are lower bounds (see Antidynamo and bounding theorems). Estimates of fluid flow in the core, based on inferences from secular variation, yields  $R_{\rm m} \approx 200$ , low but well above the critical values required for dynamo action.

#### Péclet numbers—advection: diffusion

Like the magnetic Reynolds numbers,  $P_{\rm e}$  and  $P_{\rm D}$  measure the importance of advection in the heat and mass transfer equations, respectively. They are the ratios of the day to viscous diffusion time, and day to compositional diffusion times, respectively.

#### Elsasser number-magnetic: Coriolis force

A is a dimensionless measure of the Lorentz force and an essential input parameter for magnetoconvection. The balance between magnetic, buoyancy, and Coriolis forces (MAC) leads to magnetohydrodynamic waves with periods of centuries to millennia (see *Magnetohydrodynamic waves*). They are highly dispersive and under certain simple conditions have wavespeeds given by  $V_{MAC} = kB^2/\Omega\rho\mu_0$ , where k is the wavenumber. A "MAC" timescale can then be defined as the time taken for a MAC wave with wavelength c to cross the core,

$$\tau_{\rm MAC} = \frac{c}{V_{\rm MAC}} = \frac{\Omega \rho \mu_0 c^2}{B^2}$$

The Elsasser number is then  $\Lambda = \tau_{\eta}/\tau_{MAC}$ . Small  $\Lambda$  is the condition for large-scale MAC waves to pass through the core with little dissipation. The numerical value for  $\tau_{MAC}$  in Table G4 is rather long: a typical MAC wave with wavelength 1000 km would have timescale closer to 1 ka; a stronger core field of 10 mT, the value usually taken in MAC wave studies, would reduce it by a factor of 100.

#### Less common dimensionless numbers

The above list includes those in common usage in geodynamo theory. Other numbers are used occasionally, and some have different names. The Taylor number is the inverse square of the Ekman number, the ratio of centrifugal to viscous force (and for the core is one of the biggest numbers one is ever likely to come across!). The Chandrasekhar number  $B^2 \sigma d^2$  is a useful measure of the magnetic force in place of the Elsasser number when rotation is unimportant; it measures the relative strengths of magnetic and diffusive forces. The Hartmann number,  $B\sigma^{1/2}d/\mu_0^{1/2}$ , is important in boundary layer theory; it measures the ratio of magnetic to viscous forces. The Alfvén (q.v.) number,  $V(\rho\mu_0)^{1/2}/B$ , is a magnetic Mach number, the ratio of flow speed to the speed of Alfvén waves. Its inverse is the Cowling number. Neither are in common use in geomagnetism, although Merrill and McElhinny (1996) define the Alfvén number as the Cowling number. The degree to which magnetic fields are frozen-in is usefully measured by the Lundqvist number,  $\mu_0 \sigma B \eta / \rho^{1/2}$ , the time for Alfvén waves to cross the core divided by the magnetic diffusion time.

# GEODYNAMO, ENERGY SOURCES

The magnetic field of the Earth is maintained against ohmic losses by dynamo action in the fluid core which takes its energy from several sources of different natures and amplitudes, all being consequences of the thermal evolution of the core. Moreover, each source has a different efficiency in maintaining ohmic dissipation compared to the others. The study of these problems is then of major importance for understanding dynamo theory as well as the thermal evolution of the Earth.

#### **Evolving reference state**

The core of the Earth is composed of iron, nickel, and some lighter elements, with concentrations that are still matter of lively debates (see *Core composition*, and Poirier, 1994). The light elements play a very important dynamical role in maintaining the geodynamo since their rejection upon inner core crystallization drives compositional convection in the core (see *Convection, chemical*). The core is therefore usually modeled as a binary alloy of Fe and some light element X. Including a more realistic chemistry in thermal evolution models on the core would add complexity (although no real difficulty) in the derivations without really improving the understanding, unless not yet documented coupled effects occur.

The Earth's core is different from a well-controlled convection experiment in a laboratory, in the fact that it is continually evolving on geological timescales and that the energy for the motion comes from that evolution. Fortunately, the timescales relevant for this evolution and that for the dynamics are very different and can be separated. To get expressions for the different energy sources in the balance, we need to know in what state is the core when averaged on a timescale long compared to the one relevant to the dynamics but short compared to the one associated with the thermal evolution. The short-time dynamics is responsible for maintaining the core close to that reference state whereas the evolution of the reference state provides the energy sources needed by the dynamics.

Convection in the liquid core is assumed to be very efficient so that, outside of tiny boundary layers (see *Core, boundary layers*), all extensive quantities responsible for the movement (entropy *s* and mass fraction of light elements  $\xi$ ) are uniform:  $\nabla \xi = 0$  and  $\nabla s = 0$ . In addition, the momentum equation is assumed to average to the hydrostatic balance:  $\nabla p = \rho g$ , with  $\rho$  the density and *g* the acceleration due to gravity. It is often useful to know what the temperature is in the reference state (see *Core temperature*) and isentropy and isochemistry implies it to be adiabatic (see *Core, adiabatic gradient*)

 $\nabla T = \alpha g T / C_p$ , with  $\alpha$  the coefficient of thermal expansion and  $C_p$  the heat capacity at constant pressure.

The set of partial differential equations defining the reference state must be supplemented by an equation of state relating the density to the pressure, for example at constant entropy, and by boundary conditions. In terms of temperature, the equilibrium between solid and liquid at the inner core boundary (ICB) provides the required condition, the liquidus of the core alloy being given (see *Melting temperature of iron in the core, Theory and melting temperature of iron in the core, experimental*) as a function of radius in the core. Depending on the choice of equation of state, one can get different expressions for the different profiles in the reference state, usually in the form of some series expansion of powers of the radius.

It should be noted that the actual averaged state cannot be exactly hydrostatic, owing to its being compressible and compressing with time, but the corrections to this balance are negligible for the energetics of the core (Braginsky and Roberts, 1995). The deviations from the isentropic, well mixed state can also be estimated from the amplitude of fluid velocity at the top of the core which also allows an estimate of the typical scale for the size of boundary layers. These are found to be a negligible contribution to averaged quantities (e.g., Braginsky and Roberts, 1995), although they are very important for the dynamics of the core.

### **Energy equation**

The equation for total (internal, kinetic, magnetic, and gravitational) energy conservation can be integrated over the volume of the core and it states that the total heat loss of the core, the heat flow across the core-mantle boundary (CMB), is balanced by the sum of four terms, the secular cooling  $Q_C$  associated with the heat capacity of the core, the latent heat  $Q_L$  associated with the gradual freezing of the inner core, the gravitational energy  $E_G$  associated with the rearrangement in the outer core of the light elements that are released at the ICB by the freezing of the inner core, and possibly the radioactive heating  $Q_R$ ,

$$Q_{\rm CMB} = Q_{\rm C} + Q_{\rm L} + E_{\rm G} + Q_{\rm R}.$$
 (Eq. 1)

The first three terms are related to the growth of the inner core and can be written as a function of the radius of the inner core c times its time derivative. The exact expression of these three functions depends on the choice of equation of state and parameterization and the expressions of Labrosse (2003) can be written to first order as:

$$Q_{\rm C} = \frac{8\pi}{3} b^3 \rho_0 C_P T_{\rm L}(c) \left(1 - \frac{2}{3\gamma}\right) \frac{c}{L_T^2} \frac{\mathrm{d}c}{\mathrm{d}t},$$
 (Eq. 2)

$$Q_{\rm L} = 4\pi c^2 \rho(c) T_{\rm L}(c) \Delta S \frac{\mathrm{d}c}{\mathrm{d}t}, \qquad (\text{Eq. 3})$$

$$E_{\rm G} = \frac{8\pi^2}{3} G \Delta \rho \rho_0 c^2 b^2 \left(\frac{3}{5} - \frac{c^2}{b^2}\right) \frac{\mathrm{d}c}{\mathrm{d}t},\tag{Eq. 4}$$

with *b* and *c* the radii of the outer and inner core respectively,  $\rho_0$  the central density,  $C_P$  the heat capacity,  $T_L$  the liquidus temperature,  $\gamma$  the Grüneisen parameter (see *Grüneisen's parameter for iron and Earth's core*),  $L_T$  the adiabatic length scale,  $\Delta S$  the entropy of crystallization,  $\Delta \rho$  the chemical density jump across the ICB (see *Core density*), and *G* the gravitational constant. All these physical parameters can be estimated with more or less accuracy using combinations of geophysical data (mostly seismology) and mineral physics (see *Core properties, physical; Core properties, theoretical determination*).

Convective mixing can be assumed to be sufficient to ensure a uniform mass rate h(t) of radioactive heating in the core. Therefore,

radioactive heating is not related to inner core growth and is simply equal to  $M_N h(t)$ , with  $M_N$  the mass of the core. This energy source can then be easily computed, provided one knows the concentration in radioactive elements in the core. Among all possible heat producing isotopes, 40K has always been the most popular candidate, owing to its apparent depletion in the mantle compared to Earth forming meteorites and its predicted metalization at high pressure that would allow it to enter the core. However, potassium is also somewhat volatile and its budget in the Earth is influenced by accretion processes. In addition, the concentration of potassium in the core depends strongly on the scenario of core formation, a process still far from perfectly understood (e.g., Stevenson, 1990). The most recent experiments devoted to the partitioning of potassium between iron and silicates (e.g., Gessmann and Wood, 2002; Lee and Jeanloz, 2003; Rama Murthy et al., 2003) favor a concentration of potassium in the core of O(100) ppm, producing less than 1 TW at present but exponentially more in the past. Such a value is too small to affect importantly the thermal evolution of the core (Labrosse, 2003) and radioactivity will not be considered further.

The gravitational energy actually comes in the equations as a compositional energy, due to a change of composition in a gradient of chemical potential (Braginsky and Roberts, 1995; Lister and Buffett, 1995). It is equal to the change of gravitational energy due only to chemical stratification of the core. Other sources of change of gravitational energy do not contribute significantly to this balance and are mostly stored as strain energy.

As can be seen on Eqs. (2–4), for the different energy sources to be estimated, one needs to know the growth rate of the inner core. Since there is no direct way of measuring this number, one usually uses an estimate of the heat flow across the CMB to get this number from the energy balance (1). The heat flow across the CMB is not very well-known (see *Core-mantle boundary, heat flow across*) but for a value of 10 TW (say) and no radioactive elements, one gets approximately (Labrosse, 2003)  $Q_{\rm C} = 5.5$  TW,  $Q_{\rm L} = 2.8$  TW,  $E_{\rm G} = 1.7$  TW.

The energy balance can be used for any time in the history of the Earth to give the growth history of the inner core and the evolution of all energy sources in the balance, provided the heat flow across the CMB is known as a function of time. Moreover, this equation can be integrated between the onset time of inner core crystallization and the present to compute the age of the inner core (Labrosse *et al.*, 2001). A typical example of time evolution of the energy balance is shown on Figure G12, where the onset of inner core crystallization, at an age of 1 Ga, is marked by a qualitative change in the balance: before, only secular cooling is balancing  $Q_{\rm CMB}$  (in absence

of radioactivity) but this term is greatly decreased when the inner core starts to crystallize and both latent heat and compositional energy come in the balance.

### Entropy equation

The energy equation does not involve the magnetic field directly and contains no contribution from the dissipative heating. This is a wellknown characteristic of convective engines: in contrary to Carnot engines, dissipation occurs inside the system and is then not lost. In order to relate the energy sources to the magnetic field generation, an entropy balance equation must be written. This equation comes from a combination of the momentum balance equation and the energy balance equation written above (e.g., Braginsky and Roberts, 1995) and states that the entropy that flows out through the CMB is balanced by the sum of the entropy that flows in due to the different heat sources and the entropy that is produced by nonreversible processes, mostly ohmic dissipation and conduction along the adiabatic temperature profile. This equation does not directly involve the gravitational energy, since it is not a heat source. It can however, be brought back into the equation by use of the energy balance to suppress the heat flow across the CMB, giving an efficiency equation,

$$\Phi + T_{\rm D} \int_{OC} k \left(\frac{\nabla T}{T}\right)^2 \mathrm{d}V = \frac{T_{\rm D}}{T_{\rm CMB}} \left[ E_{\rm G} + \frac{T_{\rm ICB} - T_{\rm CMB}}{T_{\rm ICB}} (Q_{\rm ICB} + Q_{\rm L}) + \frac{T_{\rm R} - T_{\rm CMB}}{T_{\rm R}} Q_{\rm R} + \frac{T_{\rm C} - T_{\rm CMB}}{T_{\rm C}} Q_{\rm C} \right],$$
(Eq. 5)

where it can be seen that each energy source contributes in maintaining both the total ohmic dissipation  $\Phi$  and the conduction along the adiabatic gradient, but with different efficiency factors. In particular, this equation shows that the gravitational energy has an efficiency factor that is the ratio of the effective temperature  $T_D$  at which ohmic dissipation occurs to the temperature at the CMB,  $T_{\rm CMB}$ , whereas all heat sources efficiency factors have a contribution from the classical Carnot engine efficiency factor,  $(T_{\rm X} - T_{\rm CMB})/T_{\rm X}$ , with  $T_{\rm X}$  the temperature at which the heat source X is provided. This shows that compositional energy is more efficiently transformed in dissipation than all heat sources and that the efficiency of each heat source depends on the temperature at which it is provided.

**Figure G12** Energy (*left*) and entropy (*right*) balances of the core as a function of time for a typical evolution model without radioactivity. (After Labrosse, 2003).

302

The energy sources on the right-hand side of Eq. (5) are the same as that appearing in the energy balance Eq. (1) and, except for  $T_D$ , their efficiency factors can be expressed using the parameters characterizing the reference state of the core. It can then be proved that all terms, except the radioactive heating one, is a function of the radius of the inner core and is proportional to its growth rate. This means that, if the heat flow across the CMB is known, this growth rate can be computed from the energy equation (1), and the entropy equation (5) then gives the ohmic dissipation that is maintained. Alternatively, one can take the opposite view and compute the growth rate of the inner core that is required to maintain a given ohmic dissipation, the energy balance being then used to get the heat flow across the CMB that makes this growth rate happen. Unfortunately, the ohmic dissipation in the core is no better known than the heat flow across the CMB, since it is dominated by small-scales of the magnetic field and possibly by the invisible toroidal part of it (Gubbins and Roberts, 1987; Roberts et al., 2003). However, the value of  $Q_{\rm CMB} = 10$  TW used above gives a contribution of ohmic dissipation to the entropy balance  $\Phi/T_{\rm D} = 500 \ {\rm MWK^{-1}}$ . The temperature  $T_{\rm D}$  is not well-known, but is bounded by the temperature at the inner core boundary and the CMB and this gives  $\Phi \simeq 2$  TW.

The evolution with time of the entropy balance associated with a given heat flow evolution can be computed and the example shown above gives the result of Figure G12. An interesting feature is the sharp increase of the ohmic dissipation in the core when the inner core starts crystallizing, latent heat and, even more so, gravitational energy being more efficient than secular cooling. Unfortunately, the link between this ohmic dissipation and the magnetic field observed at the surface of the Earth is far from obvious and the detection of such an increase in the paleomagnetic record is unlikely (Labrosse and Macouin, 2003).

Some alternative models for the average structure of the core involving some stratification have been proposed. In particular, the heat conducted along the adiabatic temperature gradient can be rather large (about 7 TW) and might be larger than the heat flow across the CMB (see Core-mantle boundary, heat flow across). In this case, two different models have been proposed. In the first one, the adiabatic temperature profile is maintained by compositional convection against thermal stratification, except in a still very thin boundary layer, and this means that the entropy flow across the CMB is less than that required to maintain the conduction along the average temperature profile. In other words, the compositional convection has to fight against thermal stratification to maintain the adiabatic temperature profile in addition to maintaining the dynamo. In the second model (see Labrosse et al., (1997); Lister and Buffett (1998)), a subadiabatic layer of several hundreds of kilometers is allowed to develop at the top of the core and the entropy flow out of the core balances the conduction along the average temperature gradient. In this case, the compositional energy is entirely used for the dynamo. Which of these two options would be chosen by the core is a dynamical question that cannot be addressed by simple thermodynamic arguments as used here.

# **GEODYNAMO: NUMERICAL SIMULATIONS**

#### Introduction

The *geodynamo* is the name given to the mechanism in the Earth's core that maintains the Earth's magnetic field (see *Geodynamo*). The current consensus is that flow of the liquid iron alloy within the outer core, driven by buoyancy forces and influenced by the Earth's rotation, generates large electric currents that induce magnetic field, compensating for the natural decay of the field. The details of how this produces a slowly changing magnetic field that is mainly dipolar in structure at the Earth's surface, with occasional dipole reversals, has been the subject of considerable research by many people for many years.

The fundamental theory, put forward in the 1950s, is that differential rotation within the fluid core shears poloidal (north-south and radial) magnetic field lines into toroidal (east-west) magnetic field; and three-dimensional (3D) helical fluid flow twists toroidal field lines into poloidal field. The more sheared and twisted the field structure the faster it decays away; that is, magnetic diffusion (reconnection) continually smooths out the field. The field is self-sustaining if, on average, the generation of field is balanced by its decay. Discovering and understanding the details of how rotating convection in Earth's fluid outer

core maintains the observed intensity, structure, and time dependencies requires 3D computer models of the geodynamo.

Magnetohydrodynamic (MHD) dynamo simulations are numerical solutions of a coupled set of nonlinear differential equations that describe the 3D evolution of the thermodynamic variables, the fluid velocity, and the magnetic field. Because so little can be detected about the geodynamo, other than the poloidal magnetic field at the surface (today's field in detail and the paleomagnetic field in much less detail) and what can be inferred from seismic measurements and variations in the length of the day and possibly in the gravitational field, models of the geodynamo are used as much to predict what has not been observed as they are used to explain what has. When such a model generates a magnetic field that, at the model's surface, looks qualitatively similar to the Earth's surface field in terms of structure, intensity, and time-dependence, then it is plausible that the 3D flows and fields inside the model core are qualitatively similar to those in the Earth's core. Analyzing this detailed simulated data provides a physical description and explanation of the model's dynamo mechanism and, by assumption, of the geodynamo.

The first 3D global convective dynamo simulations were developed in the 1980s to study the solar dynamo. Gilman and Miller (1981) pioneered this style of research by constructing the first 3D MHD dynamo model. However, they simplified the problem by specifying a constant background density, i.e., they used the Boussinesq approximation of the equations of motion. Glatzmaier (1984) developed a 3D MHD dynamo model using the anelastic approximation, which accounts for the stratification of density within the sun. Zhang and Busse (1988) used a 3D model to study the onset of dynamo action within the Boussinesq approximation. However, the first MHD models of the Earth's dynamo that successfully produced a time-dependent and dominantly dipolar field at the model's surface were not published until 1995 (Glatzmaier and Roberts, 1995; Jones et al., 1995; Kageyama et al., 1995). Since then, several groups around the world have developed dynamo models and several others are currently being designed. Some features of the various simulated fields are robust, like the dominance of the dipolar part of the field outside the core. Other features, like the 3D structure and time-dependence of the temperature, flow, and field inside the core, depend on the chosen boundary conditions, parameter space, and numerical resolution. Many review articles have been written that describe and compare these models (e.g., Hollerbach, 1996; Glatzmaier and Roberts, 1997; Fearn, 1998; Busse, 2000; Dormy et al., 2000; Roberts and Glatzmaier, 2000; Christensen et al., 2001; Busse, 2002; Glatzmaier, 2002; Kono and Roberts, 2002).

# Model description

Models are based on equations that describe fluid dynamics and magnetic field generation. The equation of mass conservation is used with the very good assumption that the fluid flow velocity in the Earth's outer core is small relative to the local sound speed. The anelastic version of mass conservation accounts for a depth-dependent background density; the density at the bottom of the Earth's fluid core is about 20% greater than that at the top. The Boussinesq approximation simplifies the equations further by neglecting this density stratification, i.e., by assuming a constant background density. An equation of state relates perturbations in temperature and pressure to density perturbations, which are used to compute the buoyancy forces, which drive convection. Newton's second law of motion (conservation of momentum) determines how the local fluid velocity changes with time due to buoyancy, pressure gradient, viscous, rotational (Coriolis), and magnetic (Lorentz) forces. The MHD equations (i.e., Maxwell's equations and Ohm's law with the extremely good assumption that the fluid velocity is small relative to the speed of light) describe how the local magnetic field changes with time due to induction by the flow and diffusion due to finite conductivity. The second law of thermodynamics dictates how thermal diffusion and Joule and viscous heating determine the local time rate of change of entropy (or temperature). Additional equations are sometimes

included that account for perturbations in composition and gravitational potential and their effects on buoyancy.

This set of coupled nonlinear differential equations, with a set of prescribed boundary conditions, is solved each numerical time step to obtain the evolution in 3D of the fluid flow, magnetic field, and thermodynamic perturbations. Most geodynamo models have employed spherical harmonic expansions in the horizontal directions and either Chebyshev polynomial expansions or finite differences in radius. The equations are integrated in time typically by treating the linear terms implicitly and the nonlinear terms explicitly. The review articles mentioned above describe the variations on the equations, boundary conditions, and numerical methods employed in the various models of the geodynamo.

## Current results

Since the mid-1990s, 3D computer simulations have advanced our understanding of the geodynamo. The simulations show that a dominantly dipolar magnetic field, not unlike the Earth's, can be maintained by convection driven by an Earth-like heat flux. A typical snapshot of the simulated magnetic field from a geodynamo model is illustrated in Figure G13 with a set of field lines. In the fluid outer core, where the field is generated, field lines are twisted and sheared by the flow. The field that extends beyond the core is significantly weaker and dominantly dipolar at the model's surface, not unlike the geomagnetic field. For most geodynamo simulations, the nondipolar part of the surface field, at certain locations and times, propagates westward at about  $0.2^{\circ} \text{ y}^{-1}$  as has been observed in the geomagnetic field over the past couple hundred years.

Several dynamo models have electrically conducting inner cores that on average drift eastward relative to the mantle (e.g., Glatzmaier and Roberts, 1995; Sakuraba and Kono, 1999; Christensen *et al.*, 2001), opposite to the propagation direction of the surface magnetic

**Figure G13** A snapshot of the 3D magnetic field simulated with the Glatzmaier-Roberts geodynamo model and illustrated with a set of magnetic field lines. The axis of rotation is vertical and centered in the image. The field is complicated and intense inside the fluid core where it is generated by the flow; outside the core it is a smooth, dipole-dominated, potential field. (From Glatzmaier, 2002.)

304

field. Inside the fluid core the simulated flow has a "thermal wind" component that, near the inner core, is predominantly eastward relative to the mantle. Magnetic field in these models that permeates both this flow and the inner core tries to drag the inner core in the direction of the flow. This magnetic torque is resisted by a gravitational torque between the mantle and the topography on the inner core surface. The amplitude of the superrotation rate predicted by geodynamo models depends on the model's prescribed parameters and assumptions and on the very poorly constrained viscosity assumed for the inner core's deformable surface layer, which by definition, is near the melting temperature. The original prediction was an average of about 2° longitude per year faster than the surface. Since then, the superrotation rate of the Earth's inner core (today) has been inferred from several seismic analyses, but is still controversial. There is a spread in the inferred values, from the initial estimates of 1° to 3° eastward per year (relative to the Earth's surface) to some that are zero to within an uncertainty of 0.2° per year. More recent geodynamo models that include an inhibiting gravitational torque also predict smaller superrotation rates.

On a much longer timescale, the dipolar part of the Earth's field occasionally reverses (see *Reversals, theory*). The reversals seen in the paleomagnetic record are nonperiodic. The times between reversals are measured in hundreds of thousands of years; whereas the time to complete a reversal is typically a few thousand years, less than a magnetic dipole decay time. Several dynamo simulations have produced spontaneous nonperiodic magnetic dipole reversals (Glatzmaier and Roberts, 1995; Glatzmaier *et al.*, 1999; Kageyama *et al.*, 1999; Sarson and Jones, 1999; Kutzner and Christensen, 2002). Regular (periodic) reversals, like the *dynamo-wave* (*q.v.*) reversals seen in early solar dynamo simulations, have also occurred in recent dynamo simulations.

One of the simulated reversals is portrayed in Figure G14/Plate 16 with four snapshots spanning about 9 ka. The radial component of

the field is shown at both the core-mantle boundary (CMB) and the surface of the model Earth. The reversal, as viewed in these surfaces, begins with reversed magnetic flux patches in both the northern and southern hemispheres. The longitudinally averaged poloidal and toroidal parts of the field inside the core are also illustrated at these times. Although when viewed at the model's surface, the reversal appears complete by the third snapshot, another 3 ka is required for the original field polarity to decay out of the inner core and the new polarity to diffuse in.

Small changes in the local flow structure continually occur in this highly nonlinear chaotic system. These can generate local magnetic anomalies that are reversed relative to the direction of the global dipolar field structure. If the thermal and compositional perturbations continue to drive the fluid flow in a way that amplifies this reversed field polarity while destroying the original polarity, the entire global field structure would eventually reverse. However, more often, the local reversed polarity is not able to survive and the original polarity fully recovers because it takes a couple of thousand years for the original polarity to decay out of the solid inner core. This is a plausible explanation for "events," which occur when the paleomagnetic field (as measured at the Earth's surface) reverses and then reverses back, all within about 10 ka.

On an even longer timescale, the frequency of reversals seen in the paleomagnetic record varies. The frequency of nonperiodic reversals in geodynamo simulations has been found to depend on the pattern of outward heat flux imposed over the CMB (presumably controlled in the Earth by mantle convection) and on the magnitude of the convective driving relative to the effect of rotation.

Many studies have been conducted via dynamo simulations to, for example, assess the effects of the size and conductivity of the solid inner core, of a stably stratified layer at the top of the core, of

**Figure G14/Plate 16** A sequence of snapshots of the longitudinally averaged magnetic field through the interior of the core and of the radial component of the field at the core-mantle boundary and at what would be the surface of the Earth, displayed at roughly 3 ka intervals spanning a dipole reversal from a geodynamo simulation. In the plots of the average field, the small circle represents the inner core boundary and the large circle is the core-mantle boundary. The poloidal field is shown as magnetic field lines on the left-hand sides of these plots (blue is clockwise and red is counterclockwise). The toroidal field direction and intensity are represented as contours (not magnetic field lines) on the right-hand sides (red is eastward and blue is westward). Aitoff-Hammer projections of the entire core-mantle boundary and surface are used to display the radial component of the field (with the two different surfaces displayed as the same size). Reds represent outward directed field and blues represent inward field; the surface field, which is typically an order of magnitude weaker, was multiplied by 10 to enhance the color contrast. (From Glatzmaier *et al.*, 1999.)

heterogeneous thermal boundary conditions, of different velocity boundary conditions, and of computing with different parameters. These models differ in several respects. For example, the Boussinesq instead of the anelastic approximation may be used, compositional buoyancy and perturbations in the gravitational field may be neglected, different boundary conditions, and spatial resolutions may be chosen, the inner core may be treated as an insulator instead of a conductor or may not be free to rotate. As a result, the simulated flow and field structures inside the core differ among the various simulations. For example, the strength of the shear flow on the "tangent cylinder" (the imaginary cylinder tangent to the inner core equator; Figure G13), which depends on the relative dominance of the Coriolis forces, is not the same for all simulations. Likewise, the vigor of the convection and the resulting magnetic field generation tends to be greater outside this tangent cylinder for some models and inside for others. But all the solutions have a westward zonal flow in the upper part of the fluid core and a dominantly dipolar magnetic field outside the core.

When assuming Earth values for the radius and rotation rate of the core, all models of the geodynamo have been forced (due to computational limitations) to use a viscous diffusivity that is at least three to four orders of magnitude larger than estimates of what a turbulent (or eddy) viscosity should be (about  $2 \text{ m}^2 \text{s}^{-1}$ ) for the spatial resolutions that have been employed. In addition to this enhanced viscosity, one must decide how to prescribe the thermal, compositional, and magnetic diffusivities. One of two extremes has typically been chosen. These diffusivities could be set equal to the Earth's actual magnetic diffusivity ( $2 \text{ m}^2 \text{s}^{-1}$ ), making these much smaller than the specified viscous diffusivity; this was the choice for most of the Glatzmaier-Roberts simulations. Alternatively, they could be set equal to the enhanced viscous diffusivity, making all (turbulent) diffusivities too large, but at least equal; this was the choice of most of the other models. Neither choice is satisfactory.

## **Future challenges**

Because of the large turbulent diffusion coefficients, all geodynamo simulations have produced large-scale *laminar* convection. That is, convective cells and plumes of the simulated flow typically span the entire depth of the fluid outer core, unlike the small-scale turbulence that likely exists in the Earth's core.

The fundamental question about geodynamo models is how well do they simulate the actual dynamo mechanism of the Earth's core? Some geodynamo modelers have argued, or at least suggested, that the large (global) scales of the temperature, flow, and field seen in these simulations should be fairly realistic because the prescribed viscous and thermal diffusivities may be asymptotically small enough. For example, in most simulations, viscous forces (away from the boundaries) tend to be 10<sup>4</sup> times smaller than Coriolis and Lorentz forces. Other modelers are less confident that current simulations are realistic even at the large-scales because the model diffusivities are so large. Only when computing resources improve to the point where we can further reduce the turbulent diffusivities by several orders of magnitude and produce strongly turbulent simulations will we be able to answer this fundamental question.

In the mean time, we may be able to get some insight from very highly resolved 2D simulations of magnetoconvection. These simulations can use diffusivities a thousand times smaller than those of the current 3D simulations. They demonstrate that strongly turbulent 2D rotating magnetoconvection has significantly different spatial structure and time-dependence than the corresponding 2D laminar simulations obtained with much larger diffusivities.

These findings suggest that current 3D laminar dynamo simulations may be missing critical dynamical phenomena. Therefore, it is important to strive for much greater spatial resolution in 3D models in order to significantly reduce the enhanced diffusion coefficients and actually simulate turbulence. This will require faster parallel computers and improved numerical methods and hopefully will happen within the next decade or two. In addition, subgrid scale models need to be added to geodynamo models to better represent the heterogeneous anisotropic transport of heat, composition, momentum, and possibly also magnetic field by the part of the turbulence spectrum that remains unresolved.

Gary A. Glatzmaier
