The name Taylor cell is a useful reminder of the Proudman-Taylor theorem, which the flow is trying to obey by being as two-dimensional as possible, consistent with allowing convection to occur at all. We have already seen that, if v = 0, small amplitude motion must be geostrophic, since the thermal forcing  $T_{c}(r)$  is independent of latitude. But geostrophic motions have no radial components to carry heat outward. Convection can occur only if the buoyancy force is large enough to break the rotational constraint of the theorem. Thus, although  $Ra_c$ would be O(1) if E were O(1), the critical Rayleigh number is large when  $E \ll 1$ ; in fact  $Ra_c = O(E^{-4/3}) \sim 10^{20}$ , and the number of cells in the cartridge belt is then of order  $E^{-1/3} \sim 10^5$ , i.e., the scale  $\mathcal{L}_{\perp}$  of the motions perpendicular to  $\Omega$  is  $O(E^{1/3}\mathcal{L}) \sim 30$  m. Convective heat transport is mainly in the s-direction, i.e., away from the rotation axis (Busse, 1970). The instability criterion  $Ra_c = O(E^{-4/3})$  may also be written as  $N_c = (\nu \kappa / \mathcal{L}^4)^{1/2} E^{-2/3}$ , where  $N = \sqrt{(g \alpha \beta)}$  is the buoyancy frequency that, if imaginary, would usually be called the Brunt-Väisälä frequency (Gill, 1982). It is worth pointing out that, in the absence of diffusive effects, the density stratification would be unstable when  $N_c = O(\Omega)$ . This value of  $N_c$  is greater than  $(\nu \kappa / \mathcal{L}^4)^{1/2} E^{-2/3}$  by a large factor, of order  $E^{-1/3}$ . In other words, the effects of diffusion are destabilizing. There is also a basic difference between the convective instability that onsets when  $Ra = O(E^{-4/3})$  and the Rayleigh-Taylor instability of the diffusionless system. The latter releases gravitational energy in a single spasm that transforms a top-heavy mass distribution into a bottom-heavy configuration. The heat conduction necessary to renew constantly the top-heavy distribution is (by assumption) absent, and therefore the continuously overturning motions characteristic of thermal convection do not occur. We return to this topic in the Section on CMHD for imperfect fluids.

#### **Classical and Coriolis MHD**

#### Classical MHD

In this section we shall suppose that  $\Omega \equiv 0$  and initially also exclude buoyancy ( $\mathbf{g} \equiv 0$ ). We give a rudimentary account of relevant concepts in the MHD in nonrotating systems. For a more complete treatment, see Davidson (2001).

Much of classical MHD theory was originally developed to explain laboratory flows of liquid metals, and two dimensionless numbers were introduced to quantify the importance of the Lorentz force relative to the viscous and inertial forces, the *Hartmann number*, *Ha*, and the *interaction parameter*, *N*. These can be written in several equivalent ways:

$$Ha = \mathcal{BL}\left(\frac{\sigma}{\rho\nu}\right)^{1/2} = \frac{\mathcal{BL}}{\sqrt{(\mu_0 \rho \nu \eta)}} = \frac{\mathcal{V}_{\rm A}\mathcal{L}}{\sqrt{(\nu \eta)}} = \left(\frac{\tau_{\nu}}{\tau_{\rm m}}\right)^{1/2} = \frac{Lu}{\sqrt{P_{\rm m}}},$$
(Eq. 103)

$$N = \frac{\sigma \mathcal{B}^2 \mathcal{L}}{\rho \mathcal{V}} = \frac{\mathcal{B}^2 \mathcal{L}}{\mu_0 \rho \eta \mathcal{V}} = \frac{\mathcal{V}_A^2 \mathcal{L}}{\eta \mathcal{V}} = \frac{\tau_V}{\tau_m} = \frac{Lu}{Al} = \frac{Ha^2}{R_k}.$$
 (Eq. 104)

The current  $\mathcal{J}$  created by motions  $\mathcal{V}$  in a field  $\mathcal{B}$  is  $\mathcal{J} \sim \sigma \mathcal{V} \mathcal{B}$  so that the Lorentz force per unit volume is approximately  $\sigma \mathcal{B}^2 \mathcal{V}$ . This is greater than the inertial acceleration  $\rho \mathbf{V} \cdot \nabla \mathbf{V} \sim \rho \mathcal{V}^2 / \mathcal{L}$  by a factor of N and exceeds the viscous force per unit volume, which is of order  $\rho \mathcal{V} / \mathcal{L}^2$ , by a factor of  $Ha^2$  which is often called the *Chandrasekhar number*, particularly in the literature dealing with magnetoconvection (see *Magnetoconvection*). Even though  $R_m$  and Lu may be very small in laboratory systems (see the Section on the imperfect conductor, reconnection), Ha may be large because of the smallness of  $P_m$  for liquid metals; the Lorentz force can therefore profoundly affect the motion. In large systems for which  $R_m \gtrsim 1$ , a more appropriate measure of  $\mathcal{J}$  may be  $\mathcal{B} / \mu_0 \mathcal{L}$ , with a corresponding Lorentz force of order  $\mathcal{B}^2 / \mu_0 \mathcal{L}$  per unit volume. This is greater than the viscous force by order  $N / P_m$  and exceeds the inertial force by order  $1/Al^2$ , where Al is the *Alfvén number* (also sometimes called the magnetic Mach number):

$$Al = \mathcal{V}/\mathcal{V}_{A}.\tag{Eq. 105}$$

It is frequently argued that an MHD system capable of generating its own magnetic field will favor a dynamical balance in which inertial and Lorentz forces are comparable (Al = O(1)) so that the magnetic and kinetic energies are comparable also:  $u^B/u^K = Al^{-2} = O(1)$ . In a highly rotating system however, this is not necessarily true (see the Section on the CMHD for imperfect fluids).

MHD boasts an analogue of the Proudman-Taylor theorem. This has already been foreshadowed in the Section on the perfect conductor, where an anisotropic friction was identified for  $R_m \ll 1$  that acts to damp out motions perpendicular to **B** in a time of order  $\tau_m$ . If  $\tau_m \ll \tau_v$  and  $\tau_V$ , i.e., if *Ha* and *N* are so large that viscous and inertial forces are negligible, the steady state form of Eq. (74) becomes

$$0 = \nabla(\rho \Pi) + \mathbf{J} \times \mathbf{B}, \tag{Eq. 106}$$

which is the equation for magnetostatic equilibrium. Nevertheless, because  $Ha \gg 1$ , small motions create large enough currents to make the Lorentz force significant in Eq. (106). Let  $\mathbf{B} = \mathbf{B}_0 + \mathbf{b}$ , where  $\mathbf{B}_0$  is a uniform field applied across the system and  $\mathbf{b} (\ll B_0)$  is the small response to the flow. Then  $\mathbf{J} = \mathbf{j} = \nabla \times \mathbf{b} / \mu_0$  and Eq. (106) give

$$\mathbf{B}_0 \cdot \nabla \mathbf{J} = 0. \tag{Eq. 107}$$

If it is also true that  $R_m \gg 1$  so that magnetic diffusion is negligible, Eq. (73) and the steady induction equation (47) gives

$$\mathbf{B}_0 \cdot \nabla \mathbf{V} = \mathbf{0}. \tag{Eq. 108}$$

The MHD two-dimensional theorem follows from Eqs. (107) and (108):

In a steady dissipationless MHD system across which a uniform magnetic field is applied, the flow and current are two dimensional with respect to the direction of the applied field.

Taking  $\mathbf{B}_0 = B_0 \mathbf{1}_z$ , we have

$$\mathbf{V} = \mathbf{V}(x, y),\tag{Eq. 109}$$

$$\mathbf{J} = \mathbf{J}(x, y). \tag{Eq. 110}$$

This result may be compared with Eq. (89).

Solutions such as Eqs. (109) and (110), obtained on the assumption that  $R_k$  and  $R_m$  are large, are subject to boundary conditions such as

$$\llbracket \mathbf{n} \cdot \mathbf{B} \rrbracket = 0,$$
 on the boundaries; (Eq. 111)

$$\mathbf{n} \cdot \mathbf{V} = 0$$
, on the boundaries; (Eq. 112)

cf. Eq. (80). Boundary layers are required to make the solutions satisfy the full set of wall conditions; these are known as Hartmann layers. As for the Ekman layer, the Hartmann layers are of a type sometimes called "active" or "controlling," since mainstream solutions involving unknown functions, like Eqs. (109) and (110), cannot be completely determined until certain "Stewartson conditions" that are demanded by the Hartmann layer are applied:

$$P_{\mathbf{m}}^{1/2} \llbracket \mathbf{n} \times \mathbf{V} \rrbracket_{\mathbf{b}\mathbf{l}} = \operatorname{sgn}(\mathbf{n} \cdot \mathbf{B}) \llbracket \mathbf{n} \times \mathbf{B} \rrbracket_{\mathbf{b}\mathbf{l}} / \mu_0 \rho.$$
(Eq. 113)

Here the unit normal  $\mathbf{n}$  is directed from the boundary layer into the fluid and the suffix bl signifies that the discontinuity is right across the Hartmann layer, i.e., is the difference between mainstream and boundary values; Eq. (113) is valid only where  $\mathbf{n} \cdot \mathbf{B}$  is nonzero.

In the limit of zero dissipation  $(v \rightarrow 0, \eta \rightarrow 0)$ , the Hartmann layer becomes a combined surface current **C** and surface vorticity **Z**, defined in analogy to Eq. (14) as  $[\mathbf{n} \times \mathbf{V}] = \mathbf{Z}$ . The origins of Eq. (113) can be qualitatively understood as in the Section on the perfect conductor by demanding that the viscous force associated with the shear generated by the integrated Lorentz force,  $(\mathbf{n} \cdot \mathbf{B})(\mathbf{n} \times \mathbf{C})/\mu_0$ , balances that force, and by arguing that the emf created by **Z** is  $(\mathbf{n} \cdot \mathbf{B})\mathbf{Z}$  and generates **C**. This also shows that the thickness of the Hartmann layer is of order  $\delta_{\rm M} = \mathcal{L}/Ha = (v\eta)^{1/2}/\mathcal{V}_{\rm A}$ .

What is perhaps most remarkable is that Eq. (113) applies even in the absence of diffusion ( $v = \eta = 0$ ) but that nevertheless it depends on the ratio  $P_{\rm m}$  of the two diffusivities! When **B** is nonuniform and the boundaries are curved,  $\nabla_{\rm S} \cdot {\bf C}$  is generally nonzero, so that the Hartmann layer pumps current into or out of the mainstream (see Eq. (18)).

The MHD two-dimensional theorem has implications for thermal convection resembling those that the Proudman-Taylor theorem has for rotating convection (see the Section on the Classical theory of rotating fluids). Consider a Bénard layer, i.e., a uniform horizontal layer of fluid, of depth  $\mathcal{L}$ , heated from below and cooled from above. Suppose a large uniform vertical field of strength  $\mathcal{B}$  is applied  $(Ha \gg 1)$ . If v = 0, weak motions must satisfy Eq. (109); by Eq. (112), they are horizontal everywhere and therefore have no zcomponent to carry heat across the layer. Convection can occur only if the buoyancy force is large enough to break the magnetic constraint of the two-dimensional theorem. Thus, although  $Ra_c$  would be O(1) if Ha were O(1), the critical Rayleigh number is large when  $Ha \gg 1$ ; in fact  $Ra_c = O(Ha^2)$ , and the (horizontal) scale  $\mathcal{L}_{\perp}$  of the motions perpendicular to **B**<sub>0</sub> is  $O(Ha^{-1/2}\mathcal{L})$ . If the applied field is horizontal instead of vertical, it has no effect on the marginal mode, in which the pattern of convection consists of horizontal rolls parallel to  $\mathbf{B}_0$ , for which the two dimensional theorem applies, though now the two-dimensional motions have a vertical component that transports heat across the layer. (See *Magnetoconvection*.)

#### CMHD for ideal fluids

In a way reminiscent of MHD itself (see the Introduction), the combination of the classical theories of MHD and rotating fluids gives rise to new phenomena that are absent from the two subjects in isolation. The subject becomes so different that it deserves its own name and acronym. The obvious choice, RMHD, has already been appropriated by both "relativistic MHD" and "reduced MHD," so it is called here "Coriolis magnetohydrodynamics" or "CMHD." Phenomena in which diffusion plays a central role will be described in the Section on the CMHD for imperfect fluids. Here we focus on ideal flows and, to illustrate as dramatically as possible how different CMHD is from MHD, we shall suppose that the *magnetic Rossby number*,

$$Ro_{\rm m} = \mathcal{V}_{\rm A}/\Omega \mathcal{L},$$
 (Eq. 114)

is small:

$$Ro_{\rm m} \ll 1.$$
 (Eq. 115)

In the Earth's core,  $Ro_{\rm m} = O(10^{-3})$ .

One of the ways in which the magnetic field transforms the classical theory of rotating fluids is by removing the geostrophic degeneracy of the inertial waves discussed in the Section on the Classical theory of rotating fluids. These are replaced by a discrete set of torsional waves (see *Oscillations, torsional*). These arise because the geostrophic cylinders sketched in Figure M151 are coupled together by the *s*-component of **B**, i.e., the component that threads the cylinders together. It was seen in the Section on the Classical theory of rotating fluids that the Coriolis force associated with geostrophic motions can be absorbed into the pressure gradient. Since this otherwise dominating force is then essentially absent, the remaining forces become influential, including the inertial term  $\rho \partial_t \mathbf{V}$ . The torsional waves therefore resemble Alfvén waves and have the same timescale,  $\tau_A = \mathcal{L}/\mathcal{V}_A$ , where  $\mathcal{V}_A = \sqrt{\langle V_A^2 \rangle}$  is now based on the rms strength of  $B_s$  on the geostrophic cylinder C(s):

$$\mu_0 \rho \langle V_{\rm A}^2 \rangle(s,t) = \langle B_{\rm s}^2 \rangle(s,t) = \frac{1}{A(s)} \int_{\mathcal{C}(s)} B_{\rm s}^2(s,\phi,z,t) \mathrm{d}S.$$
(Eq. 116)

Even if  $\sqrt{\langle B_s^2 \rangle}$  were as small as  $10^{-3}$  T, the Alfvénic timescale  $\tau_A$  is less than a decade. This may be compared with the timescale of the ageostrophic waves which (see below) is of order  $10^3$  y. It is also short in comparison with the timescales,  $\tau_{spin up}$  and  $\tau_\eta$ , of the diffusive processes. The high frequency character of the torsional waves means that in describing them we may ignore the time-dependence of  $\langle B_s \rangle$  and all diffusive effects.

The dissipationless geostrophic component of V obeys the inviscid form of Eq. (98), now written as

$$\rho \partial_t \overline{V}_{\mathbf{G}} = \langle (\mathbf{J} \times \mathbf{B})_{\phi} \rangle, \tag{Eq. 117}$$

and by the induction equation (61) for a perfect conductor. (The term  $2\Omega \langle V_s \rangle$  has been omitted from Eq. (117) because of mass conservation; see Eq. (99).) In a steady state,  $\langle (\mathbf{J} \times \mathbf{B})_{\phi} \rangle = 0$ , i.e.,

$$\int_{\mathcal{C}(s)} (\mathbf{J} \times \mathbf{B})_{\phi} \mathrm{d}S = 0.$$
 (Eq. 118)

This important result, due to Taylor (1963) defines what are called *Taylor states* (see *Taylor's condition*).

If Eq. (118) does not hold initially, a torsional wave is launched in which the geostrophic cylinders oscillate about a Taylor state,  $\mathbf{V}_{\mathrm{G}}^{\mathrm{T}}(s)$ . Denoting by  $v(s,t) = \overline{V}_{\mathrm{G}}(s,t) - \overline{V}_{\mathrm{G}}^{\mathrm{T}}(s)$  the departure of the geostrophic state from this Taylor state, Braginsky (1970) showed that the associated shear  $\zeta = v/s$  satisfies the *torsional wave equation* 

$$\frac{\partial^2 \zeta}{\partial t^2} = \frac{1}{s^2 A} \frac{\partial}{\partial s} \left[ s^2 A \langle V_A^2 \rangle \frac{\partial \zeta}{\partial s} \right].$$
(Eq. 119)

The waves transport the z-component,  $\rho s \overline{V}_{\phi}$ , of the angular momentum density to and fro across the core, but do not change the integrated angular momentum of core flow:

$$M = \int_{\text{SIC}} \rho s V_{\phi} dV = \rho_0 \int_0^{R_1} s \overline{V}_G A ds.$$
 (Eq. 120)

In the simplest application of Eq. (119), the existence of the SIC is ignored. The ordinary differential equation obtained by substituting  $\zeta(s,t) = Z(s) \exp(i\omega t)$  into Eq. (119) has regular singularities at both s = 0 and  $s = R_1$  where A = 0. The implicit requirement that Z be bounded at both these points transforms Eq. (119) into an eigenvalue problem for the torsional wave frequencies,  $\omega$ .

The picture is complicated by the SIC. This has a composition similar to the FOC but, being a solid, its conductivity is even greater and the justification for ignoring its resistivity is even stronger. Since ohmic and viscous diffusion are absent, the boundary layer at the ICB is of Hartmann type (see the Section on Classical MHD) so that Eq. (113) applies and  $P_m$  is involved. Since however  $P_m \ll 1$ , the condition (113) reduces to  $[\mathbf{B}] = 0$ . In consequence,

$$\zeta = \Omega_{\text{SIC}}, \quad \text{for } s < R_2. \tag{Eq. 121}$$

In other words, in torsional wave motion, the entire contents of the tangent cylinder  $C_2$ , both solid and liquid, move together as a solid body. (For an alternative point of view, see Jault and Légaut, 2005.) As Buffett (1996) showed, this part of the torsional motion is mainly determined by the gravitational couple exerted by the mantle on the SIC and by the EM torque on  $C_2$ , which can be computed from Eq. (43). As in the Section on the Basic equations, the simplified condition  $\Omega_{SIC} = 0$  is adopted here. The torsional waves therefore exist only outside the tangent cylinder and the appropriate condition of wave reflection at  $C_2$  is  $\zeta(R_2) = 0$ .

If viscous and ohmic dissipation is allowed for, it is plausible that the torsional waves will die out, so returning the system to the Taylor state,  $\overline{V}_{G}^{T}$ . Roberts and Soward (1972) demonstrated that viscosity would quench the waves on the spin-up timescale, but over such a long period the evolution of **B**, and therefore of  $\sqrt{\langle V_A^2 \rangle}$ , would be significant and the coefficients in Eq. (119) would change secularly. It is plausible that ohmic dissipation in the fluid and in the mantle (assumed weakly conducting) will quench the waves even more rapidly on the  $\tau_{\eta}$  timescale of the core, or perhaps (since it differs less from  $\tau_A$ ) on the even shorter  $\tau_{\eta}$  timescale of the mantle.

Electromagnetic coupling, either directly across the CMB, or indirectly via the inner core with the gravitational coupling between the mantle and inner core acting as catalyst (Buffett, 1996), provides one of three ways in which angular momentum can be exchanged between the core and the mantle, the other two being topographic coupling, which depends on the roughness of the CMB, and viscous coupling, which is generally thought to be negligibly small. Since the total angular momentum of the Earth is unchanged by such internal processes, a correlation should exist between variations in the length of the day and changes in the angular momentum of the core. Jault *et al.* (1988) were the first to establish such a connection. From an analysis of the geomagnetic record they could trace the evolution of the core's angular momentum and could show that it was in antiphase with the mantle's angular momentum. The excitation of torsional oscillations is inexplicable according to the ideas presented here but it seems clear that it must be due to some other higher frequency processes in the core, such as turbulence. For further analysis see Jault (2003), Oscillations, torsional; Core-mantle coupling, electromagnetic; Core-mantle coupling, gravitational; and Core-mantle coupling, topographic. Bloxham et al. (2002) have associated torsional waves with the observed secular variation "impulses" (see Geomagnetic jerks).

Consider next the ageostrophic waves. When  $Ro_m = O(1)$ , the waves are an inextricable mixture of inertial and Alfvén waves, but when Eq. (115) holds, little remains of the Alfvén wave! This illustrates again how Coriolis forces can transform classic MHD. When  $Ro_{\rm m} \ll 1$ , the inextricable mixture neatly separates into two families: inertial waves and slow waves, also known as "Lehnert waves." The former differ little from the inertial waves discussed in the Section on the Classical theory of rotating fluids; they are "fast," since their timescale is diurnal. The latter are very unlike Alfvén waves. They are called "slow" because their timescale,  $\tau_s = \Omega \mathcal{L}^2 / \mathcal{V}_A^2$ , is of order 10<sup>3</sup> y. This is comparable with the timescale of the secular variation of the main geomagnetic field (see Geomagnetic secular variation). The corresponding velocity,  $c_s = \mathcal{L}/\tau_s = \mathcal{V}_A^2/\Omega \mathcal{L}$ , is of order  $10^{-4}$  m s<sup>-1</sup>, which the speed at which discernable magnetic features at the CMB drift westward. The time dependence of the slow waves is governed by the left-hand side,  $\partial_t \mathbf{B}$ , of the induction equation (61); the inertial forces in Eq. (74) play essentially no role. For this reason the waves are sometimes called MC waves, to emphasize that the essential ingredients governing their propagation are the magnetic and Coriolis forces alone (and of course the pressure gradient). The relative unimportance of the inertial waves suggests that MC waves can be analyzed in a clearer way by discarding the inertial forces in Eq. (74). If this is done, however, the torsional waves are filtered out too. By retaining the key part of the inertial force as in Eq. (101), both the torsional and MC waves are retained but the inertial waves are removed (see also Magnetohydrodynamic waves).

MC waves, like inertial waves, are dispersive but possess abundant helicity, making them potentially efficient components of a dynamo. Although they have axisymmetric parts, they are characteristically large-scale planetary waves, i.e., they are asymmetric and, if they have finite amplitude, they create an emf  $(\mathbf{V}' \times \mathbf{B}')_{\phi}$  that drives a current  $\overline{J}_{\phi}$ that potentially can defeat Cowling's theorem (see the Section on the kinematic dynamo). They are, however, obliterated by ohmic diffusion in traveling a distance of order  $c_s \tau_{\eta} = (\mathcal{V}_A^2 / \Omega \eta) \mathcal{L}$ . Buoyancy forces can prevent their demise. This provides a strong motivation for studying MAC waves, which are MC waves modified by the insertion of Archimedean (buoyancy) forces. As in the example discussed in the Section on the Classical theory of rotating fluids, it may be expected that, if buoyancy is strong enough, instability occurs. More specifically, instability occurs when the buoyancy frequency N is of order  $\mathcal{V}_A/\mathcal{L}$ , i.e., when the magnetic Rayleigh number,  $Ra_m$  is O(1), where

$$Ra_{\rm m} = g\alpha\beta\mathcal{L}^2/\mathcal{V}_{\rm A}^2. \tag{Eq. 122}$$

If we accept the estimate  $\mathcal{V} = O(g\sigma\Delta T/\Omega)$  made in the Section on the Classical theory of rotating fluids, we may rewrite Eq. (122) as

$$Ra_{\rm m} = \Omega \mathcal{VL} / \mathcal{V}_{\rm A}^2 = \mathcal{V} / c_{\rm s}.$$
 (Eq. 123)

From  $\Omega = 7 \times 10^{-4} \text{ s}^{-1}$ ,  $\mathcal{V} = 2 \times 10^{-4} \text{ m}^{-1}$ ,  $\mathcal{L} = 10^6 \text{ m}$ , and  $\mathcal{V}_{\rm A} = 0.1 \text{ m} \text{ s}^{-1}$ , we obtain  $Ra_{\rm m} = 1$ . This suggests that MAC wave instability is relevant to core dynamics.

The simplest demonstrations of MAC waves and their instabilities (Braginsky, 1964) assume that they infinitesimally perturb a uniform applied field  $\mathbf{B}_0$  in a plane layer of fluid. Braginsky (1967) also studied small amplitude MAC waves and instabilities in a spherical system in which the imposed field  $\mathbf{B}_0$  is zonal. In this case the waves travel in the  $\pm \phi$ -directions with speeds of order  $c_s$ . Braginsky (1964)

suggested that the geomagnetic secular variation and westward drift are manifestations of MAC waves. Since  $c_s$  and  $\mathcal{V}$  are approximately equal when  $Ra_m = 1$ , it appears that our method (see Section on The imperfect conductor, reconnection) of estimating  $\mathcal{V}$  from the speed of westward drift speed  $c_s$  is defensible. MAC wave instability is, as in the Section on the Classical theory of rotating fluids, a single spasm of overturning. To maintain the waves continuously it is necessary to invoke diffusion, and this (as will be seen in the Section CMHD for imperfect fluids) is destabilizing.

#### CMHD for imperfect fluids

Although the core is rapidly rotating in the classical sense ( $E \ll 1$ ,  $Ro \ll 1$ ), it is not rapidly rotating according to the criterion  $\Lambda \ll 1$  of CMHD, where  $\Lambda$  is the *Elsasser number*, a dimensionless parameter that can be written in several equivalent ways:

$$\Lambda = \frac{\mathcal{V}_{A}^{2}}{\Omega \eta} = \frac{R_{m}Ro}{Al^{2}} = Ha^{2}E = \frac{\tau_{\eta}}{\tau_{s}} = \frac{\tau_{\Omega}}{\tau_{m}} = \left(\frac{\delta_{E}}{\delta_{M}}\right)^{2} = Ro_{m}Lu.$$
(Eq. 124)

Far from being small, the value of  $\Lambda$  in the core is better described by

$$\Lambda = O(1). \tag{Eq. 125}$$

Equation (125) defines the scale for strong fields:

$$\mathcal{B} = \sqrt{(\rho\Omega/\sigma)} = \sqrt{(\mu_0 \rho\Omega\eta)},$$
 in strong field regime.  
(Eq. 126)

This, like the Elsasser number, is independent of the length scale  $\mathcal{L}$ . According to Eq. (126),  $\mathcal{J} = O(\sigma \mathcal{VB}) = O(\mathcal{V}\sqrt{(\sigma \rho \Omega)})$ , so that the Lorentz force,  $\mathbf{J} \times \mathbf{B}$ , is of order  $\rho \Omega \mathcal{V}$ , i.e., the Lorentz and Coriolis force,  $2\mathbf{\Omega} \times \mathbf{V}$ , are about equal in magnitude. This suggests that the primary force balance in the core is between  $2\mathbf{\Omega} \times \mathbf{V}$  and  $\mathbf{J} \times \mathbf{B}$ . It is often said that the fact that the magnetic compass needle points approximately north proves that the Coriolis force dominates core dynamics. This however is an oversimplification. The Coriolis force has a preferred direction, that of  $\mathbf{\Omega}$ . To counter the rotational constraint (see below), the magnetic field configures itself so that it and the Lorentz force share the same preferred direction.

In the same way that  $R_m = O(1)$  numerically underestimates the magnetic Reynolds number required for dynamo action (see Section on the kinematic dynamo), it appears from the Section on Classical MHD that Eq. (125) numerically underestimates  $\Lambda$ . Writing Eq. (122) as

$$Ra_{\rm m} = R_{\rm m}/\Lambda, \tag{Eq. 127}$$

we see that marginal MAC wave instability  $(Ra_m \sim 1)$  requires that  $\Lambda = O(100)$ . Numerical estimates bear this out: if we take  $\mathcal{V}_A = 0.1 \text{ m s}^{-1}$  and  $\eta = 2 \text{ m}^2 \text{ s}^{-1}$  as before, we obtain  $\Lambda \sim 100$  from Eq. (124), and  $\mathbf{B} \sim 0.01$  T, rather than the  $10^{-3}$  T given by Eq. (126). Far from being rapidly rotating, the core is, according to this value of  $\Lambda$ , slowly rotating. Equation (124) shows that the magnetic energy density  $u^B$  exceeds the kinetic energy density  $u^K$  in the rotating frame by a factor of order  $Al^{-2} = \Lambda/R_m Ro \sim 10^5$ , assuming as before that  $\Lambda \sim 100$ ,  $R_m \sim 100$  and  $Ro \sim 10^{-5}$ .

A striking way in which CMHD differs from the classical theories of rotating and MHD flows is that the two-dimensional theorems of those subjects are no longer so constraining. If  $Ha \gtrsim E^{-1/2}$ , the Lorentz force weakens the Proudman-Taylor constraint; if  $E \lesssim Ha^{-2}$ , the Coriolis force weakens the MHD constraint. When  $\Lambda(=Ha^2E)$  is O(1), both constraints have diminished force. This has very significant consequences for CMHD convection. Suppose that the Bénard layer of the Section on Classical MHD rotates about a vertical axis. It is found that  $Ra_c = O(E^{-1})$  for  $E \to 0$ , instead of the  $Ra_c = O(E^{-4/3})$  for the same rotating system when nonmagnetic (see the Section on Classical theory of rotating fluids). The horizontal scale of motions is comparable in the marginal state with the vertical scale  $\mathcal{L}$ , in contrast to the Section on Classical theory of rotating fluids where the length scale  $\mathcal{L}_{\perp}$  in directions perpendicular to  $\Omega$  was found to be small,  $O(E^{1/3}\mathcal{L})$ . The result  $Ra_{\rm c} = O(E^{-1})$  may be written as  $Ra_{\rm mod,c} = O(1)$ , where

$$Ra_{\rm mod} = g\alpha\beta\mathcal{L}^2/\Omega\kappa = RaE \tag{Eq. 128}$$

is the *modified Rayleigh number*, which is often used in preference to *Ra* in CMHD convection studies. The fact that this, like  $\Lambda$  and  $\mathcal{L}_{\perp}$ , is independent of v serves to emphasize how Lorentz forces completely take over from viscous forces in breaking the Proudman-Taylor constraint when  $\Lambda = O(1)$ .

The Bénard example is the simplest to show how convection adapts to changes in field strength. The convection pattern arranges itself to provide the Lorentz force necessary to break the rotational constraint. For example, if  $\mathbf{B}_0$  is horizontal and  $\Lambda$  is small, the convection pattern in the marginal state consists of horizontal rolls that are *perpendicular* to  $\mathbf{B}_0$  and not parallel as in the Section Classical MHD. For larger  $\Lambda$ , the rolls counter the Coriolis force by becoming inclined to  $\mathbf{B}_0$  at an angle that diminishes as  $\Lambda$  increases.

This approach to rotating magnetoconvection is so simple that it borders on the simplistic. It ignores processes that may be significant in a naturally occurring CMHD system: the effects of nonlinearity, boundary curvature, velocity shear, self-generation of field, etc. In particular, it assumes that the magnetic field in which convection occurs is *given*. One might wonder whether a dynamo, which is required to generate its own magnetic field, would expend more energy in doing so than it saved by recouping its convective energy losses. This qualm can be most easily allayed by investigating finite amplitude convection in the Bénard layer, in the absence of the applied field  $\mathbf{B}_{0}$ .

Suppose *Ra* is progressively increased from zero. Convection does not occur until *Ra* reaches its critical value,  $Ra_c = O(E^{-4/3})$ , for which convective motions of horizontal scale  $\mathcal{L}_{\perp} = O(E^{1/3}\mathcal{L})$  become possible. As *Ra* is enhanced,  $\mathcal{L}_{\perp}$  increases, **V** grows in amplitude and, at another critical value  $Ra_B$  of Ra,  $\mathcal{L}_{\perp}$  becomes  $O(E^{1/6}\mathcal{L})$  and  $\mathcal{V}$  becomes  $O(E^{-1/6}\eta/\mathcal{L})$  so that dynamo action occurs ( $R_m = \mathcal{L}_{\perp}\mathcal{V}/\eta = O(1)$ ), and supports a field of infinitesimal amplitude. As *Ra* increases further,  $\mathcal{L}_{\perp}$  becomes larger as do **V** and **B**, but the system remains in a *weak field* state in which the Hartmann number is O(1), i.e., by Eq. (103),

$$\mathcal{B} = \sqrt{(\mu_0 \rho v \eta)} / \mathcal{L},$$
 in weak field regime. (Eq. 129)

Unaided by viscosity, the Lorentz force is still too weak to counter the rotational constraint, but this becomes less and less true as the imposed Ra is made larger still;  $\mathcal{L}_{\perp}$  increases toward  $\mathcal{L}$  and  $\mathcal{B}$ approaches an asymptote at  $Ra = Ra_A$  (see Figure M153). The weak field regime exists only for  $Ra_B < Ra < Ra_A$ ; it terminates at the asymptote. As Ra increases to  $Ra_B$  there is *runaway field growth* from Ha = O(1) to the strong field regime where  $Ha = O(E^{-1/2})$ .

The scenario just described, apart from the final runaway process, has been demonstrated by Soward (1974). His analysis showed that the asymptote  $Ra = Ra_A$  exists. Strong field solutions were obtained numerically by Jones and Roberts (2000). Once the strong field dynamo is established, hysteresis occurs: the dynamo can continue to function even if Ra is reduced below  $Ra_B$  (Rotvig and Jones, 2002). The dynamo is then in a "subcritical state." It may even be that it can regenerate the field when  $Ra < Ra_c$ , but this has not been demonstrated; it is clear however that the strong field branch is bounded below by some value  $Ra_{\min}$  of Ra of order  $E^{-1}$  or larger, i.e., the dynamo will fail if the buoyancy forces cannot make good the ohmic losses.

It may be wondered whether the spherical convecting system considered in the Section on Classical theory of rotating fluids would behave in a fundamentally different way from the plane layer. This qualm is significantly harder to allay because the analytical and numerical

**Figure M153** A cartoon showing the weak and strong field branches of the plane layer dynamo (full lines). The dashed curve displays the unstable branch connecting them (see text for full explanation).

approaches are much more difficult to implement. There seems, however, to be no reason to doubt that, by opposing the rotational constraint, a magnetic field will generally allow convection to occur on large scales, as planetary waves, with correspondingly less ohmic and viscous energy losses, and that a strong field branch of dynamo solutions will result. Numerical simulations of convective dynamos have demonstrated that the field adapts itself to oppose the Coriolis force. They have also confirmed the increase in the scale,  $\mathcal{L}_{\perp}$ , created by the magnetic field; far fewer Taylor cells lie on the cartridge belt of the Section on Classical theory of rotating fluids. Through the analysis of magnetic features on the CMB, Gubbins and Bloxham (1987) have inferred flux concentrations that may be associated with the ends of four, but no more than four, Taylor cells (see also Kahle *et al.*, 1967).

In the parameter range just considered ( $E \ll 1$ ,  $P_t = O(1)$ ,  $P_m = O(1)$ ), the criterion  $Ra_m = O(1)$  of the Section on CMHD for ideal fluids for MAC wave instability is essentially the same (for  $\Lambda = O(1)$ ) as the criterion  $Ra_{mod} = O(1)$  for thermal instability. This range is however irrelevant to the core, where  $E \ll 1$ ,  $P_t = O(1)$ ,  $P_m \ll 1$ . It is hard to make progress in this difficult parameter range, and the theory is still somewhat speculative. Since  $Ra_m/Ra_{mod} = (P_m/P_t)\Lambda^{-1} = O(\kappa/\eta) \sim 10^{-5}$ , thermal convection can occur in the range  $1 < Ra_{mod} < Ra_m$  in which MAC wave instability is impossible. Since, by Eq. (127),  $R_m < \Lambda \sim 100$  in this range of  $Ra_{mod}$ , convective motions are too weak to maintain a dynamo. Only when the convection is strongly supercritical and the MAC wave bifurcation is reached ( $Ra_{mod} \sim 10^6$ ,  $Ra_m \sim 1$ ) can magnetic field be generated. (For analogous behavior in a simpler system, see Jones *et al.*, 1976.)

The observed geomagnetic field shows a tendency to drift in longitude (see *Westward drift*). Three mechanisms may contribute to this motion: field diffusion, MAC wave propagation and actual fluid motions. Field lines can diffuse with velocity  $c_d = \eta/\mathcal{L}$  relative to the moving conductor (see the Section on The imperfect conductor, reconnection), and this velocity is comparable for  $R_m = O(1)$  with V and  $c_s$ . It is therefore hard to decide quantitatively how much of the observed drift to attribute to each of the mechanisms. A CMHD model of Roberts and Stewartson (1975) demonstrated a clear preference for westward flux diffusion (see also Acheson, 1972). The recent geodynamo simulations of Glatzmaier and Roberts (1997) have shown a striking propensity for flux diffusion to the west despite zonal fluid motion predominantly to the east. As shown in the Sections on the Classical theory of rotating fluids and Classical MHD, boundary layers arise when  $E \ll 1$  and also when  $Ha \gg 1$ . Another characteristic of CMHD is that, when  $\Lambda(=Ha^2E)$  is O(1), neither Ekman nor Hartmann layers exist; they are replaced by a composite *Ekman-Hartmann layer*. Its thickness,  $\delta_{EH}$ , is of the same order as  $\delta_E$  and  $\delta_M$ . It pumps both fluid and current into or out of the mainstream beyond the boundary layer. As for the Ekman and Hartmann layers, the Ekman-Hartmann layer provides a link through which angular momentum can be exchanged between the fluid and surrounding solid walls. This is accomplished by a viscous stress and, if the wall is electrically conducting, by a magnetic stress (see Eq. (39)). The role of boundary layers in geomagnetic simulations has been controversial (see *Core, boundary layers*).

## MAGNETOMETERS, LABORATORY

Magnetometers in paleomagnetic laboratories are used for the determination of the geomagnetic field directions and intensities that have been recorded in rocks, and also for the discrimination of magnetic minerals and their magnetic properties. For paleomagnetism, the main consideration is to measure that magnetization vector in a rock, whereas for environmental magnetism the requirement is to identify a sample's magnetic mineralogy and grain size distribution. In either case the magnetometers employed can operate by one of two fundamentally different processes. Either the magnetization of the sample can be used to induce a current in a sensing coil, or the magnetization can create a force by interacting with an instrument-generated magnetic field gradient, and the force measured by a variety of methods.

## Magnetometers used for determination of paleomagnetic vectors

Standard paleomagnetic samples are 2.5 cm diameter cores, approximately 2.5 cm in length, and most paleomagnetic magnetometers will be designed for this sample size. The major exception of this will be whole core sections commonly collected from lake and deep-sea sediments and used in environmental studies. These cores are typically 10 cm in diameter and can be several meters in length.

#### Astatic magnetometers

Astatic magnetometers were the most common type of instrument in paleomagnetic laboratories in the 1950s and 1960s. They are a force-type magnetometer, where the magnetization of a sample is used to exert a force on a pair of identical suspended magnets. The bar magnets are set with their axis horizontal and are suspended vertically above each other via a torsional wire (Figure M154). Although in

**Figure M154** The arrangement of magnets in an astatic magnetometer. If sample is either placed in the horizontal plane containing magnet B, or vertically below B, then only the magnetization component normal to that of B is measured. If the sample is placed midway between A and B, then the vertical component of its magnetization is measured.

principle, just one magnet could be used, the vertical pairing of the magnets increases accuracy by making the deflection insensitive to uniform field gradients. Addition of a third magnet (parastatic magnet-ometers) reduces sensitivity to changes in vertical field gradients. The accuracy of astatic magnetometers largely depends on the magnets having a large magnetization and small moment of inertia, but typically sensitivities are less than  $10^{-8}$  A m<sup>2</sup>. One of the first such instruments was used for paleomagnetism by Blackett (1952) and similar instruments were in common usage in paleomagnetic laboratories into until the mid-1970s.

#### Spinner magnetometers

These are a range of magnetometers that induce a signal in a static sensor by spinning the sample about its own axis. The spinning sample will produce a time-varying magnetic flux with respect to one or more stationary sensors. The sensor determines the magnetization component in the plane normal to the sample rotation axis. Within this plane, the magnetization vector is found with reference to a fixed direction by comparing the sensor output to a signal linked to the rotation mechanism (Collinson, 1983). The overall sensitivity of the spinner magnetometer will depend on the speed at which the sample is rotated and the sensitivity of the sensors themselves, and so a wide range of sensitivities are possible depending on the type of sensor employed. The simplest sensor is an induction coil placed around the sample chamber, and in this case the signal output will increase with sample size (limited by the induction coil size) and with the rotation frequency. The highest sensitivities for such instruments approach  $10^{-10}$  A m<sup>2</sup>. Fluxgate sensors (see Observatories, instrumentation) may be used instead of induction coils or increased sensitivity can be obtained using a superconducting quantum interference device (SQUID) detector (see Cryogenic magnetometers below).

# Cryogenic magnetometers (see also *Rock magnetometer, superconducting*)

Cryogenic magnetometers are currently the most sensitive device for measuring magnetizations, commonly achieving sensitivities of  $10^{-12}$  A m<sup>2</sup>. They consist of a superconducting coil that surrounds the sample to be measured. The magnetization of the sample changes the magnetic flux that passes through the sensing coil, which then induces a current to flow through the sensor coil. The current is detected by a SQUID, and these magnetometers are sometimes referred to as SQUID magnetometers. There are two types of SQUIDs, direct current (DC) and radio frequency (RF), depending on the exact method used to detect the current induced in the sensing coil. DC SQUIDs are more expensive but much more sensitive, and it is this type that is usually used in modern paleomagnetic magnetometers.

SQUID magnetometers can only measure the change in magnetic flux through its sensing coils, and there will be an output signal even when no sample is present. Thus, in order to determine a sample's magnetization, it must be cycled in and out of the sensing coil and the background reading subtracted.

The main disadvantage of cryogenic magnetometers is the requirement of having to keep the sensing coil superconductive, since this normally requires immersion in liquid helium (recently 4.2 K cryocoolers have been used without the need of liquid helium). High-temperature SQUIDs are able to operate at liquid nitrogen temperatures but the increased thermal noise prevents then from attaining the sensitivities available for conventional SQUIDs.

# Magnetometers used for discrimination of magnetic minerals

#### Alternating gradient magnetometers (AGM)

Electromagnets are used to produce an alternating magnetic field gradient across a region in which a sample is placed. The sample is mounted

**Figure M155** A schematic of an alternating gradient magnetometer. The force on the sample is generated by a set of field coils, and the motion of the sample is proportional to its magnetization.

at one end of a vertical cantilever, the other end of which is attached to the bottom of a piezoelectric transducer (see Figure M155). The alternating field gradient exerts an oscillatory force on the sample, and the bending of the transducer produces a voltage proportional to the amplitude of the oscillation.

The amplitude of the displacement of the rod at the sample is then given by  $A = M \cdot \nabla H(Q/k)$ , where *M* is the sample magnetization,  $\nabla H$  is the field gradient generated by the instrument, *Q* is the mechanical quality factor of the cantilever (its resonance frequency divided by its resonance width), and *k* is the effective spring constant of the rod. The AGM needs to be operated at the resonance frequency of the cantilever system, and this will change with the weight of the sample. The sensitivity of the instrument is limited by thermal noise in the mechanical oscillator, and typical sensitivities are comparable to cryogenic magnetometers (~10<sup>-12</sup> A m<sup>2</sup>).

A DC field may also be applied during measurements, allowing the magnetization as a function of field to be determined. Often a heater or cryostat is also fitted to such instruments allowing both field and temperature variation of the magnetization to be determined (O'Grady *et al.*, 1993).

AGMs are not well suited to measuring paleomagnetic samples since they only measure the magnetization component along the applied field gradient, and the sample size is relatively small (usually a few millimeters in size) compared with the standard paleomagnetic sample size of 2.5 cm diameter cores. AGMs are good for characterization of magnetic minerals and determining the magnetization dependence as a function of applied field or temperature.

#### Vibrating sample magnetometers

These are similar to AGMs, but rather than using a field gradient, the sample is mechanically vibrated at a fixed frequency (see Figure M156). The sensing coils will have an emf induced within them due to the changing flux produced by the vibrating sample. For a sample magnetization M, the induced voltage V in the sensing coils is given by  $V = \mu_0 GM\omega A \sin \omega t$ , where  $\omega$  is the angular frequency of the vibration, and A is the vibration amplitude. G is a factor relating to the geometry of the sensing coils. A uniform magnetic field in the region

656

of the sample is provided by an electromagnet, or superconducting solenoid if fields greater than 3T are required. A heater or cryostat can be fitted for variable temperature measurements.

VSMs are usually at least an order of magnitude less sensitive than AGMs but have the advantage of being able to handle much larger sample sizes (Lindemuth *et al.*, 2000), and are thus more suitable for standard paleomagnetic samples. The VSM, like the AGM, is generally used for high-field measurements, such as hysteresis properties. The large metal poles of the DC electromagnets used to generate the uniform field will have a residual field even when no current flows through the coils (the residual remanence of the pole pieces is avoided by using a field-controlled (with Hall sensor) power supply). The difficulty in reducing the ambient field in the region of the sample to a sufficiently low value makes these instruments unsuitable for low field (remanence) measurements.

## Translation balance

A translation balance in its simplest form consists of a rod suspended by wires so it is free to make small movements along its axis (see Figure M157). The sample is placed at one end of the rod, and a field

**Figure M156** A schematic of a vibrating sample magnetometer. The sample is vibrated mechanically, and the induced signal in the sensing coils will be proportional to its magnetization.

**Figure M157** The principle elements of a horizontal translation balance. An electromagnet produces a large magnetizing field  $H_y$  along the *y*-axis and a field gradient along the *x*-axis that generates a force on the sample proportional to its magnetization.

is created perpendicular to the rod axis, by means of a large electromagnet. The field produced by the electromagnet will have a gradient along the rod axis, and the force on the magnetic sample will therefore be given by  $F = M \, dH_y / dx$ , where *M* is the sample magnetization (see-Figure M157). This force causes a translation of the rod, which is calibrated against the samples magnetization. Such instruments will normally have an oven surrounding the sample so that the magnetization can be measured as a function of temperature, allowing the Curie point to be determined. Sensitivities of  $10^{-9}$  A m<sup>2</sup> can be achieved with these instruments.

#### Cryogenic magnetometers

SQUID magnetometers (described above) are also used in magnetic mineralogy. Here, the requirement for liquid helium to keep the sensing coils superconducting can also be used to cool the sample, and provide large fields (greater than 5T) in superconducting solenoids. It is therefore possible to measure over a wide range of temperatures (down to less than 2K) and fields. However SQUID sensors do not allow continuous measurement of magnetization versus field strength. To change the field within a superconducting coil it must be switched out of its superconducting state. This requirement makes field dependency observations much more time consuming compared to similar measurements on a VSM or AGM.

## MAGNETOSPHERE OF THE EARTH

The Earth's magnetosphere is the region surrounding the planet, above the outer atmosphere and *ionosphere* (q.v.), which contains and is controlled by the Earth's magnetic field. It extends from an altitude of ~500 km above the Earth's surface to an outer boundary which is formed by the interaction of the planetary magnetic field with the solar wind, the plasma (charged particle) gas that streams continuously outward from the Sun. On the dayside, the compressive effect of the solar wind confines the field to a region extending ~10 Earth radii from the Earth, while on the nightside the field is stretched into a long comet-like tail which extends typically in excess of ~1000 Earth radii. The Earth's radius,  $R_E \sim 6400$  km, is thus a convenient measure of magnetospheric spatial scales. Electric currents flowing in these regions, whose magnetic effects can be observed at the Earth's surface, include those flowing at the solar wind-magnetosphere boundary, those produced by the drift of energetic charged particles inside the magnetosphere, and those associated with the coupling between the magnetosphere and the ionosphere Ohtani *et al.* (2000). Magnetic perturbations observed at the Earth's surface due to these three sources peak typically at a few tens, a few hundreds, and a few thousands of nanoteslas, respectively, and vary on a range of timescales from minutes to hours and days. In this article we first concentrate on the overall structure and basic physics of the coupled solar wind-magnetosphere-ionosphere system, and then consider the dynamic processes which occur, leading to strong temporal variations.

#### Structure of the magnetosphere

In Figure M158 we show a cross-section through the Earth's magnetosphere in the noon-midnight meridian plane, where the arrowed solid lines indicate magnetic field lines. The small symbols indicate the main plasma populations, while the arrows show their principal flows. The small dashes show the solar wind plasma, together with the magnetospheric "boundary layer" plasma populations derived directly from it. The direction of the Sun is toward the left, so that the solar wind flows from left to right as indicated. The solar wind derives from hydrogen gas in the solar atmosphere, which is heated sufficiently strongly in the solar corona, to temperatures in excess of a million degrees, that the atoms are fully broken up by collisions to form a plasma of electrons and protons (plus a few percent  $\alpha$ -particles from helium), which then streams continuously out into the solar system at speeds  $\sim$ 500 km s<sup>-1</sup>. At the orbit of the Earth, the proton and electron number densities are  $\sim 10 \text{ cm}^{-3}$ , sufficiently low that the particles in the gas are collision-free, meaning that the mean free path for particle collisions is comparable with or larger than the size of the system. A second source of plasma in the magnetosphere derives from the Earth's upper atmosphere, which is relatively cool ( $\sim 1000$  K) but is partially ionized by solar far-UV and X-rays at altitudes above

**Figure M158** Sketch of a cross section through the Earth's magnetosphere in the noon-midnight meridian plane. The direction of the Sun is toward the left, such that the solar wind blows from left to right. The arrowed solid lines show magnetic field lines, while the heavy dashed lines show locations of principal field and plasma discontinuities at the bow shock and magnetopause. The small symbols indicate the principal plasma populations present, while the arrows indicate their direction of flow. The dashes indicate the solar wind, and the plasma populations derived directly from it in the magnetosheath and magnetosphere (cusp and plasma mantle). The crosses indicate plasma originating from the Earth's ionosphere (plasmasphere and polar wind), while the dots indicate the heated plasma of mixed origin that originates in the tail (plasma sheet and ring current).

~100 km, forming the ionosphere. These charged particles, consisting of protons and heavy ions, principally singly-charged oxygen, together with corresponding electrons, can also stream out of the topside ionosphere into the magnetosphere, as indicated by the small crosses in the figure. In the ionosphere, collisions between ions and neutral atoms are significant at altitudes up to  $\sim$ 500 km. Above this altitude, however, the ionospheric ions also become collision-free due to falling densities,  $\sim$ 500 km thus being chosen (rather arbitrarily) above as the "base" of the magnetosphere, where it interfaces with the ionosphere. Like the solar wind, therefore, the plasma of charged particles in the Earth's magnetosphere is also collision-free. Although the Earth's neutral atmosphere is detectable throughout the magnetosphere to distances of at least  $\sim 10 R_{\rm E}$  (forming a hydrogen "geocorona" originating from the photodissociation of water vapor lower in the atmosphere), the behavior of neutral and charged particle populations within it are largely decoupled due to the lack of collisions, apart from the occasional charge-exchange reaction between them.

When collisions can be ignored, the motion of ions and electrons in the plasma is governed by the forces of the large-scale fields prevailing, and for both solar wind and magnetosphere the most important forces by far are electromagnetic. Solar and planetary gravity is only important in the regions close to the bodies concerned, i.e., in the solar corona near the Sun, and in the ionosphere near the Earth. The motion of charged particles in a large-scale electromagnetic field consists of a number of components, which take place on generally widely separated timescales. The first is a rapid gyration of the particles around the magnetic field lines in nearly circular orbits whose radius is generally tiny compared with the scale size of the systems. The second is a uniform motion along the magnetic field lines, which is subject to the magnetic mirror force which repels particles from regions of increasing field strength along the field lines (i.e., is directed away from regions where field lines converge). The mirror force is produced by the action of the field strength gradient on the magnetic dipole formed by the gyrating particle. In the quasidipolar field of a planetary magnetosphere, for example, the field strength along a given field line is weakest at the equator and increases greatly toward the planet (see Figure M158). This configuration can therefore trap charged particles almost indefinitely, the mirror force resulting in a bounce motion between mirror points in the northern and southern hemisphere. Only those particles that are directed almost along the field lines at the equator, which thus have small magnetic moments, can reach down to the upper layers of the atmosphere. The third motion consists of large-scale plasma flows transverse to the magnetic field lines, such as that shown for the solar wind in Figure M158. Such flows are associated with an electric field *E* directed transverse to the magnetic field B, related to the plasma velocity V by the vector relation  $E = -V \times B$ . (The effect of additional cross-field drifts associated with magnetic field inhomogeneity will be discussed further below.) Inspection of the flows indicated in Figure M158 shows that the electric field is directed everywhere out of the plane of the diagram, though it is not everywhere of equal strength. In such "crossed" electric and magnetic fields, charged particles drift perpendicular to the magnetic field with velocity  $V = (E \times B)/B^2$  independent of their charge or mass, this expression being exactly equivalent to the vector relation for E given above.

This " $E \times B$  drift" has a very special property, first discovered by Alfvén in 1942 (see *Alfvén's theorem*), that particles whose centers of gyration lie initially on the same field line as each other, remain on the same field line as each other for all time, thus showing why plasma structures are strongly organized by magnetic field lines, as indicated by various features in Figure M158. We may picture the collective behavior as one in which the magnetic field and the plasma are "frozen" together. However, we can think either of the plasma as moving and carrying the field lines, or equivalently of the field lines as moving and carrying the plasma. Which of these pictures is the most appropriate for a given system depends upon the relative energies in the plasma and magnetic field. Thus, for example, since the plasma energy exceeds the magnetic energy in the solar wind, the solar magnetic field is carried outward "frozen" into the expanding plasma flow, forming a large-scale interplanetary magnetic field (IMF) that pervades the entire solar system (see Figure M158). The strength of the IMF at the Earth's orbit is typically  $\sim$ 5–10 nT, directed, on the average, in the ecliptic plane at an angle of  $\sim$ 45° to the Earth-Sun line. The latter tilt is due to the rotation of the Sun, which winds the IMF into a spiral form as the field lines are carried out into the solar system by the plasma flow. On the other hand, in the quasidipolar field regions of the magnetosphere and ionosphere, where the magnetic energy dominates, we instead think of the field lines as moving, transporting the plasma.

We may apply this "frozen-in" concept to the interaction between the solar wind and the planetary magnetic field. Since the solar wind and IMF are frozen together, as well as the planetary field and planetary plasma (e.g., from the ionosphere), then when these two media interact they will not mix. Instead, the solar wind confines the planetary field to a cavity surrounding the planet, around which it flows, as first deduced by Chapman and Ferraro in 1931 (see *Chapman, Sydney*). This magnetic cavity is the planet's magnetosphere, whose outer boundary, shown by the dashed line in Figure M158, is called the "magnetopause." A "bow shock" forms ahead of the cavity, also shown by a dashed line in Figure M158, due to the fact that the magnetosphere represents a blunt obstacle in the supersonic solar wind flow. Across the shock the solar wind is slowed, compressed, and heated, forming the turbulent "magnetosheath" layer located between the shock and the magnetopause boundary.

The size of the magnetospheric cavity is set by the condition of pressure balance at the boundary. A simple estimate of the distance of the equatorial boundary at noon (the minimum distance in the direction facing the Sun) can be made by equating the ram pressure of the solar wind on one side of the boundary, with the magnetic pressure  $(B^2/2\mu_0)$  of the compressed planetary field on the other. With typical solar wind values the radial distance of the boundary is estimated to be  $\sim 10 R_{\rm E}$  on this basis, as observed, a position which may vary by factors of up to two in either direction under extreme solar wind conditions. The strength of the compressed planetary field just inside the boundary is typically  $\sim 60$  nT, representing a planetary dipole field of  $\sim$ 30 nT enhanced by a factor of  $\sim$ 2 by the electric current flowing in the magnetopause boundary. This latter current is termed the "Chapman-Ferraro" current, and inspection of Figure M158 with Ampere's law in mind shows that it flows out of the plane of the diagram in the equatorial region on the dayside, closing over the magnetopause into the plane of the diagram over the polar regions and on the nightside. These rings of magnetopause current produce a perturbation magnetic field in the near-Earth magnetosphere whose strength is typically a few tens of nanoteslas directed northward (i.e., upward in Figure M158), hence enhancing the horizontal field at low and middle latitudes at the Earth's surface.

Frozen-in behavior of the field and plasma associated with the  $E \times B$  drift is not, however, a universally valid description. In a collision-free medium it is broken in particular by the presence of additional particle drifts, the most significant of which cause ions and electrons to drift in opposite directions across the field (thus producing a current) due to the presence of gradients in the strength and direction of the magnetic field. These "field inhomogeneity" drifts are proportional to the field gradients, and also to the particle energy, thus being more important for particles of higher energy. When the field gradients are weak, these additional drifts are important only for particles in the high-energy tail of the energy distribution, and frozen-in motion then represents a useful organizing concept for the bulk of the plasma population. This limit applies essentially throughout the solar wind, and through most of the Earth's magnetosphere. However, when the field gradients are very strong, such that the motion of the bulk of the plasma particles is affected, then the frozen-in picture breaks down. One such place where this happens is the magnetopause boundary, where the field strength and direction in general switch rapidly from

magnetosheath to magnetosphere values across the magnetopause current sheet. The simplest theoretical description of the consequence of frozen-flux breakdown is that the magnetic field diffuses through the plasma, locally, in the region of the strong gradient. As first pointed out by Dungey in 1961, this then allows magnetic field lines to become joined across the boundary, producing "open" magnetic field lines which pass from the solar wind at one end, through the magnetopause, to the Earth's polar regions at the other. This process is called "magnetic reconnection." Two newly reconnected open field lines are shown in Figure M158 passing through the dayside magnetopause shortly after reconnection has taken place near the equator. Sharply bent magnetic field lines exert a tension force on the plasma like the force of rubber bands (the force per unit volume being  $j \times B$ , where *j* is the current density in the plasma), in this case accelerating the boundary plasma poleward away from the equator, such that the field lines also contract poleward, releasing energy to the plasma and allowing further reconnection to proceed at the equator. Subsequently, the open field lines are carried downstream frozen into the magnetosheath flow, and are stretched out into a long cylindrical comet-like tail. This tail consists of two lobes, D-shaped in cross-section, one connected to the northern polar region at Earth, the other to the southern, as indicated in Figure M158. Observations show that the tail lobe field lines remain open typically for a few hours, such that with a downstream speed of  $\sim$ 500 km s<sup>-1</sup>, the tail is typically  $\sim$ 1000  $R_{\rm E}$  long.

The open field lines form magnetic pathways along which the magnetosheath plasma may enter the magnetosphere. Such plasma thus flows along newly opened field lines to form a boundary layer adjacent to the dayside magnetopause, and the "cusp" population as it then moves down toward the Earth (see the magnetospheric dashed regions in Figure M158). The majority of the particles, however, are repelled by the magnetic mirror force as the field strength increases near the Earth, and hence move back out again toward the outer magnetosphere. Due to the antisunward motion of the open field lines, however, the cusp plasma flows back out into the lobes of the tail, in the region adjacent to the magnetopause, forming the "plasma mantle" population. As the open field lines are carried down the tail, so the field lines and mantle plasma sink in toward the center plane of the tail, followed by further entry of antisunward flowing magnetosheath plasma at the tail magnetopause, such that the mantle grows wider and with increasing density at larger distances. Plasma from the Earth's polar ionosphere also flows into the lobes (cross symbols in Figure M158), but because of its low velocity along the field lines  $(\sim 10 \text{ km s}^{-1})$ , it does not reach far down the tail on the few-hour timescale that the lobe field lines remain open. Overall, the plasma density in the inner part of the tail lobes is very low,  $\sim 0.01-0.1$  cm<sup>-3</sup>, and with temperatures typically of order a few tens to a few hundred electronvolts, most of the system energy resides in the lobe magnetic field. (Note that while temperatures in the solar and terrestrial ionized atmospheres are generally quoted in Kelvin, as above, the temperatures of magnetospheric plasmas are usually indicated by the mean or typical energy of the particles W, in eV. To convert between them, we note that for a near-Maxwellian velocity distribution  $T(K) \approx 10^4 W(eV)$ . Thus, for example, typical hot magnetospheric plasma of  $\sim 1$  keV mean energy corresponds to a temperature of  $\sim 10^7$  K.)

The residency of the oppositely directed open field lines in the two tail lobes is terminated when they sink into the center plane of the tail and reconnect in the equatorial current sheet that separates them, as shown by the X-shaped field configuration on the right side of Figure M158. On the tailward side of the tail reconnection site the lobe field lines become disconnected from the Earth, and the  $j \times B$  (rubber band) tension force accelerates the tail plasma rapidly away from the Earth, where it eventually rejoins the solar wind. On the Earthward side, the process forms new "closed" field lines, connected to the Earth at both ends, which similarly contract rapidly earthward, compressing and heating the lobe plasma as they do so. This hot plasma, containing both solar wind and ionospheric contributions, is termed the "plasma sheet" population, and is shown by the dotted

region in Figure M158. In the near-Earth tail it is characterized by densities  $\sim 0.1-1$  cm<sup>-3</sup>, and electron and ion temperatures of  $\sim 0.5$ and  $\sim$ 5 keV, respectively, but both density and temperatures increase as the plasma flows earthward into the quasidipolar inner magnetosphere and is further compressed and heated. Throughout these regions the hot plasma sheet population carries a current, due to the fieldinhomogeneity effects mentioned above, which is directed westward, i.e., out of the plane of Figure M158 on the nightside of the Earth, and into the plane of the diagram on the dayside. On the nightside within the tail, the current paths reach the tail boundary, and close over the magnetopause to form two D-shaped solenoids lying back-to-back, as required by the lobe magnetic field structure. Nearer the Earth, the current paths may close wholly round the Earth to form a plasma "ring current" (q.v.). Overall, these currents produce a perturbation field at the Earth, which is directed southward (i.e., downward in Figure M158), and is usually a few tens of nanoteslas in amplitude. However, as we discuss below, these currents become greatly enhanced during magnetic storms (q.v.), producing perturbation fields up to an order of magnitude larger.

The closed field lines and hot plasma produced in the tail subsequently flow sunward around the Earth in the quasidipolar magnetosphere, eventually reaching the dayside magnetopause where they become open again, allowing the hot magnetospheric plasma to escape into the magnetosheath, as indicated by the dotted region outside the magnetopause. Overall, therefore, reconnection at the magnetopause and in the tail results in the formation of a large-scale cyclical flow of field lines and plasma through the Earth's magnetosphere, first discussed by Dungey in 1961. The overall cycle time is  $\sim 12$  h, of which the field lines spend  $\sim$ 4 h open in the tail lobes, and  $\sim$ 8 h closed flowing sunward through the central magnetosphere. The solar wind is not, however, the only source of momentum that drives magnetospheric flow. A second source resides in the rotation of the Earth, and the coupled rotation of the Earth's upper atmosphere. Collisions between ions and neutral atmospheric particles in the ionosphere produce a frictional force on the feet of the magnetospheric field lines which tends to spin them up toward rotation with the planet, a flow called "corotation." In general, the overall magnetospheric flow results from a summation of the effects of the planetary and solar wind driving forces. The corotation effect tends to produce a flow in the equatorial plane increasing linearly with the distance from the planet (i.e., a flow with the planetary angular velocity), while in the simplest picture of a dipole magnetic field and uniform cross-system electric field, the equatorial Dungey-cycle flow increases as the cube of the distance (i.e., as the inverse of the field strength). Reflection on these relative dependencies then shows that corotation will dominate close-in, and Dungey-cycle convection at larger distances. For Earth, the boundary between these flow regimes is located typically at  $\sim 5 R_{\rm F}$  in the equatorial plane, about half-way to the dayside magnetopause. The hot plasma flowing in from the tail is therefore excluded from this inner core of corotating field lines, as indicated in Figure M158, which is instead filled to relatively high densities ( $\sim 100-1000 \text{ cm}^{-3}$ ) by cold ( $\sim 1-10$  eV) hydrogen and oxygen plasma from the ionosphere. This population is termed the plasmasphere, and is indicated by the near-Earth region of dense crosses in Figure M158.

## Magnetosphere-ionosphere coupling

The magnetospheric flows discussed above produce corresponding motions of the field and plasma in the polar ionosphere, resulting in large-scale current systems flowing between these regions. Figure M159 shows a view looking down on the North Polar Region, with noon (the direction toward the Sun) at the top of the diagram, dusk to the left, dawn to the right, and midnight at the bottom. The central circular dashed line shows the outer boundary of the "open" field region (located typically at magnetic latitudes of  $\sim$ 75° at noon and  $\sim$ 70° at midnight), while the arrowed solid lines show plasma streamlines. The open field lines within the dashed line boundary,

**Figure M159** Sketch looking down onto the northern polar ionosphere, with noon (the direction toward the Sun) at the top of the diagram, dusk to the left, dawn to the right, and midnight at the bottom. The dashed line shows the boundary between open and closed magnetic field lines, while the arrowed solid lines show the streamlines of the Dungey-cycle plasma flow driven by solar wind-magnetosphere interaction. The short arrows marked *E* indicate the directions of the electric field associated with the flow,  $E = -V \times B$  (the magnetic field points into the northern ionosphere), while the circled dots and crosses indicate regions of upward and downward field-aligned current (FAC) flow, respectively. The small symbols indicate the principal plasma regimes into which the field lines map in the magnetosphere, with the same format as Figure M158.

mapping to the northern tail lobe, flow antisunward from noon to midnight at speeds typically of a few 100 m  $s^{-1}$ , while the closed field lines at lower latitudes return sunward. This twin-vortex flow is the signature of the Dungey-cycle in the ionosphere. The  $-V \times B$  electric field associated with the flow is directed from dawn to dusk across the open field line region as indicated, reversing in sense to poleward at dusk and equatorward at dawn. The small symbols also show the magnetospheric plasma populations into which the ionospheric field lines map, the symbol code corresponding to that in Figure M158. Ions and electrons from the cusp (dashes) and plasma sheet (dots) precipitate into the upper atmosphere, excite the atoms (typically at altitudes  $\sim$ 100–300 km), and cause them to emit photons, giving rise to one component of auroral light emissions (see Auroral oval) Paschmann et al. (2002) and Sandholt et al. (2001). They also ionize the neutral atoms and increase the plasma density of the ionosphere, a process that is especially important at night when the solar production mechanism is inoperative.

The Dungey-cycle flow drives two components of electric current in the lower ionosphere, both resulting from the effects of collisions between ionospheric ions and atmospheric neutral particles. At altitudes below  $\sim$ 120 km, these collisions become sufficiently frequent that the ions do not move with the field lines at all, but are essentially tied to the generally smaller motions of the upper atmosphere (i.e., the winds in the neutral thermosphere). However, the electron motion remains almost unaffected by collisions, frozen to the field line motion
660

throughout the ionosphere, to altitudes below  $\sim 100$  km. Consequently, in the layer between  $\sim 100$  and 120 km, ionospheric electrons flow around the streamlines shown in Figure M159, carrying a current in the opposite direction, while the ions in the layer remain almost motionless, tied to the neutral atmosphere. This current, directed transverse to both the electric and magnetic fields is thus termed a Hall current, and with a height-integrated ionospheric conductivity of ~10 mho and typical ionospheric flows of several hundred meters per second, it produces equal and opposite magnetic perturbations on either side of the ionospheric Hall layer which are typically ~100-200 nT in strength. At the Earth's surface in the northern hemisphere these perturbation fields are roughly in the direction of the overhead ionospheric electric field (opposite in the southern hemisphere). These currents are nondissipative (i.e.,  $\mathbf{j} \cdot \mathbf{E} = 0$ ), and in principle can close wholly within the ionosphere (for uniform conductivity), flowing round the plasma flow streamlines.

The second current component flows at a slightly higher altitude of  $\sim$ 120–150 km, where the ion motion is affected by collisions with neutrals, but is not yet wholly dominated by them. In this layer collisions provide the ions with some mobility in the direction of the electric field, while continuing to move approximately with the electrons along the plasma streamlines. An ion current thus flows in the direction of E, termed the Pedersen current, and its magnitude is such that the  $j \times B$  force of the current, directed along the plasma streamlines, just balances the frictional drag on the ionospheric plasma due to ion-neutral collisions in the ionosphere. A key fact about the Pedersen current is that it cannot, in principle, close within the ionosphere itself, but is instead part of a large-scale current system which flows between the magnetosphere and ionosphere, which imposes the flow of the former onto the latter in the presence of ionospheric ion-neutral drag. It can be seen in Figure M159, for example, that the Pedersen currents, directed along E, flow away from the open-closed field line boundary on both sides at dawn, while flowing toward the boundary from both sides at dusk. Current continuity then requires the presence of fieldaligned currents (FACs), which flow down the field lines from the magnetosphere to the ionosphere at the dawn boundary, and up the field lines from the ionosphere to the magnetosphere at the dusk boundary. These are called the "region 1" FACs, whose direction is indicated in Figure M159 by the circled dots and crosses for upward and downward currents, respectively. These FACs close across the field lines at large distances in the plasma which is the source of the momentum producing the flow, i.e., in the magnetosheath plasma at the tail magnetopause. The magnetic perturbations produced by the overall current circuit bends the magnetic field lines in such a way that the  $\mathbf{j} \times \mathbf{B}$  force slows the magnetosheath plasma, while transferring the momentum to the ionosphere to maintain the flow against collisional frictional drag. Overall, this current system is solenoidal in nature, such that the main magnetic effects are contained within the effective current solenoid between the ionosphere and magnetopause. Thus although the ionospheric height-integrated Pedersen conductivity is generally comparable with the height-integrated Hall conductivity, such that the two height-integrated current components are of similar intensity in the ionosphere, the combined contribution of the ionospheric Pedersen current and the associated FACs approximately cancels underneath the ionosphere, and produces a much weaker magnetic perturbation on the ground than that of the Hall current. Above the ionospheric Pedersen layer, however, the perturbation field produced by the Pedersen-FAC system is directed approximately opposite to the plasma streamlines in the northern hemisphere, and along the streamlines in the southern hemisphere. Typical amplitudes in the region just above the Pedersen layer are again a few 100 nT. The total current flowing in the "region 1" FAC system is typically  $\sim 2-3$  MA.

We also note from Figure M159 that Pedersen current continuity at the equatorward boundary of the Dungey-cycle flow (typically located at magnetic latitudes of  $\sim 70^{\circ}$  at noon and  $\sim 65^{\circ}$  at midnight), also requires the presence of upward FACs at dawn and downward FACs

at dusk. These are called the "region 2" FAC system, in which the upward currents at dawn close in the downward currents at dusk via field-perpendicular currents flowing westward in the inner edge of the equatorial plasma sheet population in the nightside magnetosphere (and then via ionospheric Pedersen currents, the "region 1" FAC, and the tail magnetopause). The total current flowing in the "region 2" FACs is a little less than that in the "region 1" FACs, due to the fact that the latter currents are fed by Pedersen currents from both open and closed field line regions. We also note that regions of upwarddirected FAC are often associated with bright "discrete" auroras (e.g., structured curtain-like forms), thus forming another component of the auroral emissions. This is because upward currents are carried primarily by warm plasma sheet electrons, which flow down the field lines into the ionosphere. In order to produce a downward electron flux which is sufficient to carry the upward current, the electrons may be accelerated downward by an electric field directed upward along the field lines (this being another scenario in which the frozenin picture breaks down). Typically the required field-aligned voltages are a few kilovolts, such that the precipitating electrons carry a sufficient energy flux to produce a bright aurora.

## Magnetosphere dynamics

The above discussion has centered on the plasma physics principles which govern the structure and properties of the coupled magnetosphere-ionosphere system, focusing particularly on the nature of the current systems that flow within it. For clarity of exposition we have viewed the system as being steadily driven, principally by the solar wind, but also by planetary rotation. However, it is now important to emphasize that the Earth's plasma environment is almost never in such a steady state, but generally varies strongly with time Cowley et al. (2003). There are two reasons for this. The first is that the interplanetary medium which impinges on the Earth's field itself varies strongly with time, on timescales from a few minutes to the  $\sim$ 27-day rotation period of the Sun. There are also variations over the 11-year period of the solar cycle. The second factor is that even when the solar wind is relatively steady, the processes in the key interaction regions at the magnetopause and in the tail show a propensity for pulsed behavior. We will now outline these behaviors, beginning here with those which are driven essentially directly by variations in the interplanetary medium.

Although the density and velocity of the solar wind determine the size of the magnetospheric cavity and the speed with which open flux tubes are transported to the tail, by far the most important upstream parameter which determines the overall nature of the magnetospheric interaction with the solar wind, and hence the dynamics of the Earth's plasma-field environment, is the direction and strength of the IMF. This determines how much flux is reconnected at the magnetopause per unit time, where on the magnetopause it is reconnected, and how the newly formed open tubes move into the tail. Although the IMF on average lies in the ecliptic plane at the  $\sim 45^{\circ}$  spiral angle mentioned above, pointing either toward or away from the Sun along this direction, variable north-south fields are also produced by a variety of effects, such as waves and other disturbances propagating in the wind outward from the Sun. Open flux production is largest, and the Dungey-cycle flow and related currents strongest, when the IMF is directed southward opposite to the Earth's equatorial field (i.e., points downward in Figure M158, as drawn in the figure), and is weak when the IMF is directed northward. From Faraday's law the overall magnetic flux transfer in the Dungey-cycle, in Wb s<sup>-1</sup>, is equal to the voltage of the cross-system electric field associated with the flow, in volts. This cannot be measured directly in the magnetosphere, but can routinely be measured at ionospheric heights using a network of groundbased radars, which determine the flow in the polar ionosphere. These observations show that when the IMF, of strength  $\sim$ 5–10 nT, points south, the voltage associated with the flow is  $\sim 100$  kV, i.e., the flux throughput in the Dungey-cycle is  ${\sim}100~k~\text{Wb}~\text{s}^{-1}.$  This compares with voltages in the solar wind across the magnetospheric diameter of about

five times this value. Reconnection is thus  ${\sim}20\%$  efficient during such southward field intervals, in the sense that  $\sim 20\%$  of the interplanetary magnetic flux which is directed toward the magnetosphere in the solar wind becomes reconnected with the terrestrial field. At the same time, of course,  $\sim 80\%$  of the magnetic flux is deflected around the sides of the magnetosphere, such that most of the impinging solar wind flow is so deflected, as envisaged in Chapman and Ferraro's early considerations. Nevertheless, it is the breakdown of perfect deflection at the  $\sim 20\%$  level which is critical to magnetospheric dynamics. As the IMF direction rotates away from southward, however, reconnection becomes less efficient. For example, when the IMF lies in its average direction in the ecliptic plane, the voltage values fall to  $\sim$ 50 kV, while when it rotates to northward they fall to "background" values of ~20 kV or less. The Dungey-cycle flow in the magnetosphereionosphere system is therefore strongly modulated by the sense and magnitude of the north-south component of the IMF, and is found to respond rapidly to changes in this component on timescales down to a few minutes.

The form of the flow is also found to change not only in response to the north-south field component of the IMF, usually referred to as the z component (with  $B_z$  positive northward), but also to the component which points into or out of the plane of the diagram in Figure M158, referred to as the y component (with  $B_y$  positive out of the plane of the diagram). When dayside reconnection takes place in the presence of IMF  $B_{\nu}$ , the  $\mathbf{i} \times \mathbf{B}$  force on newly opened flux tubes pulls the open tubes "sideways" (i.e., east-west) as well as poleward, oppositely in the two hemispheres. This is illustrated schematically in Figure M160, which shows a view of the dayside magnetosphere looking from the direction of the Sun shortly after reconnection has taken place with an IMF having a positive  $B_v$  component (pointing from left to right in the figure). The  $j \times B$  (rubber band) tension force pulls the newly opened field lines westward (to the left) in the dayside cusp in the northern hemisphere, and simultaneously eastward (to the right) in the dayside cusp in the southern hemisphere. The open field lines are correspondingly carried asymmetrically into the tail lobes, preferentially into the dawn side of the northern lobe, and into the dusk side of the southern lobe, an effect that tends to twist the tail structure on the nightside. The corresponding ionospheric flows in the northern hemisphere are shown in the upper row of diagrams in Figure M161, for near-zero or negative IMF  $B_z$  and various IMF  $B_y$  as indicated. Again noon is at the top of each diagram and dusk to the left. In this case the region of open field lines is relatively expanded and the twin cell Dungey-cycle flows well-developed due to the negative IMF  $B_{z}$ , while the IMF  $B_{\nu}$  component produces dawn-dusk asymmetries in the flow with newly opened cusp field lines flowing west for  $B_{\nu}$  positive (as indicated in Figure M160), and east for  $B_v$  negative. The simultaneous east-west flows are opposite in the southern hemisphere. These variations of the flow in the cusp region (and beyond) produce corresponding variations in the Hall and Pedersen-FAC current system that can be sensed both on the ground and above the ionosphere according to the general principles outlined above. The perturbations observed at magnetic observatories lying under the cusp (at  $\sim 75^{\circ}$ magnetic latitude near noon) can be used in particular to reconstruct the large-scale structure of the IMF over long intervals from historic magnetic records.

Observations indicate that reconnection at the dayside magnetopause tends to occur preferentially in regions where the magnetospheric and magnetosheath field adjacent to the magnetopause are antiparallel, such that the "magnetic gradients" across the boundary are largest. When the IMF turns from southward to northward, these regions migrate from low to high latitudes, such that reconnection can then take place between northward IMF and open field lines in the tail lobes that were produced by earlier intervals of southward field. Such "lobe reconnection" does not change the amount of open flux in the tail, but causes it to circulate within the region of open field lines, as the newly reconnected field lines flow around the dayside magnetopause and back into the lobe. The patterns of lobe circulation produced by this

**Figure M160** Schematic of newly opened field lines on the dayside of the magnetosphere, following low-latitude reconnection in the presence of an IMF with a positive  $B_y$  component (directed toward the right). The view is from the direction of the Sun. Under these conditions the  $j \times B$  (rubber band) tension force pulls open field lines westward toward dawn (*left*) in the northern hemisphere, and simultaneously eastward toward dusk (*right*) in the southern hemisphere, as shown. This leads to dawn-dusk asymmetries in the dayside ionospheric flow on open field lines as indicated schematically, which are oppositely directed in opposite hemispheres.

**Figure M161** Sketches of the ionospheric flow in the northern hemisphere ordered according to the direction of the IMF, in a format similar to Figure M159. The dashed line shows the open-closed field line boundary, while the arrowed solid lines show the plasma streamlines. The upper row show flows for IMF  $B_z$  near zero and negative, while the lower row shows flows for IMF  $B_z$  significantly positive. The three columns show flows for IMF  $B_y$  negative (*left*), near zero (*center*), and positive (*right*). Dawn-dusk asymmetries are simultaneously oppositely directed in the southern hemisphere.

effect are shown in the lower row of diagrams in Figure M161, which also indicate that the amount of open flux present is usually smaller under these conditions. Again, these patterns of ionospheric flow are associated with corresponding patterns of magnetic perturbations above and below the ionosphere, produced by the corresponding Hall and Pedersen-FAC currents that are driven.

# Magnetospheric substorms

The above sections have discussed the flows and currents that are driven in the coupled magnetosphere-ionosphere system by the Dungeycycle, viewed as a quasisteady process that is strongly modulated by variations in the strength and direction of the IMF. Observations show, however, that even when interplanetary conditions are relatively steady, the driving processes in the key interaction regions at the magnetopause and in the geomagnetic tail are not. Reconnection on the dayside, in particular, often occurs as waves that propagate east-west over the magnetopause from the dayside toward the tail, which recur on timescales of  $\sim$ 5–10 min. These "flux transfer events" (FTEs) give rise to pulsed magnetic and plasma signatures at the magnetopause, and pulsed flow, current, plasma injection, and auroras in the cusp ionosphere on the dayside. Due to the typically overlapping nature of the effect of these pulses, however, the overall flow and current modulations are generally modest.

The pulsed behavior in the tail takes place on longer timescales of around 1-2 h, however, and produces major perturbations of the flow and current in the nightside magnetosphere-ionosphere system, termed magnetospheric substorms (see Storms and substorms). Substorms are initiated by intervals of southward-directed IMF, typically southward fields of a few nanoteslas lasting for several tens of minutes. Such intervals, which happen rather frequently (often several per day), are sufficient to produce enhanced open flux production at the dayside magnetopause which in turn enhances the radius and field strength of the lobes of the tail. The current carried by the plasma sheet at the center of the tail is also correspondingly intensified, while the thickness of this current layer is also found to decrease, within the near-Earth tail, to only a few thousand kilometers. After  $\sim$ 30–40 min of such tail development, termed the "growth phase" of the substorm, a disruption is observed to occur within the plasma sheet. The origin and development of the disruption remain controversial, but it involves the formation within a minute or two of a new reconnection region within the plasma sheet in the central tail at down-tail distances of 20-30  $R_{\rm E}$ . Reconnection at this site first pinches off the tailward portion of the preexisting plasma sheet, forming a closed-loop plasmoid field structure, illustrated schematically on the right-hand side of Figure M158, which is expelled tailward into the solar wind at speeds in excess  $\sim$ 500 km s<sup>-1</sup>. Subsequently, open field lines in the tail lobes are also reconnected, reducing the amount of open flux in the system. Earthward of the new reconnection region, new closed field lines collapse toward the Earth, "dipolarizing" the extended tail field lines, and heating and compressing the plasma sheet plasma. Precipitation from this hot plasma into the nightside ionosphere produces an expanding patch of bright active auroras, called the "substorm auroral bulge," and also considerably enhances the density of the nightside ionosphere. Consequently the height-integrated Hall and Pedersen conductivities in this "bulge" are also strongly enhanced, from  $\sim 1$  mho or less in the presubstorm nightside ionosphere, to values of ~10-100 mho. This has the effect of suppressing the flow and electric field within the perturbed region, but even so intense currents flow within the region, consisting principally of a westward-directed Hall current or "substorm electrojet." The total current flow is typically  $\sim 0.5-1$  MA, yielding magnetic perturbations on the ground underneath the electrojet of several hundred nanoteslas. The disturbance field is directed equatorward, weakening the horizontal component of the planetary dipole field in both hemispheres. Current continuity is maintained by FACs which flow from the tail plasma sheet into the ionospheric electrojet at its eastern end, and return from the ionosphere to the plasma sheet at its western end, as shown in Figure M162, forming the "substorm current wedge". The FACs then close in the cross-tail current on either side of the dipolarized region, and from thence, over the tail lobe magnetopause as shown. It can therefore be seen that the current wedge is associated with a reduction in the cross-tail current within the dipolarized region, the FACs being associated with the shears in the tail field that occur in the interface between the dipolarized field within the wedge, and the (as yet) undipolarized taillike field outside.

**Figure M162** Sketch showing the form of the nightside "current wedge" current system that is excited during the expansion phase of magnetospheric substorms. A portion of the plasma sheet current in the center of the tail is diverted along the field lines north and south toward the Earth, and closes in the ionospheric substorm westward electrojets. The arrowed vortices drawn on the sphere representing the Earth's ionosphere indicate the concurrent Dungey-cycle flow, similar to Figures M159 and M161.

As indicated above, substorm tail reconnection and field dipolarization begin in a localized region near the center of the tail (generally displaced to the dusk side of midnight), but then spreads in both directions across the tail. The bright auroral and electrojet current region in the ionosphere correspondingly starts as a small oval region in the premidnight sector, located typically at  $\sim 65^{\circ}$  magnetic latitude, and then spreads toward dusk and dawn, as well as poleward as flux continues to be reconnected and plasma compressed and heated in the nightside tail. This is called the "expansion phase" of the substorm, and was first described by Akasofu in 1964. Sometimes the auroral bulge expands to cover much of the nightside polar ionosphere, though it does not generally reach to the magnetic pole itself. After 20-30 min the auroral bulge reaches its maximum size, and the auroral intensity and the currents then decline, signaling the start of the substorm "recovery phase" which typically lasts a further 30-40 min. In the tail, "recovery" is associated with the down-tail propagation of the new substorm reconnection region to large distances from Earth, such that the plasma sheet re-forms in the near-Earth tail. On the ground underneath the bulge, where the magnetic effects are dominated by the overhead electrojet current, the magnetic depression in the horizontal field typically grows rapidly and impulsively during the expansion phase, and then declines somewhat more gradually during recovery, giving rise to a signature which is called a "magnetic bay" in high-latitude magnetic records. Substorm signatures are also observed in nightside midlatitude magnetic fields, but in this case both the ionospheric currents and the FACs of the current wedge contribute to the form of the overall disturbance.

Several substorm cycles often occur each day, driven by individual episodes of modest southward field in the IMF, producing magnetic disturbances in the polar region under the electrojet of  $\sim 100-1000$  nT which grow and decay over intervals of  $\sim 1$  h. During rarer extended intervals of strong southward IMF, however, impulsive electrojet activity is essentially continuously present in the high-latitude nightside ionosphere, with variable magnetic disturbances on the ground underneath peaking at  $\sim 1000-2000$  nT. These high-latitude perturbations occur simultaneously with worldwide field depressions of typically  $\sim 50-250$  nT which are produced under the same conditions. These are termed geomagnetic storms and will be discussed in the next section. The largest high-latitude disturbance observed since systematic records began in 1957 was of  $\sim 3000$  nT, corresponding to  $\sim 5\%$  of the planetary field, this being the largest magnetic effect produced at the Earth's surface

due to external currents. At other times, however, the IMF may remain small and northward-pointing for extended intervals, leading to prolonged intervals of "magnetic quiet" on the ground, when only the variations due to the effects of the Sq-current system are present, driven by the daily thermal-tidal motions of the upper atmosphere.

## Geomagnetic storms

Usually the north-south component of the IMF is a few nanoteslas in magnitude and fluctuates in sense on timescales of minutes to a few tens of minutes, as indicated above. This drives variable Dungey-cycle flows and substorms in the magnetosphere, as discussed in the previous sections. However, under some rather rare but specific circumstances the IMF can become very strong (e.g., several tens of nanoteslas), and can remain southward-pointing for extended intervals of several hours. Under these circumstances a geomagnetic storm is produced at the Earth in which the horizontal (northward) field is depressed globally over intervals of hours and days, the depression typically maximizing at a few tens to a few hundreds of nanoteslas. These effects are masked at high-latitudes, however, by the stronger and more variable magnetic perturbations associated with magnetosphere-ionosphere coupling discussed in the previous section.

For reasons that will be outlined below, the occurrence of magnetic storms tends to follow the 11-year solar sunspot cycle, as first noted by Sabine in 1852, but on average there are roughly 10 storms each year whose midlatitude field depression exceeds 50 nT, and one that exceeds 250 nT. The largest depression observed since systematic records began in 1957 was of ~600 nT during a storm in March 1989, which occurred near solar maximum. After a variable "initial phase" to be discussed below, the magnetic depression typically grows fairly gradually over an interval of several hours ( $\sim 2-12$  h), termed the "main phase," and then decays even more gradually over the following several days ( $\sim 1-5$  days), termed the "recovery phase." These effects result from a prolonged enhancement of the Dungey-cycle flow, which is produced by the prolonged interval of strong southward IMF. During such intervals the boundary between corotating and Dungey-cycle flow in the inner equatorial magnetosphere shrinks significantly in size, such that the outer layers of the preexisting plasmasphere are stripped off and flow out to the dayside magnetopause. Correspondingly, the hot plasma produced in the tail flows inward to replace it, significantly enhancing the westward-directed "ring current" produced by the differential drift of energetic ions and electrons in the inhomogeneous quasidipolar planetary magnetic field, as outlined above. The perturbation field produced by the hot inner plasma is a major contributor to the "main phase" field depression at Earth. However, the picture is complicated by the fact that the inflowing hot plasma is usually asymmetric in its distribution around the Earth, leading to partial current "rings" that close in the ionosphere via "region 2"-type FACs. These FACs also contribute to the overall magnetic disturbance, as do the combined "fringing" fields of the enhanced plasma sheet and tail currents on the nightside. During the recovery phase, however, Dungey-cycle convection is reduced, so that these current systems also decline. Hot "ring current" plasma now marooned within the newly expanded corotating region slowly decays due to wave-scattering followed by precipitation into the midlatitude atmosphere, and due to charge-exchange with neutral atoms of the geocorona. The outer newly corotating flux tubes also refill with cold plasma from the ionosphere on timescales of a few days, thus re-forming a more extended plasmasphere.

As indicated at the beginning of this section, the extended intervals of strong southward IMF which excite geomagnetic storms, are associated with specific phenomena in the interplanetary medium which link storms with processes on the Sun and the solar cycle. Two principal mechanisms are responsible. In the first, a large loop-like field structure located in the solar corona suddenly becomes unstable and is ejected away from the Sun, forming a "coronal mass ejection" (CME). The ejection speed is sometimes very rapid, exceeding ~1000 km s<sup>-1</sup>, such that the CME plasma and frozen-in field plow into

the slower solar wind ahead of it. This creates a giant shock wave, which propagates through the solar system compressing and heating the ambient solar wind medium ahead of the CME "driver gas". Behind the shock the IMF is also compressed to high field strengths. When such a shock impinges on the Earth, the magnetosphere is impulsively compressed, such that the horizontal field at the Earth's surface is suddenly increased, typically by a few tens of nanoteslas, corresponding to the effect of the increased Chapman-Ferraro current at the magnetopause. What happens after this depends on the direction of the enhanced IMF in the compressed solar wind and CME driver gas. These fields may have any orientation depending on the individual circumstances of the event, and may also fluctuate in direction during the event. A magnetic storm "main phase" occurs only if the enhanced IMF points southward during some extended interval after the shock wave has passed. If this occurs (typically in about one in six events), the impulsive field enhancement at the Earth's surface produced by the shock is called the "storm sudden commencement" (SSC), while the variable interval between the SSC and the onset of the main phase (when the upstream IMF happens to turn southward) is called the "initial phase" of the storm. If such an enduring interval of southward field does not occur, and with it no "main phase" field depression, then the shock-related compression event is simply termed a "sudden impulse". The connection between these events and the solar cycle results from the fact that  $\sim$ 3 CMEs occur each day near solar cycle maximum (only a small number of which impinge on Earth), reducing to one every several days during solar cycle minimum. The connection with solar flares, first noted by Carrington in 1860, results from the fact that flares often occur near the sites in the solar corona where CMEs have formed.

During the declining phase of the solar cycle, extended intervals of strong southward IMF can also be produced by another interplanetary mechanism, which thus can also generate geomagnetic storms. The Sun typically produces two types of quasisteady solar wind outflow (as opposed to CMEs), a "slow" variable wind of  $\sim$ 300–500 km s<sup>-1</sup> from regions surrounding closed field regions of the solar corona, and a "fast" steady wind of  $\sim 800$  km s<sup>-1</sup> from open-field "coronal holes." During solar maximum, the solar field is typically very disordered, and with it the solar wind outflow. During the declining phase of the cycle, however, large-scale off-axis coronal holes tend to form, which migrate slowly toward the poles of the Sun as activity decreases toward solar minimum. Initially, however, these coronal holes may extend down to the solar equator, such that during each solar rotation the Earth experiences a pattern of fast and slow solar wind output that may persist in form for many solar rotations. The corotating variable solar wind source regions on the Sun thus give rise to "corotating interaction regions" (CIRs) in the interplanetary medium, in which fast plasma outflow from an equatorial coronal hole "runs into" slower plasma that was emitted earlier into the same direction from a noncoronal hole source region on the rotating Sun. This compresses the plasma and may enhance the frozen-in field by factors of  $\sim$ 5-10 above the usual values. As the solar wind velocity subsequently drops, however, after the passage of the material from the coronal hole, a rarefaction region is created in the solar wind, and with it regions of weak IMF occur. Geomagnetic storms can be excited by the enhanced fields of the compression phase of CIRs, during intervals in which the solar wind speed is increasing locally at the Earth, if the enhanced field happens to point southward for a significant interval. Such storms, however, are typically not as intense as those generated by CMEs, because the field directions tend to fluctuate more during these events, as opposed to the more ordered field structures produced by CMEs. In addition, these events are not associated with interplanetary shocks, such that no SSC and "initial phase" occurs prior to the onset of the main phase.

## Summary

Overall, it can be seen from this discussion that a variety of interlinked and rather complex plasma physical processes affect the magnetic field 664

observed at the Earth's surface, and throughout the magnetospheric region containing the Earth's magnetic field. The current systems involved are those concerned with the magnetopause boundary of the magnetosphere, the hot plasma that flows inside it, and the current systems that link the magnetosphere and ionosphere and are associated with the auroras. These produce peak perturbation fields at the Earth's surface of typically a few tens, a few hundreds, and a few thousands of nanoteslas, respectively, varying on a range of timescales from minutes during substorms to hours and days during worldwide geomagnetic storms. These current systems are linked to the Sun and solar activity through the solar wind outflow, which forms the Earth's magnetosphere and conditions its dynamics. The variable output of the Sun similarly produces effects on a wide range of timescales, from the minute scales associated with interplanetary shocks, up to the  $\sim 11$  year timescales of the solar activity cycle.

# MAGNETOSTRATIGRAPHY

Magnetostratigraphy refers to the description, correlation, and dating of rock sequences by means of magnetic parameters. A rock interval in which a magnetic parameter has a constant value is called a magnetozone. Most commonly, the parameter is the polarity of the Earth's magnetic field during acquisition of a primary magnetization that is contemporaneous with the rock formation. Magnetozones of alternating polarity yield a magnetic polarity stratigraphy. This form of magnetostratigraphy plays an important role in the construction of geomagnetic polarity timescales. However, in principle, any rock magnetic parameter can serve as a magnetostratigraphic indicator.

Although the most widespread and successful use of magnetostratigraphy has been in sediments and sedimentary rocks, the method can be applied to any succession of layered rocks. In igneous rocks and high-deposition rate sediments, magnetostratigraphy provides fine details of geomagnetic field behavior. For example, the analysis of paleomagnetic vectors in radiometrically dated lava flows from Steen's Mountain (Oregon, USA) showed details of the behavior of magnetic field direction and intensity during a Miocene polarity reversal (Prévot *et al.*, 1985). The study gave an estimated duration of about 4500 years for the polarity transition. Other estimates range from 3500 to 10000 years. The time intervals (chrons), during which the geomagnetic field maintains constant normal or reverse polarity, are many times longer than the transitional interval, and may last hundreds of thousands to millions of years; they are interspersed with shorter subchrons lasting only some tens of thousands of years. The reversals apparently occur at random separations, so that a sequence of reversals defines polarity chrons and subchrons of very variable lengths. Each polarity reversal is a global feature, which is very useful for magnetic stratigraphy because a short sequence of 10–20 reversals forms a distinctive pattern, like a fingerprint, which can be used for geological correlations on a worldwide basis.

## Marine magnetic anomaly sequences

Seafloor spreading since the Middle Jurassic has created sequences of lineated marine magnetic anomalies in the ocean basins, which have yielded the most complete and detailed record of geomagnetic polarity for this time interval. An episode of alternating polarity began about 157 Ma ago in the Late Jurassic and lasted until about 120 Ma ago in the Early Cretaceous; it gave rise to the M-sequence of marine magnetic anomalies. The field apparently rested in a state of normal polarity for the next 37 Ma. A further episode of reversals began 83 Ma ago in the Late Cretaceous and has lasted throughout the Cenozoic until the present; it produced a sequence of magnetic anomalies that is referred to here as the C-sequence. It is possible that the known C-sequence is incomplete. Short wavelength, low amplitude magnetic anomalies (so-called "tiny wiggles" or "cryptochrons") that could correspond to very short-polarity chrons have been observed in the marine magnetic anomaly record that defines the C-sequence, especially in the Oligocene and Paleocene. The origin of these magnetic anomalies is uncertain because they can be modeled equally well as short polarity intervals and intensity fluctuations of the paleomagnetic field (Cande and LaBrecque, 1974; Cande and Kent, 1992b).

Major magnetic anomalies in each sequence are numbered in order of increasing age. The corresponding polarity chron is identified with the prefix "C" in the C-sequence and "CM" in the M-sequence; the suffix "n" or "r" is appended to designate normal or reverse polarity, respectively. Thus, the C-sequence of polarity chrons extends from C1n to C33r, and the M-sequence extends from CM0r to CM29r. The two anomaly sequences are separated in the oceanic record by the Cretaceous Quiet Zone (equivalent to C34n) in which lineated magnetic anomalies are not found. It corresponds to a time interval, the Cretaceous Normal Polarity Superchron (CNPS), in which the Earth's magnetic field did not reverse polarity for more than 37 Ma. Regions of the oceanic crust older than CM29r form a Jurassic Quiet Zone, which, like the Cretaceous Quiet Zone, is characterized by the absence of correlatable magnetic anomalies at the ocean surface. Deep-tow magnetometer studies have revealed a tentatively correlated sequence of short wavelength, low amplitude magnetic anomalies numbered M29-M41 (Sager et al., 1998). These anomalies suggest that the Jurassic Quiet Zone may result from a high reversal frequency, in contrast to the origin of the CNPS.

## Geomagnetic polarity timescales

The association of radiometric ages with key biostratigraphic stage boundaries, which have been correlated by magnetostratigraphy to the marine polarity record, yields a dated geomagnetic polarity timescale (GPTS). Several GPTS have been proposed for each reversal sequence, accompanying refinements in defining the fundamental polarity record and improvements in confirming, correlating, and dating the polarity chrons. A comparison of the different GPTS that have been proposed for the Late Cretaceous and Cenozoic is given by Opdyke and Channell (1996). A databank of the C-sequence timescales has been compiled and stored electronically on-line (Mead, 1996). The optimum GPTS for this time interval is the CK95 timescale (Cande and Kent, 1995), based upon a reevaluation of the C-sequence marine magnetic anomalies and the corresponding block models (Cande and Kent, 1992a).

The M-sequence of marine anomalies is not as well dated as the C-sequence and it also may still be incomplete. The old end of the

M-sequence merges into the Jurassic Quiet Zone, whose origin is less well understood than its Cretaceous counterpart. A comparison of different GPTS for the M-sequence shows that appreciable discrepancies still exist. The optimum GPTS for this part of the record is currently the CENT94 timescale (Channell *et al.*, 1994), which is based on revised block models for the origin of the marine magnetic anomalies and covers magnetic polarity chrons CM0 to CM29. Because of their still uncertain origin, anomalies M29-M41 are not yet accepted as polarity chrons that can be included in the GPTS.

For each polarity sequence, tie-levels are established by magnetostratigraphic correlation of radiometrically dated biostratigraphic stage boundaries or other datum-levels to the C- and M-sequence polarity record. The rest of each timescale is dated by conversion of polarity boundary locations to numeric ages by interpolation between the tielevels. There are several inherent sources of error in this process, including errors of absolute dating of the stage boundary or other tie-levels, stratigraphic errors in correlation, etc. Consequently, the "absolute ages" in a GPTS are known less exactly than the relative lengths of the polarity chrons.

## Magnetic polarity stratigraphy

## Methodology

Shallow, unconsolidated sediments from lakes and seas have been sampled with gravity-driven piston cores, whereas older sediments from deep ocean basins have been sampled with drilled cores in the international Ocean Drilling Project (ODP). Indurated sedimentary rocks can be sampled by ordinary paleomagnetic techniques. Long, continuous, continental outcrops or drillholes are necessary for successful magnetostratigraphy. Marine and nonmarine sedimentary rocks that have not been adversely disturbed by local tectonic conditions have given good results. Marine rocks can be dated paleontologically, whereas cyclostratigraphy has enabled the dating of some continental deposits.

The sample and data processing methods are the same as in a customary paleomagnetic study, and strict criteria have been proposed to define the quality of a magnetostratigraphy (Opdyke and Channell, 1996). It is possible to measure and partially demagnetize whole cores of sediments virtually continuously with specially designed pass-through magnetometers. More commonly, the cores are subsampled, either using long, so-called u-channels or by taking conventional 1 in. paleomagnetic samples at discrete intervals. Whatever their source, the prepared samples are treated using standard paleomagnetic methods such as progressive stepwise demagnetization. In soft wet sediments this treatment is limited to alternating field demagnetization, which in many cases is quite adequate, as the carrier of remanent magnetization is often primary magnetite. Secondary magnetic phases cannot be excluded. In soft marine sediments obtained from piston cores and ODP they are usually unimportant, but in lake sediments the possible presence and effects of secondary magnetizations carried by minerals such as hematite and greigite must be taken into account. In indurated sedimentary rocks such as limestones and redbeds, the primary magnetic mineral is usually magnetite, but the magnetic mineralogy may be complicated by postdepositional growth of secondary ferromagnetic minerals. Of these, hematite is the most common with serious consequences for paleomagnetic interpretation. In this case, progressive partial thermal demagnetization is the most important laboratory technique for establishing the direction of the primary magnetization on which the magnetostratigraphy is based.

The stable magnetization directions can be used to calculate the latitude of the virtual geomagnetic pole (VGP) at the time of formation of a sample. The stratigraphic plot of the VGP latitude, or in some cases the inclination of the magnetization, defines magnetozones of common polarity (Figure M163). Normal polarity magnetozones are customarily shaded black and reverse polarity zones are left unshaded. Paleontological analyses on samples from the same section based on ammonites, foraminifera, nannofossils, or other fossil types, define a biostratigraphy that is tied to the magnetostratigraphy. In this way

**Figure M163** Lower Middle Jurassic magnetic polarity stratigraphy from the Breggia Gorge, southern Switzerland (after Horner and Heller, 1983).

the locations of major biostratigraphic stage boundaries are correlated to the magnetic reversal sequence.

Magnetostratigraphic results often show individual samples with polarity opposite to adjacent samples. This is often due to misorientation of the sample, or inadequate magnetic cleaning, but it may be that some represent very short-lasting polarity chrons.

# Magnetostratigraphic verification of the C- and M-sequences

Magnetic polarity stratigraphy is most successful when a reference record is available, such as that provided by marine magnetic anomalies since the Late Jurassic. Numerous investigations of magnetic polarity stratigraphy have been carried out in marine limestones and marls to verify, correlate, and date the history of geomagnetic polarity for this time interval (Opdyke and Channell, 1996). Studies in continental exposures of marine limestones have confirmed the main features of the C- and M-sequences of polarity reversals. Improvements in drilling technology and the use of pass-through cryogenic magnetometers have yielded excellent magnetostratigraphies in several ODP studies. Coordinated biostratigraphic and magnetostratigraphic investigations have correlated most important paleontological stage and substage boundaries from the Late Jurassic to the present with the corresponding geomagnetic polarity sequences.

The reversal history of the Pleistocene and Upper Pliocene was established in the 1960s jointly from radiometrically dated lavas and modern deep-sea sediments (Opdyke, 1972). During the 1970s and 1980s, magnetostratigraphic research confirmed the marine magnetic record in Paleogene and older rocks. The verification of Miocene polarity chrons was delayed by high reversal rate, weak magnetization, and unstable remanent magnetizations in many sections. However, coordinated magnetostratigraphy, biostratigraphy, and cyclostratigraphy in marly sections in Sicily and Crete confirmed and dated the Early Pliocene and Upper Miocene polarity sequence (Krijgsman *et al.*, 1995). Recent results from ODP sites have given excellent "fingerprint" correlation of Early Miocene polarity chrons (Parés and Lanci, 2004).

Magnetostratigraphic studies in limestone sections in the Umbrian Apennines and Southern Alps confirmed and dated geomagnetic polarity history from the Jurassic-Cretaceous boundary to the Oligocene-Miocene boundary (Channell and Erba, 1992; Channell *et al.*, 1979, 2000; Lowrie *et al.*, 1980, 1982; Channell and Medizza, 1981; Lowrie and Alvarez, 1981, 1984). The Cretaceous-Tertiary boundary was correlated within polarity chron C29r and the Santonian-Campanian stage boundary was located just older than polarity chron C33r (Alvarez *et al.*, 1977; Lowrie and Alvarez, 1977) (Figure M164).

Occasional reports of reversed polarity zones in magnetostratigraphic sections have given rise to speculation about the continuity of the 37-Ma long CNPS and the origin of the Cretaceous Quiet Zone. However, in each instance the magnetostratigraphic results have been associated with a rock magnetic complication, such as remagnetization in redbeds, lack of independent verification, or possible sample inversion. The paleomagnetic evidence supports the interpretation of the CNPS as an uninterrupted interval of constant normal polarity. It may represent a distinct behavioral regime of the geomagnetic field, different in its nature from the preceding and following episodes of reversing polarity.

The youngest reverse polarity chron CM0r of the M-sequence is located just above the Barremian-Aptian boundary (Channell and Erba, 1992). Correlation of the Jurassic-Cretaceous boundary with the M-sequence anomalies was found to be slightly dependent on the paleontological dating scheme used to define the boundary (Lowrie and Channell, 1984; Ogg, 1984; Lowrie and Ogg, 1986). Magneto-zones in the Kimmeridgian and Tithonian stages of the Upper Jurassic were correlated in magnetostratigraphic sections in southern Spain with M-sequence anomalies M18-M25 (Ogg *et al.*, 1984) (Figure M165). Many details of these correlations and polarity sequences have been further confirmed in ODP drillcores.

In addition to the well-documented magnetic anomalies of the Msequence and C-sequence, the marine magnetic record contains many short wavelength, low-amplitude magnetic anomalies (tiny wiggles). The origin of these features is uncertain, and they have been designated as "cryptochrons." They can be modeled equally well as very short polarity chrons with typical durations of 10 ka or less, or as intensity fluctuations of the paleomagnetic field (Cande and LaBrecque, 1974; Cande and Kent, 1992b). They have generally not been identified in detailed magnetostratigraphic investigations. Although some may indeed represent polarity reversals, most are probably due to paleointensity variations and are not part of the reversal sequence.

#### Magnetostratigraphy older than the M-sequence

Magnetostratigraphy in older rocks suffers from the absence of a marine magnetic anomaly record. Geomagnetic polarity history must be pieced together from magnetic stratigraphy alone. This requires overlapping sections to confirm the polarity sequence. Until now, the pre-M29 magnetic anomalies have not been securely and independently established in the oceanic record. Their appearance resembles

**Figure M164** Correlation of Cenozoic and Upper Cretaceous limestone sections in the Umbrian Apennines, Italy, with the oceanic polarity record on the basis of magnetic polarity stratigraphy (after Lowrie and Alvarez, 1981).

the controversial tiny wiggles found in the Cenozoic record (Cande and Kent, 1992b) and they may be due to paleointensity fluctuations rather than polarity reversals. Deep-tow studies are in progress to verify the anomaly correlations. The assumed polarity sequence must then be confirmed and dated independently by magnetostratigraphy. This is a difficult task. Middle Jurassic limestone sections have given good magnetostratigraphic data but the magnetozones correlate only tenuously with the marine polarity record corresponding to anomalies M29-M41 (Steiner *et al.*, 1985, 1987).

Lower Jurassic results from the Breggia Gorge in Switzerland (Horner and Heller, 1983) showed a very well-defined magnetostratigraphy for the Carixian (early Pliensbachian) to Bajocian stages of the Early to Middle Jurassic (Figure M163). This record stands as the reference magnetic polarity stratigraphy for this part of the timescale. Because of the rareness of comparable sites with suitable magnetic properties for magnetic polarity analysis, it has only been verified in part. Moreau (2002) recently established the magnetostratigraphy of a drillcore from the Paris Basin and correlated it successfully to the Pliensbachian part of the Breggia Gorge record.

It is a great challenge for current and future magnetostratigraphic research to piece together the history of geomagnetic polarity reversals for earlier periods in the Mesozoic and Paleozoic. The magnetic polarity stratigraphy of the Late Triassic is a focus of current activity. Excellent results have been obtained in overlapping drillcores from continental redbeds from the Newark Basin in New Jersey, USA (Kent *et al.*, 1995). This study required subtle analysis of

**Figure M165** Correlation of Lower Cretaceous and Upper Jurassic limestone sections with the polarity record derived from the M-sequence of oceanic magnetic anomalies (after Lowrie, 1989).

thermal demagnetization data; the polarity stratigraphy was dated by a combination of paleontology and Milankovich-related cyclostratigraphy. As the Breggia Gorge is for the Lower Jurassic, the magnetostratigraphy of the Newark Basin is the standard for comparison for the Late Triassic. Confirmation by correlation with other sections, especially of marine origin, is in progress.

## Rock magnetic stratigraphy

#### Susceptibility stratigraphy

Although polarity stratigraphy is the best-known magnetic method for establishing the stratigraphic variation in a section and for correlating between stratigraphic sections, other magnetic methods are also possible. For example, magnetic susceptibility, remanent magnetizations, and coercivity parameters have all been invoked in magnetic studies of young sediments to show small variations in mineralogy or grain size that might have an environmental or paleoclimatic cause.

Magnetic susceptibility is a measure of the ease with which a magnetization can be induced in a sample. It is determined by all the mineral grains in a sample; that is, by the type, concentrations, and grain sizes of any ferromagnetic minerals, as well as by the paramagnetic and diamagnetic (i.e., nonferromagnetic) minerals in the sample. If magnetite is present, its high intrinsic susceptibility may dominate the susceptibility of a sample, and fluctuations in susceptibility within a sedimentary sequence may be related to variations in magnetite content.

An example is shown in Figure M166. The loess deposits of Central China form great thicknesses of sediment in which loess and paleosol layers alternate with each other. The loess are windblown sediments that form in cold, dry conditions, whereas the paleosols are thought to form under warmer, moist conditions. The natural remanent magnetization of the deposits gives a well-defined magnetic polarity stratigraphy that correlates the oldest layers with the end of the Gauss Epoch (top of Chron C2An.1n) about 2.6 Ma ago (Heller and Liu, 1984; Heller and Evans, 1995). The magnetostratigraphy of samples from a borehole at Luochuan in China showed that the loess deposits were much older than previously thought. The magnetic susceptibility correlated with the lithology, showing higher values in the paleosols than in the loess layers. The magnetic mineral in both lithologies is dominantly magnetite. The magnetite enhancement in the paleosols may be related to in situ formation of a new phase of magnetite as a result of the change to a warmer, moister climate. This interpretation has been carried a stage further in an attempt to estimate the record of paleoprecipitation. The existence and interpretation of magnetite enhancement in the paleosols is still a controversial subject. Nevertheless, the example demonstrates the potential of magnetic measurements in an environmental context.

## Coercivity stratigraphy

In contrast to magnetic susceptibility, the remanent magnetization of a sample, whether naturally acquired or artificially produced by an applied magnetic field in the laboratory, is carried only by ferromagnetic minerals.

Figure M166 Magnetic polarity stratigraphy and susceptibility stratigraphy of loess and paleosol deposits in a borehole at Luochuan, China (after Heller and Evans, 1995; courtesy of F. Heller).

**Figure M167** Magnetic stratigraphy in a core from a high Alpine lake (Bachalpsee, Switzerland). The ratios of isothermal remanent magnetizations (IRM) acquired at 290 and 77 K, and in fields of 0.15 and 1 T at room temperature, are determined by variations in coercivity of ferromagnetic minerals. They are compared to climatic proxies that reflect organic content and vegetation changes (after Lanci *et al.*, 1999).

The most common are magnetite, hematite, maghemite, and pyrrhotite. The ability to retain a remanent magnetization is a coercivity parameter, and is dependent on grain size, temperature, and the applied magnetic field. A commonly used remanent magnetization is produced in the laboratory by applying a magnetic field to a sample and then removing it. The residual magnetization is called the isothermal remanent magnetization (IRM). Different grain-size fractions are activated by different applied fields, and at different temperatures. For example, ultrafine-grained magnetite that is superparamagnetic (unable to hold a remanent magnetization) at room temperature becomes stable at low temperature. The IRM of a sample containing superparamagnetic grains of magnetite is thus larger at low temperature than at room temperature. The ratio of IRM acquired at room temperature (290 K) and after immersion in liquid nitrogen at a temperature of 77 K (written IRM290 K/IRM77 K) is an indication of the relative amounts of superparamagnetic magnetite in a sediment. Similarly, the ratio of IRM acquired in fields of 0.15 and 1.0 T (written IRM<sub>0.15 T</sub>/IRM<sub>1.0 T</sub>) is an indication of the relative magnitude of low-coercivity magnetite and higher coercivity grains in a sample. For example, in a magnetostratigraphic section of Upper Cretaceous Scaglia Rossa limestone at Gubbio, Italy, the variation of this parameter showed the relative amounts of magnetite and hematite in the section (Lowrie and Alvarez, 1977). In a sediment core from Bachalpsee (Figure M167), a high-alpine lake in the Swiss Alps, this ratio has a value around 0.8 at the bottom of the core. About 80% of the IRM is carried by low-coercivity magnetite at this depth, which corresponds to the Younger Dryas biozone. The remainder may be due to highcoercivity magnetite or even harder magnetic minerals. Higher in the core, where the ratio is almost 1.0, low-coercivity magnetite is virtually the only ferromagnetic mineral present. The ratio decreases again upward in the core. The parallel behavior of the IRM290 K/IRM77 K ratio shows that grain-size variation of the magnetite is probably the cause of both curves.

The loss of ignition at  $550^{\circ}$ C, an indicator of organic carbon content, parallels the magnetic profiles. The <sup>14</sup>C ages on samples from the core show that all the major changes that took place began 10 ka ago at the end of the last ice age. Analysis of pollens showed a reduction in coniferous types as more deciduous types were transported into the lake accompanying the climatic warming in the early Holocene. These changes are reflected in the magnetic stratigraphies that reflect directly the paleoclimatic changes.

## MAGNETOTELLURICS

## Introduction

Magnetotellurics (MT) is the use of natural electromagnetic signals to image subsurface electrical conductivity structure through electromagnetic induction. The physical basis of the magnetotelluric method was independently discovered by Tikhonov (1950) and Cagniard (1953). After a debate over the length scale of the incident waves the technique became established as an effective exploration tool (Vozoff, 1991; Simpson and Bahr, 2005).

## **Basic method of magnetotellurics**

Electromagnetic waves are generated in the Earth's atmosphere and magnetosphere by a range of physical processes (Vozoff, 1991). Below a frequency of 1 Hz, most of the signals originate in the magnetosphere as periodic external fields including magnetic storms and substorms and micropulsations. These signals are normally incident on the Earth's surface. Above a frequency of 1 Hz, the majority of electromagnetic signals originate in worldwide lightning activity. These signals travel through the resistive atmosphere as waves and when they strike the surface of the Earth most of the signal is reflected. However, a small fraction is transmitted into the Earth and is refracted vertically downward, owing to the decrease in propagation velocity (Figure M168). The oscillating magnetic field of the wave generates electric currents in the Earth through electromagnetic induction, and the signal propagation becomes diffusive, resulting in signal attenuation with depth. The signals diffuse a distance into the Earth that is defined as the skin depth,  $\delta$ , in meters by

$$\delta = \frac{1}{\sqrt{\pi\mu\sigma f}} \approx \frac{503}{\sqrt{\sigma f}}$$

where  $\sigma$  is the conductivity (S m<sup>-1</sup>), *f* is the frequency (Hz), and  $\mu$  is the magnetic permeability. The skin depth is inversely related to the frequency and thus low frequencies will penetrate deeper into the Earth. The impedance of the Earth is defined as

$$Z_{xy} = \frac{E_x}{H_y}$$

where  $E_x$  is the horizontal electric field and  $H_y$  is the orthogonal, horizontal, magnetic field. From this impedance, apparent resistivity can be defined as

$$\rho_{xy} = \frac{1}{2\pi f \mu} |Z_{xy}|^2$$

and the electric and magnetic field components will have a phase difference

$$\Phi_{xy} = \arg(Z_{xy}).$$

In general, the impedance is written as a tensor,

$$\begin{bmatrix} E_x \\ E_y \end{bmatrix} = \begin{bmatrix} Z_{xx} & Z_{xy} \\ Z_{yx} & Z_{yy} \end{bmatrix} \begin{bmatrix} H_x \\ H_y \end{bmatrix},$$

which relates the horizontal components of the electric and magnetic fields. The impedance relates the applied magnetic fields to the resulting electric fields and can be considered a *transfer function*. Note that the apparent resistivity depends on the ratio of the electric and magnetic field components. This makes the MT method simple to apply by combining values of  $E_x$  and  $H_y$  recorded at different times. The other useful characteristic is that the direction of the incident wave does not affect the value of apparent resistivity. The apparent resistivity can be considered an average value of the Earth's resistivity over a hemisphere of radius  $\delta$ . Thus, by computing apparent resistivity as

**Figure M168** Propagation of electromagnetic waves from a distant lightning strike to the location where MT data is recorded. The resistive atmosphere forms a waveguide between the conductive Earth and ionosphere. The electric field (E) and magnetic field (H) are both orthogonal to the direction of propagation (k). Note that the electromagnetic energy travels as a wave in the atmosphere, but diffuses in the Earth. This type of signal propagation occurs above 1 Hz.

**Figure M169** Variation of apparent resistivity and phase that would be measured at the surface of a two-layer Earth model. Note that the depth sounding of resistivity is achieved by varying the frequency of the signal. The dip in apparent resistivity below 10  $\Omega$ m at 1 Hz is a resonance phenomenon.

a function of frequency, the variation of resistivity with depth can be determined. This is illustrated in Figure M169. At high frequency (1000–10 Hz) the apparent resistivity is equal to the true resistivity of the upper layer. As the frequency decreases, the skin depth increases and the MT signal penetrates further into the Earth and the apparent resistivity rises. The MT phase ( $\Phi_{xy}$ ) is the phase delay between the electric and magnetic fields at the Earth's surface. The apparent resistivity and phase are related through

$$\Phi_{xy} = 45 \left( 1 + \frac{d(\log_{10} \rho_{xy})}{d(\log_{10} f)} \right)$$

where  $\Phi_{xy}$  is in degrees. Thus, when the apparent resistivity increases with decreasing frequency, the phase will be less than 45°. Similarly, a decrease in resistivity will correspond to a phase greater than 45°. At the lowest frequency, the apparent resistivity asymptotically approaches the true resistivity of the lower layer, and the phase returns to 45°. Note that the phase is sensitive to changes in subsurface resistivity with depth. For a multilayer model, MT data can reliably determine the conductance of a layer. Conductance is the vertically integrated conductivity, and for a uniform layer the conductance is the product of conductivity and thickness. A consequence of the *inverse problem of electrical conductivity* is that MT data cannot individually determine the conductivity and thickness of a layer. Thus layers with differing values of conductivity and thickness, but the same overall conductance cannot be distinguished with MT.

Early studies analyzed MT data in terms of a one-dimensional (1D) conductivity model. In this class of model, conductivity only varies with depth. This approach is sometimes valid in locations where the geoelectric structure does not change rapidly in the horizontal direction. However, it is usually necessary to consider at least a two-dimensional (2D) Earth model. In this case, the apparent resistivity

**Figure M170** Geometry of electromagnetic field components over a two-dimensional Earth. The transverse electric (TE) mode is also called the E-polarization. Similarly, the transverse magnetic (TM) mode is also called the B-polarization.

computed from  $E_x$  and  $H_y$  will differ from that derived from  $E_y$  and  $H_x$  and the application of a 1D MT analysis can give misleading results. For a 2D Earth,  $E_x$  is dependent only on  $H_y$  and  $H_z$ , and these three field components comprise the transverse electric (TE) mode with the impedance  $(Z_{xy})$  computed from  $E_x$  and  $H_y$ . The transverse magnetic (TM) mode comprises the  $H_x$ ,  $E_y$ , and  $E_z$  field components, with the impedance  $(Z_{yx})$  computed from  $E_y$  and  $H_x$  (Figure M170). In a 2D Earth with the x-axis parallel to the geoelectric strike direction, the impedance tensor can be written as:

$$\begin{bmatrix} E_x \\ E_y \end{bmatrix} = \begin{bmatrix} 0 & Z_{xy} \\ Z_{yx} & 0 \end{bmatrix} \begin{bmatrix} H_x \\ H_y \end{bmatrix}$$

The TE mode is most sensitive to along-strike conductors. In the TM mode the electric current flows across the boundaries between regions of differing resistivities, which causes electric charges to build up on interfaces. Thus the TM mode is more effective than the TE mode at locating interfaces between regions of differing resistivity.

If the subsurface structure is three-dimensional (3D) then all four elements of the impedance tensor are nonzero. Progress has been made in the last decade in 3D MT modeling and inversion. However, if a single profile of MT stations is available, and 3D effects can be shown to be small, then a 2D analysis can be used. If the subsurface conductivity structure exhibits electrical anisotropy, this will influence the measured impedance tensor. However, it can be difficult to convincingly distinguish heterogeneity from anisotropy in MT data. Small-scale, near-surface bodies can generate electric charges on their boundaries. If the body is small, then insignificant electromagnetic induction occurs and the only effect is galvanic distortion. This changes the magnitude of the electric field at the surface and can cause a static shift, which is a frequency-independent offset in the apparent resistivity curve (Jones, 1988). The phase curve is not affected. Static shifts are an example of spatial aliasing. A range of techniques is used to remove static shifts, and include external measurements of surface resistivity and estimation of the static shift coefficient in modeling and inversion.

# Magnetotelluric data collection and time series processing

MT data are recorded in the time-domain, with the electric fields measured using dipoles 50–200 m in length that are connected to the ground with nonpolarizing electrodes. Audiomagnetotelluric (AMT) data (10000–1 Hz) typically sample the upper 1–2 km and are often used in mineral exploration (see *EM, industrial uses*). Magnetic fields are measured with induction coils, and in noisy environments the natural signals are supplemented with a transmitter. This modified technique is termed controlled-source audio magnetotellurics (CSAMT). Broadband MT data (1000–0.001 Hz) are used for sounding to midcrustal depths. Induction coils are generally used and a recording time of one day is required. In the presence of excessive cultural noise additional recording may be needed. Noise can originate in a wide range of

**Figure M171** Estimates of apparent resistivity and phase at an MT station in central California in 1999. The open circles were derived from remote reference processing, while the black circles were derived from local data only. The MT data are contaminated by magnetic noise due to ocean wave-induced ground motion. Note the downward bias in the apparent resistivity in the frequency band 3–0.3 Hz when local MT data processing is used.

sources, including power lines, cathodically protected pipelines, railways, water pumps, and electric fences. Long-period magnetotelluric (LMT) data measure very low frequencies (1-0.0001 Hz) and are used for imaging the lower crust and upper mantle. A specialized LMT instrument is used with a *fluxgate magnetometer*, solar panels, and low power electronics. MT data can also be collected on the seafloor.

MT time series data are processed to yield frequency-domain estimates of apparent resistivity and phase. Modern processing schemes compute fast Fourier transforms of subsections of the time series and then utilize robust statistical techniques to average the multiple estimates of the impedance. The application of robust statistics has dramatically improved the quality of responses and allowed many types of noise to be effectively suppressed (Jones *et al.* 1989; Egbert, 1997). In MT data collection, time series data should be recorded simultaneously at several locations to allow for the removal of noise at the measurement location through the remote-reference method (Gamble *et al.* 1979). This is important even in locations with minimal cultural noise (Figure M171). In this example, ground motion from ocean waves caused oscillations of the magnetic sensors and resulted in the apparent resistivity being artificially low in the band 3-0.3 Hz. When the data were processed with a remote reference, the bias was removed.

#### Magnetotelluric data interpretation

Before modeling or inverting MT data, it is vital to understand the dimensionality of MT data. Tensor decomposition is a common approach and several techniques exist (Groom and Bailey, 1989; Bahr, 1991). Each method determines how well the measured MT impedance data can be fit to a 2D geoelectric model and gives an estimate of the geoelectric strike direction. It is common for a well-defined, consistent geoelectric strike to only be defined in a subset of an MT dataset. Decomposition can also determine if shallow conductivity structures are causing *galvanic distortion* of the surface electric fields. *Galvanic distortion* is a more general case of the process responsible for static shifts, and changes both the magnitude and direction of the electric fields. In extreme cases, near-surface structure can also cause distortion of the magnetic field through intense current channeling (Lezaeta and Haak, 2003).

Once the dimensionality has been understood, and distortion addressed, MT can be *forward modeled* or *inverted* in 1D, 2D, or 3D to recover a model of subsurface electrical conductivity. The *inverse problem of electrical conductivity* is nonunique (Berdichevsky and Dmitriev, 2002), which implies that a finite set of MT data containing noise can be reproduced by an infinite number of geoelectric models. To overcome this nonuniqueness and select a preferred model, additional constraints must be imposed on the solution. One of the most successful methods is to require that the geoelectric model derived from the inversion satisfies both the MT data and some additional requirements (regularization). In the absence of any other geoelectric information, the most common requirement is that the resistivity model should be as spatially smooth as possible in the horizontal and vertical directions (Constable et al., 1987). Widely used inversion algorithms for MT data include those of Rodi and Mackie (2001) and Siripunvaraporn and Egbert (2000). The fit of the model is usually measured in term of the root-mean-square (rms) misfit of the predicted model response to the measured data. An rms misfit significantly greater than one indicates that the inversion is incapable of fitting the MT data, and usually indicates excessive noise in the data, or 3D effects that cannot be physically reproduced by a 2D inversion algorithm. A misfit significantly less than one indicates that either the error bars were too large or that the data is being over fit. In this second scenario, the resistivity model usually appears spatially rough, with the appearance of a checkerboard.

The MT method is now routinely used in both commercial exploration and in research. Commercial applications include exploration for minerals, hydrocarbons, and geothermal resources (see *EM, industrial uses*). Researchers use MT to study the structure of the continents and the dynamics of plate boundaries (Brown, 1994) and also in *EM, regional studies*. MT measurements are also made on the seafloor for both commercial and academic investigations (see *EM, marine controlled source*).

# MAGSAT

NASA (US) scientific satellite (1979–1980) made the first precise, globally distributed measurements of the vector magnetic field near Earth. The satellite flew at an altitude of 300–550 km, in a near-polar inclination. Researchers modeling the Magsat data have developed representations of the internal field extending from *spherical harmonic* (q.v.) 1–36 for the vector field (Lowe *et al.*, 2001), with additional resolution to 65 for the scalar field (Sabaka *et al.*, 2004). Magsat also contributed significantly to the understanding of the ionospheric magnetic field, and the meridional current systems through which the satellite flew. The most demanding aspect of making vector magnetic measurements from space is in precise alignment, which must be at the arc-second level. Magnetic field measurements have been made from near-Earth space since 1958, when Sputnik 3 (USSR) collected fluxgate magnetometer measurements of the near-Earth vector field with accuracies of about 100 nT. Magsat's measurements of the near-Earth vector field

were not improved upon, or even repeated, until the launchings of  $\emptyset$ *rsted* (*q.v.*) (1999) and *CHAMP* (*q.v.*) (2000), led by Denmark and Germany, respectively. Follow-on magnetic field missions by NASA focused on planetary magnetic fields (e.g., Mercury, Venus, Mars, and the outer planets), on the Earth's magnetosphere, and the dynamics of the high-latitude ionosphere.

The Magsat project scientist was Robert A. Langel (q.v.), the project manager was Gilbert Ousley, and the spacecraft design, development, and testing was done by the Applied Physics Laboratory (APL) of John Hopkins University (Potemra et al., 1981). The vector magnetometer was designed and built at Goddard Space Flight Center's Laboratory for Extraterrestrial Physics by Mario Acuña (instrument scientist) and his group. Scientists and scientific organizations in the United States, Europe, and Japan formed the largest group of users of Magsat observations. Magsat weighed 182 kg, and cost 19.2 million US dollars from inception through production of the finished data products. Magsat was modeled on the Small Astronomical Satellite (SAS-3), built by APL in 1975. SAS-3 utilized a Doppler tracking system for position determination to within 60 m vertically and 200 m horizontally, and had two star trackers that could provide attitude information to 10". However, the magnetic fields associated with these star trackers and the spacecraft itself would have introduced unacceptably large errors into the magnetic field determinations. Therefore, a deployable scissors boom and an infrared attitude transfer system (ATS) were developed for Magsat that put the scalar and vector magnetometers six meters away from the star trackers, and the body of the spacecraft (Figure M172). The deployable boom was designed, developed, and tested by APL, and the ATS was based on one used for submarines and adapted for Magsat by the Barnes Engineering Company. The sunsynchronous orbit of Magsat, resulting in a sampling of the magnetic field only at dawn and dusk local time, was a compromise dictated by the carrying capacity of the Scout launch vehicle. The chosen orbit, and mission lifetime (October 1979 through June 1980) allowed for a maximum exposure of the fixed solar array to the sun, a near-constant thermal environment, and a fixed flight attitude that allowed the star trackers to always face away from the earth.

The orientation of the vector magnetometer was determined, at 0.25 s intervals, using the two star cameras. If only one star camera was tracking an identified star, a precision sun sensor immediately adjacent to the vector magnetometer was used instead. Jumps in the vector data of 10-15 nT can occur at locations where the method of determining the orientation of the vector magnetometer changes. The system for transferring the attitude determined by the star camera on the spacecraft body to the vector magnetometer on the end of the boom involved two optical systems, one for pitch and yaw (utilizing a plane mirror), and a second for roll (using a dihedral mirror). As predicted, the system for measuring roll had the largest errors, estimated at about eight times the pitch and yaw error.

Magsat carried both scalar and vector magnetometers. The scalar magnetometer, a two-sensor, cesium 133 vapor optically pumped magnetometer, was used to calibrate the vector magnetometer. The twosensor arrangement was chosen to minimize null zones, where the magnetometers are incapable of sensing the ambient field. In practice, intermittent noise in the cesium lamp excitation circuits caused the tracking filters to lose lock, and reduced the amount of data returned to well below the nominal 8 Hz rate. System errors in the determination of the scalar field were 0.5-1.5 nT. The vector instrument was a triaxial fluxgate magnetometer with a dynamic range of  $\pm 2000$  nT, and digitally controlled current sources to increase its range to  $\pm 64000$  nT. The vector instrument sampled the ambient field 16 times per second with a resolution of  $\pm 0.5$  nT. Each of the three orthogonal sensors was wound with platinum wire on a highly permeable toroidal magnetic core. The sensors were mounted on a stable ceramic block and temperature controlled to minimize alignment shifts with respect to the reference mirrors of the ATS.

Each observation has associated with it an attitude uncertainty, and details on the sensors that were used to calculate the attitude (Langel

Figure M172 Line drawing of Magsat, its orientation, and critical systems. The roll axis is along the orbital velocity vector, the yaw axis is vertical, and the pitch axis completes the orthogonal coordinate system.

*et al.*, 1981). The mission requirements specified that the three axes of the vector magnetometer be determined within 60", although in practice it was often known within 20", corresponding to an attitude error of 5 nT. A detailed error budget can be found in Langel and Hinze (1998) in Table 3.4. The observations can be accessed (as daily files) at the FTP server (ftp.spacecenter.dk/data/magnetic-satellites/Magsat) of the Danish National Space Center.

## MAIN FIELD MAPS

Historically, in navigating long distances, the compass was as important an instrument for indicating direction as the sandglass was for marking time. However, until the 17th century, everyone believed that magnetic north coincided with true north, and mariners were unaware of this variation (see *Geomagnetism, history of*); consequently, as they sailed west they found their position did not correspond with their location according to charts. Having learned that true north differed from magnetic north, instrument makers in some of the northern countries produced compasses in which the compass card was mounted on the magnetic needle in alignment with the amount of magnetic variation. Thus, while the needle pointed to magnetic north, the *fleur-de-lis* on the compass card indicated true north. By this arrangement the compass had a built-in correction for the magnetic variation. This was fine, as long as voyages were limited to regions where the amount of variation did not appreciably change.

#### The earliest magnetic charts—before 1700

As the geomagnetic poles lie at some distance from the geographical poles, the deviation of the compass needle (known as the "magnetic variation" by mariners and "magnetic declination" by geophysicists) can vary considerably over the Earth's surface and can be directed either to the East (positive) or to the West (negative).

What led people to include magnetic information on charts? The first practical reason was navigation, and the earliest map that included magnetic information was a road map, around 1500, indicating the pilgrim's route from Germany to Rome (*Das ist der Rom Weg*). On this map, Erhard Etzlaub represented a pictorial pocket sundial (known at that time as a compass), on which he clearly showed an easterly declination (Hellmann, 1909).

During the 16th century, the number of voyages increased, and nautical charts were being drawn. In 1576, William Borough produced a chart for Martin Frobisher's first voyage in search of a North-West passage. On this manuscript, numerical values for declination were indicated for several locations situated along the likely trip (Barraclough, 2000). A global map indicating magnetic poles, magnetic meridians, and the magnetic equator was published by Guillaume de Nautonnier (1602–1604). In Edward Wright's book (1610), a chart with values for declination is included. Between 1625 and 1634, Jean Guérard, a French pilot and hydrographer, produced seven world maps; one of them includes declination values, marked in small circles at the places of measurements (Ultré-Guérard and Mandea, 2000).

If knowledge of the declination was acquired during the 15th century, the variation of declination with geographical position became more widely known around the end of 15th century. One very interesting application was to use the declination to find the longitude at sea. A sailor can find the latitude by the length of day or by the height of the Sun or other known star above the horizon. To measure longitude one needs to know, at the same moment, the time at the departure place, and the time aboard ship. Then, measuring longitude means measuring the time. However, until John Harrison's (1760) very precise ship-chronometer, it was not obvious how to measure time with enough accuracy. One proposed method was to use the magnetic compass, and thus declination, to find the longitude. According to Hellman (1909) Columbus was the first to have the idea, but, this has since been discredited (Mitchell, 1937). Mitchell indicated that in 1544, Sebastian Cabot (Pilot Major of Spain) produced a planisphere on which the contour of zero declination was indicated. Another

attempt to solve the longitude problem using declination was made by Guillaume de Nautonnier (1602–1604); for more details about Nautonnier's map and work see Mandea (2000). In another book, published in 1609 by Antony Linton (strongly influenced by Nautonnier), it was suggested that the declination resulting from a model with different positions for the magnetic and geographic poles could be represented on a sphere by "*helique* and *tortuos* lines".

## The earliest magnetic charts—1700 onward

Feeling the need for more accurate magnetic charts of the Atlantic Ocean, the lordships of the British Admiralty lent Edmund Halley a small sailing ship, *Paramore*, and instructed him to carry out a magnetic survey of the Atlantic Ocean and its bordering lands. From Halley's survey measurements the first magnetic map of the Atlantic was compiled (Figure M173/Plate 1). This earliest surveying, magnetic contour

Figure M173/Plate 1 Halley's Atlantic chart. This is the version of the chart with the cartouche over Africa containing a dedication to King William III.

chart was published by Halley in 1700, and was entitled "A New and Correct CHART Shewing the Variations of the Compass in the Western and Southern Oceans as Observed in y<sup>e</sup> Year 1700 by his Maties Command by Edmund Halley." This map was the first published chart to include isolines of declinations (called for a while "Halleyan lines," until Hanssen used the term "isogone" for a contour line of equal declination). This map became widely used as it allowed navigators to estimate declination variation when they could not get sight of an astronomical body (see Clark (2000) for more details).

William Whiston produced the first known charts showing the direction of magnetic inclination for south-eastern England, in 1719 and 1720. The contours are straight lines and are thus a very smooth representation of the distribution of inclination (see Howarth (2003) for more details). In 1768, Wilcke published the first approximately global inclination map, based on observations made during sea voyages.

The first chart of magnetic field intensity, covering the Northern part of South America, was produced by Alexander von Humboldt (Humboldt and Biot, 1804). On this map the geographic and magnetic equators are indicated, and five "isodynamic zones" are defined by the average number of oscillations per minute of the magnetized needle used during Humboldt's expeditions (Malin and Barraclough, 1991). To quote Hellman (1909), the first "true" magnetic field intensity map was produced by Hansteen (1824) for a region of the Northern part of Europe. The intensity values shown on this chart are in relative units ("Humboldt units"), as it was produced before Gauss' demonstration on how to measure the magnetic field in absolute units.

## Official magnetic maps

The naval authorities from different countries have published world magnetic charts for different epochs. The first official chart was of declination for the epoch 1858, produced by F.J. Evans, under the superintendence of the hydrographer of the Royal Navy. The first German chart was published in 1880, with the United States following in 1882. Other countries, such as France and Spain, have published copies of the British charts with titles and text translated into the appropriate language. Hellmann (1909) gives details of the earlier examples of these charts.

Present-day maps are produced from different geomagnetic field models for the main field and its secular variation (see *Main field modeling*; *Geomagnetic secular variation*). Geomagnetic models such as the World Magnetic Model (WMM) and the International Geomagnetic Reference Field (IGRF) only predict the values of that portion of the field originating in the fluid outer core. In this respect, they are accurate to within 1° for 5 years into the future, after which they need to be updated. Maps produced from these models are used widely in civilian navigation systems.

#### World Magnetic Model (WMM)

The WMM is a product of the United States National Geospatial-Intelligence Agency (NGA). The US National Geophysical Data Center (NGDC) and the British Geological Survey (BGS) produce the WMM as the standard model for navigation and attitude/heading referencing systems for the US Department of Defense, the UK Ministry of Defence, the North Atlantic Treaty Organization (NATO), and the World Hydrographic Office (WHO). The model, associated software, and documentation are distributed by NGDC on behalf of NGA and used widely in civilian navigation systems. The model is produced at 5-year intervals, with the current model, WMM-2005, expiring on December 31, 2009 (McLean *et al.*, 2004).

#### International Geomagnetic Reference Field (IGRF)

Production of the IGRF is an international collaborative effort relying on cooperation between magnetic field modelers, institutes, and agencies responsible for collecting and publishing geomagnetic field data (see *IGRF, International Geomagnetic Reference Field*). The first model, designated IGRF 1965, was of spherical harmonic degree and order 8, in both main field and secular variation (Langel, 1987). The latest version of the model—the 10th generation—includes models of the core field at 5-year intervals from 1900 to 2005, and a secular variation model for 2005–2010. Magnetic charts based on different generations of IGRF are available on several Web sites, including http://swdcwww.kugi.kyoto-u.ac.jp/igrf/; http://www.geomag.bgs.ac. uk/navigation.html.

#### Maps accuracy

The WMM and IGRF/DGRF geomagnetic models, and the charts produced from these models characterize only that portion of the Earth's magnetic field that is generated in the Earth's fluid outer core (the main magnetic field). The portions of the geomagnetic field generated by the Earth's upper mantle and crust, and by the ionosphere and magnetosphere, are not represented (see Internal external field separation). Consequently, a magnetic sensor such as a compass or magnetometer may observe spatial and temporal magnetic anomalies when referenced to these models. In particular, certain local, regional, and temporal magnetic declination anomalies can exceed 10°. Anomalies of this magnitude are not common but they do exist. Local anomalies distort the WMM or IGRF predictions, and frequently induce an error of 3-4° (ferromagnetic ore deposits; geological features, particularly of volcanic origin, such as faults and lava beds; topographical features such as ridges, trenches, seamounts, and mountains; ground that has been hit by lightning and possibly harboring fulgurites; cultural features such as power lines, pipes, rails, and buildings; personal items such as crampons, ice axe, stove, steel watch, hematite ring, or even a belt buckle).

## Main field and secular variation maps at the Earth's surface

To create an accurate main field model, data with good global coverage and as low a noise level as possible are needed. The Danish Ørsted and German CHAMP satellite data sets satisfy these requirements. Both satellites provide high-quality vector and scalar data at all latitudes and longitudes, but not during all time periods needed for modeling. These satellite data were augmented with ground observatory data, which have been available almost continuously over the period of interest, although with poorer spatial coverage. Used together, satellite and observatory data provide an exceptional quality data set for modeling the behavior of the main magnetic field in space and time, and for producing main field magnetic maps for a given epoch. Such maps at the Earth's surface field were drawn using a main field model based on data from the Ørsted magnetic field satellite (Neubert et al., 2001). For the main field and its secular variation representation some other models are available, derived from Ørsted, CHAMP and Ørsted-2/SAC-C measurements, such as IDEMM, CO2, OSVM and OIFM (see http://www.dsri.dk/Oersted/Field\_models/ for more details).

Among the multitude of geomagnetic models based on satellite data, POMME, derived from Ørsted and CHAMP data, is used here to draw maps for three field components. This model provides a representation of the strongest contributions to the geomagnetic field: the time-varying core field, the ring current field modulated by the Dst index, a time-averaged magnetospheric field, the penetration of the horizontal part of the Interplanetary Magnetic Field (IMF), and the fields induced by Earth's rotation in the external fields (Maus *et al.*, 2004). From POMME coefficients, synthetic data for the main field components are computed for the whole Earth's surface, on a grid of  $30' \times 30'$ . Each set of synthetic data is then interplated and plotted as maps, generally on global scale. In Figures M174-M176 maps of declination, inclination, and total intensity for the epoch 2002.5, and their secular variations, derived from the POMME model are shown. The isolines on the declination map (isogones) show the distribution

**Figure M174** Contour maps of declination (degrees) at 2002.5 and secular variation of declination (arc-min  $y^{-1}$ ), at the Earth's surface, computed from POMME model (Maus *et al.*, 2004).

**Figure M175** Contour maps of inclination (degrees) at 2002.5 and secular variation of inclination (arc-min  $y^{-1}$ ), at the Earth's surface, computed from POMME model (Maus *et al.*, 2004).

**Figure M176** Contour maps of total intensity (nT) at 2002.5 and secular variation of total intensity (nT  $y^{-1}$ ), at the Earth's surface, computed from POMME model (Maus *et al.*, 2004).

of the declination (or of the compass needle eastward or westward from the true north), the isolines on the inclination map (isoclines) show the distribution of the inclination (angle between the geomagnetic field vector and its horizontal projection), and the isolines on the total field intensity map (isodynamics) show the distribution of the total geomagnetic field (the scalar value of the geomagnetic field vector). The lines of equal secular variation (isopods) are used for dates outside the epoch for which the main field charts have been drawn.

Unfortunately, the same potential theory that allows us to generate these maps also tells us that, formally, little more about the origin of the field can be said: the field certainly originates within the Earth, but where in the Earth cannot be distinguished. However, by looking at the structure of the field-and making assumptions about its sources-further inferences can be made. The spectrum of the field has clearly two parts, first a rapidly declining part down to wavelengths of approximately 3000 km, with a much more gentle decline at shorter wavelengths (see Geomagnetic spectrum, spatial). The presented maps reflect only the first part of the spectrum corresponding to the core field. The lithospheric contributions could be included in extended models, expanded to high degrees. The crustal field is almost constant in time, which can be inferred from all available marine, aeromagnetic, and high-resolution Ørsted, CHAMP, and future satellite data, measured at all times. However, these extended models and maps would differ significantly in format and form from the current main field models and maps.

# MAIN FIELD MODELING

The history of modeling the geomagnetic field stretches back four centuries, to William Gilbert's *De Magnete*, the first book on geomagnetism. His assertion, that the Earth is a great magnet, can be regarded as the first model of the geomagnetic field. The development of geomagnetic field models is explained by the need to draw magnetic maps. The practical reasons were mainly connected with navigation: the use of the magnetic compass and portable sundials that included a compass needle, the problem of determining longitude at sea, and also the construction of road maps on land. These practical applications in turn provided the motivation to seek a more fundamental understanding of the geomagnetic field.

Before modeling the geomagnetic field, some fundamental properties of the field had to be discovered, like the existence of magnetic variation or declination, the spatial variation of declination, the existence of magnetic inclination or dip, and the secular variation. The history and definitions of these fundamental discoveries are given elsewhere. Here, some different ways of modeling the geomagnetic field since William Gilbert's first attempt in 1600 are given. A milestone in main field modeling was achieved in 1839, when Gauss published in his famous description of the geomagnetic field using spherical harmonics.

## Empirical models: dipoles and magnetized spheres

The first geomagnetic field model was a physical one, the terrella built out of lodestone and used by Gilbert in his experiments. He investigated the behavior of very small magnetized iron needles on the surface of such a sphere, and compared the results with what was known about the magnetic field from direct measurements made with compass needles and dip needles. Gilbert believed that the positions of the magnetic poles of the Earth were the same as those of the rotation poles. He also believed that declination, which with his assumption would have been zero everywhere, was caused by the effects of the continents, whose magnetic rocks attracted the needles toward them. In his experiments Gilbert modeled this effect by using an irregularly shaped sphere, and he concluded that "the variation in any one place is constant." At about the same time that Gilbert wrote his famous book, a French cartographer, Nautonnier de Castelfranc came to a similar conclusion concerning the terrestrial source of the geomagnetic field (Mandea, 2000). However, Nautonnier believed that the positions of the magnetic and geographic poles were not coincident, and this property explained the phenomenon of declination. Nautonnier produced the first known chart showing magnetic poles, magnetic meridians, and the magnetic equator.

The first attempt to model inclination was published by Edward Wright in 1610, who gave an empirical expression, obtained from a geometrical construction, apparently devised to give  $0^{\circ}$  at the equator,  $90^{\circ}$  at the pole, and an acceptable value of dip for the position of London (note that his tables of inclination were not very accurate for locations other than London). Wright's model did not take into account the secular variation. This was first addressed some years later, when Henry Bond attempted to take into account the secular variation by using a tilted dipole model, with the magnetic poles moving around the geographical poles (Barraclough, 2000).

Halley's theory of the Earth's magnetic field has been lauded as a great achievement. In his first paper, Halley used observational data to examine previous theories (Barraclough, 2000). Finding the theories lacking in certain respects, Halley proposed a new model, which explained the observations qualitatively. Having presented his data, and discussed the shortcomings of previous theories, Halley turned to his own hypothesis. He suggested that the pattern of declination could be explained by four magnetic poles, roughly situated at: N1 (75°N, 129°W); N2 (83°N, 6°W); S1 (70°S, 120°E); S2 (74°S, 95°W). He had no means to quantitatively describe the effects that these poles would have, but he demonstrated that they did qualitatively explain the pattern of variation seen in his data. Nine years later he further developed these ideas by proposing a geomagnetic field model which could incorporate the secular variation (Halley, 1692). He suggested that the Earth consisted of an outer shell with poles corresponding to N1 and S1, and an inner shell with poles corresponding to N2 and S2. The inner shell rotated with respect to the outer one, and consequently these poles would shift with time and result in a secular change in declination. At least in part to provide an observational test of this model, he undertook an extensive survey (accomplished in his three voyages in the Atlantic Ocean between 1698 and 1701) to remedy the lack of data in ocean areas. Other priorities evidently prevented him from using these new data to refine his model, but he used them to produce magnetic charts, far more useful and important than his four-pole model.

In 1757, Euler introduced a new model, in which the two magnetic poles were not antipodal (what would today be called *an eccentric dipole model*). Using a method of successive approximations he found the positions of these poles for 1757. During the 19th century, Halley's four-pole model was not forgotten. Hansteen collected as many measurements of declination and inclination as he could find and used them to derive a model with four poles, including their changes in time (Barraclough, 2000). Although the concept of modeling the geomagnetic field using two magnetic axes and four magnetic poles is today only of historical interest, the data collected and published by Hansteen have proved to be very valuable in studying how the field has evolved with time (see *Geomagnetism, history of*).

In 1832, Carl Friedrich Gauss and Wilhelm Weber began investigating the theory of terrestrial magnetism after Alexander von Humboldt attempted to obtain Gauss's assistance in making magnetic observation on a grid of points around the Earth. Gauss was excited by this prospect and by 1840 he had written three important papers on the subject, all of which dealt with the current theories on terrestrial magnetism, including Poisson's equation, the potential theory equation (in 1812 Poisson discovered that Laplace's equation is valid only outside of a solid), and the absolute measure for magnetic force. In *Allgemeine Theorie des Erdmagnetismus* (1839) Gauss showed that there can only be two poles in the globe and used the Laplace equation to aid him with his magnetic field calculations (see *Gauss, Carl Friedrich*).

## Mathematical models: spherical harmonic analysis

The Earth's magnetic field is continuously changing, in such a way that it is impossible to predict accurately what the field will be at any point in the very distant future (for example, declination is accurately described by geomagnetic models to within 1° for 5 years). By measuring the magnetic field, its spatial variation and changes over a period of years, can be observed. This structure and variation can most conveniently be expressed in terms of spherical harmonics (see *Harmonics, spherical*). A review of the technique's development can be also found in Langel (1987) or Merrill *et al.* (1996).

The two Maxwell equations relating to the magnetic field are:

$$\nabla \times \vec{H} = \vec{J} + \frac{\partial \vec{D}}{\partial t}$$
 (Eq. 1)

$$\nabla \cdot \vec{B} = 0 \tag{Eq. 2}$$

where  $\vec{H}$  is the magnetic field,  $\vec{B}$  is the magnetic induction,  $\vec{J}$  is the current density, and  $\partial \vec{D} / \partial t$  is the electric displacement current density. In a region that does not contain sources of magnetic field (from the Earth's surface up to about 50 km), it is reasonable to assume that  $\vec{J} = 0$  and  $\partial \vec{D} / \partial t = 0$ , so  $\nabla \times \vec{H} = 0$ , meaning that the vector field is conservative in the region of interest, and the magnetic field  $\vec{H}$  can be expressed as  $\vec{H} = -\nabla \vec{V}$ , where *V* is a scalar potential. Because  $\vec{B} = \mu_0 \vec{H}$  above the Earth's surface (where  $\mu_0 = 4\pi \times 10^{-7} \text{ H m}^{-1}$ ), it follows that  $\nabla \cdot \vec{H} = 0$  and that *V* has to satisfy Laplace's equation:

$$\nabla^2 V = 0 \tag{Eq. 3}$$

In spherical coordinates  $(r, \theta, \phi)$ , which are the radial distance, the geocentric colatitude, and the longitude, Laplace's equation takes the form:

$$\frac{1}{r}\frac{\partial^2}{\partial r^2}(rV) + \frac{1}{r^2\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial V}{\partial\theta}\right) + \frac{1}{r^2\sin^2\theta}\frac{\partial^2 V}{\partial\phi^2} = 0 \quad (\text{Eq. 4})$$

Equation (4) has, as a solution, a product of three expressions (the first is to be only a function of r, the second only a function of  $\theta$ , and the third only a function of  $\phi$ ) and can be solved by separation of variables. A completely general solution is provided by spherical harmonics, and can be written as:

$$V(r,\theta,\phi) = a \sum_{n=1}^{\infty} \sum_{m=0}^{n} \left[ \left( A_{n,m} \cos m\phi + B_{n,m} \sin m\phi \right) \left( \frac{a}{r} \right)^{n+1} + \left( C_{n,m} \cos m\phi + D_{n,m} \sin m\phi \right) \left( \frac{r}{a} \right)^{n} \right] P_{n,m}(\cos \theta)$$
(Eq. 5)

where  $A_{n,m}$ ,  $B_{n,m}$ ,  $C_{n,m}$ ,  $D_{n,m}$  are called spherical harmonic coefficients, and  $P_{n,m}(\cos \theta)$  are the associated Legendre polynomials. In geomagnetism the partially normalized Schmidt functions  $P_m^m(\cos \theta)$  are used.

The  $P_n^m(\cos\theta)$  are functions of colatitude only. They are quasisinusoidal oscillations having n - m + 1 nodes. Figure M177 illustrates the variations of some of these functions.

The surface harmonics  $P_n^m(\cos\theta)\sin m\phi$  and  $P_n^m(\cos\theta)\cos m\phi$ divide the surface of the sphere into regions defined by the intersections of latitudinal zones and longitudinal sectors. The three situations are: (i) when m = 0, the surface harmonics are described by the Legendre polynomials and they are referred to as *zonal harmonics*; (ii) when n = m, the surface harmonics are referred to as *sectorial harmonics*, and (iii) when 0 < m < n, the surface is divided in 2m(n - m + 1) regions and the surface harmonics are referred to as *tesseral harmonics*. Some examples are given in Figure M178.

Application of spherical harmonics to the Earth's magnetic field involves writing the magnetic scalar potential as the sum of two contributions:

**Figure M177** Legendre polynomials  $P_n(x)$  up to n = 5.

$$V = V_{\rm int} + V_{\rm ext} \tag{Eq. 6}$$

where  $V_{\text{int}}$  and  $V_{\text{ext}}$  are the internal and external scalar potential, respectively (see *Internal external field separation*). These two potentials can be represented by spherical harmonic expansions:

$$V_{\text{int}} = a \sum_{n=1}^{N_i^{\text{max}}} \left(\frac{a}{r}\right)^{n+1} \sum_{m=0}^n \left(g_n^m \cos(m\phi) + h_n^m \sin(m\phi)\right) P_n^m (\cos(\theta))$$
(Eq. 7)

$$V_{\text{ext}} = a \sum_{n=1}^{N_e^{\text{max}}} \left(\frac{r}{a}\right)^n \sum_{m=0}^n \left(q_n^m \cos(m\phi) + s_n^m \sin(m\phi)\right) P_n^m \left(\cos(\theta)\right)$$
(Eq. 8)

where the reference radius is a = 6371.2 km. Measurements of the magnetic field are used to estimate the so-called Gauss spherical harmonic coefficients  $((g_n^m, h_n^m)$  for internal sources, and  $(q_n^m, s_n^m)$  for external sources), which in principle uniquely describe the geomagnetic field outside source regions. The summations in Eqs. (7) and (8) are truncated at maximum degree  $N_i^{\text{max}}$  and  $N_e^{\text{max}}$ , respectively.

In practice  $\vec{B}$  is not measured everywhere on the Earth's surface. The coefficients  $(g_n^m, h_n^m)$  and  $(q_n^m, s_n^m)$  are obtained by a least-squares fit to the data. Gauss originated this method, and with the small number of observatory measurements he had at that time, he took  $N_i^{\text{max}} = 4$  and  $N_a^{\text{max}} = 0$ . Even today, there are fewer than 200 magnetic observatories, and they are very unevenly distributed. A problem for main field modeling is that magnetic observatories, as well as being poorly distributed over the globe, may be situated in areas with large local crustal magnetic anomalies. In contrast, lowaltitude satellites in near-polar orbits rapidly provide excellent global data coverage and are much less affected by crustal magnetic fields, which are considerably attenuated at satellite altitude. A problem with magnetic satellite data is that the full vector measurements need very accurate orientation of the magnetometer. Originally it was hoped (in the POGO and OGO missions) that one could measure the field strength  $|\vec{B}|$ , which is much easier, and a very high density of measurements would then amount to knowing the vector field. Unfortunately, it was shown that even if  $|\vec{B}|$  is known exactly everywhere, a unique field model cannot be obtained (Khokhlov et al., 1999). There exist pairs of magnetic fields  $\vec{B}_a$  and  $\vec{B}_b$  satisfying  $\nabla \times \vec{H} = 0$  and  $\nabla \cdot \vec{H} = 0$ , outside the considered sphere and such that  $|\vec{B}_a| = |\vec{B}_b|$  everywhere on the sphere, but  $\vec{B}_a \neq \vec{B}_b$ . These two

**Figure M178** Surface harmonics showing three cases, with n = 7 and (a) m = 0 (*zonal harmonics*); (b) n = m (*sectorial harmonics*), and (c) for 0 < m < n, when the surface is divided in 2m(n - m + 1) regions (*tesseral harmonics*), with m = 4 in this example.

fields would give exactly the same values of total intensity, but two different models. The details of nonuniqueness of fields based on total field observations are given by Backus (1970). Empirically it has been observed that fitting MAGSAT intensity data produces models whose  $\vec{B}$  can differ from the vector field components measured by the satellite by some *thousands* of nanoteslas near the equator.

Spherical harmonic analysis is an appropriate way of modeling the geomagnetic field. Considering only the part of the geomagnetic field whose sources lie beneath the Earth's surface, Eq. (7) is used. However, this equation describes both the main field (with sources in the core) and the crustal field (with sources in the Earth's crust).

The Gauss coefficients can be interpreted in terms of "sources" at the Earth's center. The first term,  $g_1^0$ , is associated with the geocentric dipole oriented along the vertical axis, with dipole moment  $g_1^0 4\pi a^3/\mu_0$  (see *Geomagnetic dipole field*). The next two terms,  $g_1^1, h_1^1$ , correspond to geocentric dipoles oriented along the two horizontal axes. The magnitude of the *geocentric dipole* is given by  $M = (4\pi a^3/\mu_0)((g_1^0)^2 + (g_1^1)^2 + (h_1^1)^2)^{1/2}$ , and it is tilted at roughly 11° from the rotation axis. The potential for a dipole falls off as  $r^{-2}$ , and the strength of the field components as  $r^{-3}$ . Similarly, for n = 2 the terms represent the *geocentric quadrupole* (potential falls off as  $r^{-3}$ , and the strength as  $r^{-4}$ ), for n = 3 the terms represent the *geocentric octupole* (potential falls off as  $r^{-5}$ ), and so forth.

The first three Gauss coefficients  $(g_0^1, g_1^1, h_1^1)$  represent the *dipole* field, while the remaining terms represent the *nondipole field*. The lowest degree terms correspond to the largest wavelength features of the field, as can be appreciated by considering the zonal harmonics. The first Gauss coefficient has a  $\cos \theta$  dependence, so at distance *r* the "wavelength" of the associated magnetic feature is  $2\pi r$ . Generally speaking the term  $g_n^m$  has a wavelength of  $2\pi r/n$ .

The internal field at the Earth's surface contains clearly defined components from the core at least up to degree  $N_i = 13$ , beyond which they begin to become dominated by those from the crust. The maximum associated wavelengths for the crustal components are of the order of a few thousand kilometers. The relative importance of the two internal contributions is clearly illustrated by using the normalized power in spherical harmonics of the internal geomagnetic field. The spectrum of a model is constructed by plotting the contribution of each degree *n* of the spherical harmonic expansion to the mean square field over the Earth's surface (see *Geomagnetic spectrum, spatial*). The power at degree *n* is computed from the equation (Lowes, 1974):

$$W_n = (n+1) \sum_m \left( (g_n^m)^2 + (h_n^m)^2 \right).$$
 (Eq. 9)

High-quality data sets, such as those provided by the magnetic satellite surveys MAGSAT, Ørsted, and CHAMP (Langel and Estes, 1985,

**Figure M179** Geomagnetic field spectra up to degree n = 20 at the Earth's surface, from two internal models, computed from MAGSAT (stars) and Ørsted (filled circle) data. The difference between these two spectra is also shown (filled diamond).

Neubert *et al.*, 2001, Reigber *et al.*, 2002) have allowed the computation of spherical harmonic models up to high degree and order. Figure M179 shows the power spectra from models obtained from MAGSAT and Ørsted data, and also the difference between them (Langlais *et al.*, 2003). The dipole term obviously stands alone, the main field dominates the signal for degrees less than 13, while the crustal field dominates for degrees larger than 15.

The Gauss coefficients are also time-dependent. Indeed, the temporal variations of the geomagnetic field have an extremely wide spectrum, ranging over more than 20 orders of magnitude (Langel, 1987). In order to resolve time variations of internal origin, the secular variation, about 1 year of continuous observations is needed. If the secular variation is assumed to be constant over short timescales, it can be included in Eq. (7) by adding a secular-variation potential,  $V_{\rm sv}$ , truncated to  $N_{\rm sv}^{\rm max}$ :

$$V_{\rm sv} = a \sum_{n=1}^{N_{\rm sv}^{\rm max}} \left(\frac{a}{r}\right)^{n+1} \sum_{m=0}^{n} (t - T_0) \left(\dot{g}_n^m \cos(m\phi) + \dot{h}_n^m \sin(m\phi)\right) P_n^m (\cos(\theta))$$
(Eq. 10)

where  $\dot{g}_n^m$  and  $\dot{h}_n^m$  are the time derivatives of the internal Gauss coefficients.  $T_0$  denotes the reference time (i.e., the epoch of the main field model), and *t* is the considered epoch.

Since the geomagnetic field changes in space and time, magnetic observations must be made continually and models have to be generated to accurately represent the magnetic field. For example, the International Geomagnetic Reference Field (IGRF) models are adopted every 5 years (see *IGRF, International Geomagnetic Reference Field*) by the International Association of Geomagnetism and Aeronomy (Mandea and Macmillan, 2000). These models are simply truncated series (up to degree and order 10 or, more recently, 13). An extreme cutoff like this is, of course, unrealistic, and downward continuation of the models to the core-mantle boundary is unstable. Other methods, including stochastic inversion, have been used to produce reasonable models of the field at the core-mantle boundary (see *Time-dependent models of the main magnetic field*).

#### Mathematical models: other methods

The mathematical properties of the spherical harmonic representation make it a convenient method for describing the magnetic field. However, this representation does not have direct physical significance; some important limitations are linked to the precision in observations, their distribution and to the use of truncated spherical harmonic expansions. Indeed, the truncation of the spherical harmonic series followed by straightforward least squares inversion leads to solutions that are strongly dependent on the chosen truncation level. Changing the truncation level modifies all the coefficients, due to spatial aliasing of the higher-order harmonics (Whaler, 1986). Some alternative modeling methods exist, such as harmonic spline modeling (Shure et al., 1982). This approach produces models smoothed according to some objective criteria (e.g., minimizing the complexity of some well-defined parameters of the field, such as the energy outside the core, the mean-square radial field component at the core-mantle boundary, the surface gradient of the radial field, or imposing a lower bound on Ohmic losses in the core) which are nevertheless, consistent with the data. Short-wavelength fields originating in both the core and the crust are suppressed. More details about this method can be found elsewhere (e.g., Parker and Shure, 1982; Shure et al., 1982; Gubbins, 1983).

To represent both the global and the regional pattern of the magnetic field and to overcome the limitations of spherical harmonic analysis, a new method to model the Earth's magnetic field is desirable. Wavelet techniques may play a role in the solution of this challenging problem. Recently, a new representation of the magnetic field on the sphere has been sought, the chosen approach making a direct relation between spherical harmonics and wavelets. In Holschneider *et al.* (2003) the main result is a theoretical description of the wavelets on the sphere in order to use them in field modeling. The first comparisons between the spherical harmonic and wavelet bases show that wavelets are able to reproduce the spherical harmonics well.

Any kind of geomagnetic field modeling can be described as seeking a solution to optimize the cost function "*error* + *smoothness*". In general, the smoothness can be associated with some (physically plausible) norms. It is in general implemented through some *a priori* damping of the basis functions in the inversion. As it stands, it does not depend on the family of basis functions in which the actual numerical computations are carried out. Therefore, in the limit of infinitely many functions and without any numerical errors, it is possible to get the same models, whether spherical harmonics, wavelets, or any other complete family of functions are used. However, given finite resources it does matter, since for a fixed number of basis functions, wavelets have better approximation properties than spherical harmonics. Moreover, in modeling strongly heterogeneous fields, such as those due to external currents, wavelets may play an additional role, since they allow a more geometric description of the fields.

# MAIN FIELD, ELLIPTICITY CORRECTION

The first spherical harmonic analyses of the geomagnetic main field ignored the ellipticity of the Earth. This was not a serious omission, since the radial departures of the Earth's surface from a sphere never amount to more than 0.17%. However, as the quality of data improved, it was thought that they might justify inclusion of a correction for ellipticity.

The Earth's surface is closely approximated by an oblate spheroid with eccentricity 0.082. This affects both the position of an observation and the observation itself, since the horizontal component, for example, is measured tangential to the spheroid rather than perpendicular to the line joining the site to the Earth's center. Early analyses that took account of this ellipticity (Schmidt, 1898; Adams, 1900; Jones and Melotte, 1953) first determined coefficients for a spherical Earth, then adjusted these for ellipticity. A better method (Cain *et al.*, 1963) was based directly on the original observations.

#### Adjustment from geodetic to geocentric coordinates

A closer approximation to the Earth's surface than a sphere is an oblate spheroid. That adopted by the International Astronomical Union and subsequently used with the International Geomagnetic Reference Field (see *IGRF, International Geomagnetic Reference Field*) has flattening f = 1/298, where f = 1-b/a. Here *a* denotes the equatorial radius (6378.388 km) and *b* the polar radius (6356.912 km). This corresponds to a mean radius  $a_0 = (a^2b)^{1/3} = 6371.2$  km and ellipticity  $e = (1-b^2/a^2)^{1/2} = 0.082$ . Departures from this spheroid are well-known and determined, but are too small to be of concern in the context of geomagnetism.

Observations made at or near the surface of the Earth are referred to geodetic coordinates, with north and east tangential to the surface and vertical perpendicular to it. (Satellite data are usually provided in geocentric coordinates.) Geodetic latitude,  $\phi'$ , is the angle between the equatorial plane and the vertical. Height, *h*, is measured vertically from the surface (see Figure M180). In geocentric coordinates, position is defined by *r*,  $\phi$ ,  $\lambda$ , where *r* denotes the radial distance from the center of the Earth,  $\phi$  denotes latitude—the angle between the equatorial plane and a line drawn from the center of the Earth, and  $\lambda$  denotes longitude measured east from the Greenwich meridian. In geocentric coordinates, north and east are perpendicular to the radial direction and vertical is along it. The direction of east and  $\lambda$  are the same in both coordinate systems.

Two operations are needed to convert the observations from geodetic to geocentric coordinates. (1) The site must be converted from h,  $\phi'$ ,  $\lambda$ , to r,  $\phi$ ,  $\lambda$ . This may be done using the relations

$$r^{2} = h^{2} + 2hA + (a^{4}\cos^{2}\phi' + b^{4}\sin^{2}\phi')/A^{2},$$

 $\cos\phi = \cos\phi'\cos\delta + \sin\phi'\sin\delta$ 

**Figure M180** Geodetic ( $\phi'$ , h) and geocentric ( $\phi$ , r) coordinates of point *P*.

and

$$\sin\phi = \sin\phi'\cos\delta - \cos\phi'\sin\delta,$$

where  $\delta = \phi' - \phi$ ,

$$\cos \delta = (h+A)/r,$$

$$\sin \delta = [(a^2 - b^2) \cos \phi' \sin \phi']/Ar$$

and

$$A = (a^2 \cos^2 \phi' + b^2 \sin^2 \phi')^{1/2}.$$

(2) The magnetic elements X, Y, Z, the geodetic north, east and vertically downward geomagnetic components, respectively, must be rotated to X', Y, Z', the geocentric equivalents. The appropriate relations are

$$X' = X\cos\delta - Z\sin\delta$$

and

$$Z' = Z\cos\delta + X\sin\delta.$$

The treatment of nonorthogonal elements may be deduced from that described in *main field modeling* (q.v.)

Once the data are in geocentric coordinates, a standard spherical harmonic analysis may be performed. Magnetic values synthesized from spherical harmonic coefficients may, if required, be converted back into geodetic coordinates.

## Discussion

Since the advent of computers, it is just as easy to take account of the Earth's ellipticity as to ignore it, so the adjustment is now universally incorporated as outlined above. Whether or not it is justified is debatable. Precomputer analysts (Adams, 1900; Jones and Melotte, 1953) concluded that the additional labor was not justified. Before satellite data were available it was thought that there might be an advantage when upward extrapolation was involved (Kahle *et al.*, 1964; Cain *et al.*, 1965) or when external as well as internal coefficients were being determined (Winch, 1967). For modeling the main magnetic field of internal origin, the correction for ellipticity is harmless but probably unnecessary (Malin and Pocock, 1969).

A related point, which is probably only of academic interest, concerns the separation of the field into internal and external parts (see *Internal external field separation*). The boundary between internal and external should be the surface of the Earth, but, using the above method, the boundary is the reference sphere, with radius  $a_0$ , which passes some 14 km above the poles and is about 7 km below the surface at the equator. Any sources within the region between the ellipsoid and the reference sphere would be wrongly classified. For example, crustal sources near the equator would be deemed to be external. It would not help to increase the radius of the reference sphere to a, since any magnetic fields due to currents in the lower polar atmosphere would then be considered to be of internal origin.

# MANTLE, ELECTRICAL CONDUCTIVITY, MINERALOGY

The electrical conductivity profile in the mantle can be obtained by *magnetotelluric* (*q.v.*) and *geomagnetic deep sounding* (*q.v.*) methods (Figure M181). Although the profiles obtained can have significant differences from each other, the following features can be seen in the most conductivity models. Conductivity in the upper mantle is relatively low, i.e.,  $10^{-4}-10^{-2}$  S m<sup>-1</sup>. It increases with increasing depth to the top of the lower mantle. At the top of the lower mantle, conductivity is  $10^{0}$  S m<sup>-1</sup>. Conductivity does not increase significantly in the lower mantle. Some studies have shown that the electrical conductivity of the uppermost mantle to 100 km depth is about  $10^{-2} \sim 10^{-1}$  S m<sup>-1</sup>, known as the mantle high conductive layer (HCL). Local variations of electrical conductivity are large at shallow depths, and become smaller with increasing depth.

**Figure M181** The electrical conductivity of the upper part of the mantle. Long dashed curve: north Pacific region, dotted curve: northeastern China, short dashed curve: Canadian shield, one-dotted dashed curve: southwestern United States, two-dotted dashed curve: Hawaii. Thick solid curve: laboratory electrical conductivity model (Xu *et al.*, 2000).

Geochemical and petrological studies suggest that the major constituent of the uppermost mantle is olivine, with an approximate composition of  $(Mg_{0.9}Fe_{0.1})_2SiO_4$ . With an increasing pressure, olivine transforms to its high-pressure polymorph, wadsleyite at about 410 km depth (olivine-wadsleyite transition). Wadsleyite transforms to a further high-pressure polymorph, ringwoodite, at about 520 km depth (wadsleyite-ringwoodite transition). Ringwoodite dissociates to  $(Mg,Fe)SiO_3$  perovskite and (Mg,Fe)O ferropericlase at 660 km depth (postspinel transition). These minerals form a network in each region and therefore, the electrical conductivity of these minerals would be primarily responsible for that of the mantle itself. Additionally, some minor phases such as silicate melt that have high conductivity may also have important roles.

## Electrical conduction mechanisms

In metals, free electrons transfer electric charges. However, the mantle minerals are essentially ionic solids in which most electrons are bound to ions. Therefore, carriers other than free electrons play an important role in transferring electric charges. For example, if an electron is released from an ion, an electric hole is created in the ion, and the hole itself can migrate to carry an electric charge.

For the migration of carriers other than a free electron, defects play important roles in crystalline ionic solids. Here, defects in ferromagnesian silicates are briefly described using the Kroger-Vink notation in which the base character refers to the defect species, that is, ion, electron, or hole. An electron or an electron hole is expressed by element symbols, "e" and "h," respectively. The vacancy of an ion is expressed by "V". The subscript refers to the site, that is, Mg, Si, O, or an interstitial site that is expressed as "I". The dots or slashes as superscripts refer to the number of positive or negative excess charges compared to the site in a normal lattice. "x" as a superscript refers to no excess charge. In this notation, a released electron or a hole is expressed as the set of The Fe ion can have 3+ charges. The Fe<sup>3+</sup> ion in the Mg site has an extra plus charge and is expressed as  $Fe_{Mg}$ . The vacancy has a charge with an opposite sign to that of the ion that should occupy the site. The vacancies for Mg, Si, and O sites are expressed as  $V_{Mg}$  $V_{Si}^{\prime\prime\prime\prime}$ , and  $V_{O}^{\prime\prime}$ , respectively. A small cation can exist interstitially in the crystalline lattice. A typical interstitial ion is H<sup>+</sup>, which is expressed as H<sub>I</sub>.

The major mantle minerals contain significant amounts of Fe and, therefore, electron hopping from Fe<sup>2+</sup> to Fe<sup>3+</sup> ions could be the dominant electron conduction mechanism (Figure M182). An electron has to jump across an energy barrier,  $\Delta E_{\rm h}$  and, therefore the electrical conductivity,  $\sigma$ , is usually expressed as

$$\sigma = \sigma_0 \exp(-\Delta E_{\rm h}/kT) \tag{Eq. 1}$$

where k is the Boltzmann constant and T is absolute temperature. The  $\Delta E_{\rm h}$  is called the activation energy. The preexponential term  $\sigma_0$  could be a function of temperature; however, it is often regarded as a constant with a limited temperature range. For electron hopping, the energy barrier should be low.

Electron hopping can be regarded as the migration of  $Fe_{Mg}$  (Figure M182). The surrounding oxygen ions and cations, respectively, are attracted and repulsed by the excess positive charge, which causes a distortion of the lattice in the neighborhood (Figure M183). The migration of  $Fe_{Mg}$  is associated with this lattice distortion. The unit of  $Fe_{Mg}$  and its induced lattice distortion is called a small polaron. Migration of a small polaron is a thermally activated process:

$$\sigma = \sigma_0 \exp(-\Delta E_{\rm p}/kT) \tag{Eq. 2}$$

**Figure M182** Electrical conduction by electron hopping between  $Fe_{Mg}^{\chi}$  and  $Fe_{Mg}^{\chi}$ . It can be regarded as migration of the hole.

**Figure M183** Small polaron model. The  $Mg_{Mg}^{\chi}$  (and  $Si_{Si}^{\chi}$ ) and  $O_O^{\chi}$  ions are repulsed and attracted by the excess plus charge of  $Fe_{Me}$ , which induces distortion of the lattice.

where  $\Delta E_{\rm p}$  is the activation energy for the small polaron. A small polaron is less mobile than an electron itself, resulting in  $\Delta E_{\rm p} \gg \Delta E_{\rm h}$ .  $\Delta E_{\rm p}$  ranges from 0.5 to 2 eV for mantle minerals.

The charges are carried by  $Fe_{Mg}$  and, therefore, the electrical conductivity should be a function of the populations of  $Fe_{Mg}$  and  $Fe_{Mg}^{X}$ . Electrical conductivity thus increases with increasing total Fe content. With increasing oxygen partial pressure, the population of  $Fe_{Mg}$  increases; therefore, the electrical conductivity of the mantle minerals increases with increasing oxygen partial pressure even with constant Fe content.

The bodily motions of ions transfer electric charges, which is called ionic conduction. The best known material for ionic conduction is zirconia (ZrO<sub>2</sub>), in which the oxygen ion is highly mobile and carries minus charges whereas the zirconium ion is very immobile and retains the crystalline lattice. In the case of ferromagnesian silicate or oxide, the migration of  $Mg_{Mg}^{X}$  via  $V_{Mg}^{"}$  can be an effective conduction mechanism and is regarded as the migration of  $V_{Mg}^{"}$  (Figure M184).

Ionic conduction is also a thermally activated process, and can be written as:

$$\sigma = \sigma_0 \exp(-\Delta E_i/kT) \tag{Eq. 3}$$

where  $\Delta E_i$  is the activation energy for ionic conduction. The bodily motion of ions causes a very strong distortion of the lattice and so the activation energy for ionic conduction would be much larger than that of a small polaron ( $\Delta E_i \gg \Delta E_p$ ). This indicates that the temperature dependence of ionic conduction is much larger than that of small polaron conduction. Ionic conduction can dominate small polaron conduction at higher temperatures.

The population of  $V_{Mg}''$  increases with that of  $Fe_{Mg}$  so that the charge balance is maintained. The increase in oxygen partial pressure increases  $Fe_{Mg}$  and, therefore increases  $V_{Mg}''$ . Hence, the ionic conductivity of  $V_{Mg}''$  increases with increasing oxygen partial pressure.

Ionic conductivity is linked with the diffusion coefficient by the Nernst-Einstein relation:

$$\sigma = q^2 n D / kT \tag{Eq. 4}$$

where q is the charge of the carrier, n is the concentration of the carrier, and D is the diffusion coefficient. The diffusion is a thermally activated process:

$$D = D_0 \exp(-\Delta H_d / kT) \tag{Eq. 5}$$

From Eqs. (4) and (5), we have

V<sub>Mg</sub>

 $O_0^x$ 

Mg<sub>M</sub>

$$\sigma = (q^2 n D_0 / kT) \exp(-\Delta H_d / kT)$$
 (Eq. 6)

Therefore, the preexponential term for ionic conduction is inversely proportional to the absolute temperature. The migration of a small polaron is also a diffusion process and its preexponential term should also be inversely proportional to the absolute temperature.

A certain amount of water could be transported into the deep mantle by the subduction process. Although water should form hydrous minerals, olivine and its high-pressure polymorphs can contain a certain amount of water. The rate of diffusion of a proton is very high and so transportation of an electric carrier by  $H^+$  (proton conduction) could have an important role in electrical conduction in the deep

O<sub>o</sub>x

mantle. Proton conduction is a form of ionic conduction and so its temperature dependence should be also expressed by Eq. (3).

Though it is usually difficult to specify the electrical conduction mechanism, an indication may come from the sign of the dominant charge carrier that can be inferred from the thermopower. The thermopower, Q, is the ratio of the voltage,  $\Delta V$ , generated across a sample with a temperature difference,  $\Delta T$ , to  $\Delta T$ :

$$Q = -\Delta V_{\rm T} / \Delta T. \tag{Eq. 7}$$

The voltage,  $\Delta V_{\text{T}}$ , is generated because the charge carrier has a larger energy at a higher temperature. Hence, the sign of the charge carrier is the same as that of the thermopower, Q.

At high pressures, compression can change the energy barrier. We introduce the activation enthalpy,  $\Delta H$ , as follows:

$$\Delta H = \Delta E + P \Delta V \tag{Eq. 8}$$

where P is pressure and  $\Delta V$  is the activation volume.

In small polaron conduction, the energy barrier for migration of a hole decreases with increasing pressure because the distance between ions shortens. Hence, it is expected that small polaron conductivity should increase with an increasing pressure ( $\Delta V_a < 0$ ). In ionic conduction, the corridor for the bodily migration of ions narrows with increasing pressure, resulting in an increase in the energy barrier. Hence ionic conduction is expected to have negative pressure dependence ( $\Delta V_a > 0$ ).

## Electrical conductivity of mantle minerals

In this section, the electrical conductivities of the major mantle minerals are explained, which are summarized in Figure M185.

## Olivine

The electrical conductivity of olivine has been extensively studied. The measurement of thermoelectric effects has shown that the charge of the dominant carrier of olivine is positive at temperatures below 1600 K, whereas it becomes negative above 1700 K. This suggests that there should be two electrical conduction mechanisms. The mechanism dominant at lower temperatures is considered to be the small polaron conduction by  $Fe_{Mg}$ . The mechanism dominant at higher temperatures is considered to be the migration of  $V_{Mg}''$  (ionic conduction).

**Figure M185** Electrical conductivity of olivine, wadsleyite, ringwoodite, Al-free perovskite, and Al-bearing perovskite against reciprocal temperature. The shaded area denotes the conductivity of various kinds of silicate magmas.

It is reported that the electrical conductivity of natural olivine with Mg/(Mg + Fe) = 0.91 at temperatures of 1000–1770 K under an oxygen partial pressure of  $10^{-4}$  Pa can be expressed as the sum of two exponential functions:

$$\sigma = 10^{2.4} (\text{S m}^{-1}) \exp[-1.6(\text{eV})/kT] + 10^{9.2} (\text{S m}^{-1})$$
$$\exp[-4.2(\text{eV})/kT].$$
(Eq. 9)

The activation energy of ionic conduction (4.2 eV) is much larger than that of small polaron conductivity (1.6 eV). The conductivity increases by a power of 1.8 of the Fe/(Mg + Fe) ratio. Conductivity also increases by one-seventh power of the oxygen partial pressure. The pressure dependence is small. It is reported that the activation volume is  $+0.6 \text{ cm}^3 \text{ mol}^{-1}$ . The plus sign of the activation volume is not consistent with the small polaron model.

Olivine has an orthorhombic crystal structure, resulting in anisotropy of the electrical conductivity. Conductivity in the [001] crystallographic direction is about twice those in the [100] and [010] directions. Anisotropy of electrical conductivity in the upper mantle could be observed in the future.

Olivine has an  $M_2SiO_4$  stoichiometry, where M = Mg, Fe, Ni, Ca..., and does not contain  $H^+$  as a first approximation. However, a small amount of  $H^+$  up to the order 1000 ppm can be contained in olivine at high pressures. Diffusion of  $H^+$  in olivine is very fast so that even a small amount of  $H^+$  cause high-electrical conductivity.

## Wadsleyite and Ringwoodite

Ringwoodite has a spinel structure, in which structural units A and B are arranged alternatively. Unit A consists of a SiO<sub>4</sub> tetrahedron, and unit B consists of MgO<sub>6</sub> octahedra. Wadsleyite has a modified spinel structure. The structural units of wadsleyite are the doubles of those of ringwoodite. Unit AA is a Si<sub>2</sub>O<sub>7</sub> unit, and unit BB consists of MgO<sub>6</sub> octahedra. Thus, although wadsleyite has a more complex structure than ringwoodite, the structures of these two minerals are fairly similar.

The electrical conductivities of these two minerals also have similar values, which may reflect their structural similarity. The conductivities of these minerals are about two orders of magnitude higher than olivine. The conduction mechanisms of these minerals have not been clarified. They could be a small polaron of  $Fe_{Mg}$ , because the carrier charge is plus. Their activation enthalpies are about 1 eV, which are considerably smaller than that of olivine (1.7 eV). That is, the temperature dependences of the electrical conductivities of these two minerals are much smaller than that of olivine. The conductivities of these two minerals were measured over only a reasonably small temperature range, that is, 1173–1473 K. The preexponential terms are 100–1000 S m<sup>-1</sup>, which are indistinguishable from that of olivine.

The electrical conductivity of wadsleyite is about two orders of magnitude higher than that of olivine. Hence the olivine-wadsleyite transition causes a significant conductivity jump. In contrast, because conductivities of wadsleyite and ringwoodite are quite similar, the wadsleyite-ringwoodite transition does not cause a conductivity jump.

A certain amount of water (up to 3%) can be contained in wadsleyite and ringwoodite through substituting silicon. However, the contribution of proton conduction to the electrical conductivity of wadsleyite and ringwoodite has not yet been clarified.

#### Perovskite

The composition of mantle perovskite is primarily (Mg,Fe)SiO<sub>3</sub>. In addition to these components, perovskite can also contain up to 25% Al<sub>2</sub>O<sub>3</sub>. In the lower mantle, perovskite would contain up to 6% Al<sub>2</sub>O<sub>3</sub>. The Mg site is probably too large for Al. Hence, Al should predominantly substitute the Si site (Al<sub>Si</sub>'). To keep the charge valance, the Fe in the Mg site tends to be trivalent (Fe<sub>Mg</sub>') if perovskite contains an Al<sub>2</sub>O<sub>3</sub> component.

The electrical conductivity of Al-free  $(Mg_{0.9}Fe_{0.1})SiO_3$  perovskite is  $10^{-0.8}-10^{-0.5}$  S m<sup>-1</sup> at 1700–1900 K. The conductivity of  $(Mg_{0.9}Fe_{0.1})$ 

SiO<sub>3</sub> perovskite with 3% Al<sub>2</sub>O<sub>3</sub> is about half an order of magnitude higher than that of Al-free perovskite; that is,  $10^{-0.3}-10^{0}$  S m<sup>-1</sup> in the same temperature range. The higher electrical conductivity of the Al-bearing perovskite implies that the dominant conduction mechanism is the small polaron of Fe<sub>Mg</sub>. The activation enthalpies of Al-free and Al-bearing perovskites have similar values, 0.6–1.0 eV, even smaller than those of wadsleyite and ringwoodite.

The electrical conductivity of perovskite at the top of the lower mantle is  $10^0$  S m<sup>-1</sup>, and is about half order of magnitude higher than that of ringwoodite. Therefore, the postspinel transition should cause a conductivity jump by half an order of magnitude.

The electrical conductivity of perovskite has very little pressure dependence. Activation volume is about  $-0.1 \text{ cm}^3 \text{ mole}^{-1}$ . The negative sign of the activation volume (i.e., conductivity increases with increasing pressure) is consistent with the small polaron model.

Activation energy is relatively small, and the temperature gradient in the mantle is small (0.2–0.5 K km<sup>-1</sup>). Therefore, the electrical conductivity of perovskite should be nearly constant and of the order of  $10^{0}$  S m<sup>-1</sup> throughout the lower mantle.

#### Magma

Silicate melts (magma) generally have higher conductivity than solid minerals. Their conductivity is  $10^0-10^2$  S m<sup>-1</sup> at temperatures above 1500 K. The high conductivity of silicate melts is probably because of the high mobility of atoms in silicate melts. Hence the dominant conduction mechanism is considered to be ionic conduction.

Under the conditions found in the mantle, the wetting angle of silicate melts is significantly small. Hence, silicate melts easily form a network structure in mantle rocks even though their fraction is very low. The network of the melts works as a conduction path and therefore the presence of a small amount of silicate melts should drastically increase electrical conductivity. The conductivity anomalies observed in the mantle could be attributable to a certain degree of melting of mantle rocks.

# Explanation of the electrical conductivity of the mantle

A laboratory electrical conductivity model is shown with observations in Figure M181. Generally, mantle minerals with a higher-pressure stability field have higher electrical conductivity. This fact is primarily responsible for the increase of the electrical conductivity in the upper mantle. The activation enthalpy of mantle minerals with a higherpressure stability field is lower, which means they have smaller temperature dependence. This is one of the reason why the uniform electrical conductivity is more in the deeper mantle.

Conductivity increases by two orders of magnitude with the olivinewadsleyite transition, whereas it increases by half an order of magnitude with the postspinel transition. The seismic velocity jumps associated with the 410- and 660-km zone are both significant. By contrast, the conductivity jump associated with the olivine-wadsleyite transition is four times larger than that of the postspinel transition. Therefore, the conductivity jump associated with the 410-km discontinuity should be much larger than that of the 660-km discontinuity, if indeed the latter is observed at all.

The conductivity of the HCL at the top of the upper mantle is too high to be explained by the conductivity of normal mantle olivine. Some additional contribution is required. One possibility is that partial melting occurs in the region and the melt forms an electrically conductive path in the mantle rock. Another possibility is that olivine in the region contains considerable amounts of hydrogen and hence the electrical conductivity is significantly raised by proton conduction. For now, the lack of sufficient experimental evidence means we cannot posit an explanation for this situation.

# MANTLE, THERMAL CONDUCTIVITY

The thermal conductivities of familiar igneous rocks, such as basalt, at laboratory pressure, are typically  $\kappa \approx 2.5$  W m<sup>-1</sup> K<sup>-1</sup>. Taking a high-temperature specific heat,  $C_P = 1200$  J K<sup>-1</sup> kg<sup>-1</sup> and  $\rho = 2800$  kg m<sup>-3</sup> as the basalt density, the corresponding thermal diffusivity is  $\eta = \kappa/\rho C_P \approx 7.4 \times 10^{-7}$ m<sup>2</sup> s<sup>-1</sup>. For mantle minerals we find  $\kappa \approx 4.0$  W m<sup>-1</sup> K<sup>-1</sup>,  $\eta \approx 1.0 \times 10^{-6}$  m<sup>2</sup> s<sup>-1</sup>. Thermal conductivity of the crust and uppermost mantle (the lithosphere) can differ little from the conductivities of laboratory samples, but for the deep mantle, the effects of high pressure as well as high temperature must be considered. If we nevertheless assume that there is no dramatic variation in diffusivity, then thermal diffusion is too slow to influence the deep structure or thermal history. Heat transport in the mantle is by convection and conduction is important only in boundary layers with steep temperature gradients. In the context of geomagnetism this means especially the D" layer at the bottom of the mantle, adjacent to the core.

## Lattice conductivity and the effect of pressure

We have only a crude theory of thermal conductivity for complex materials, such as rocks. While we know that lattice conductivity is due to phonons, the quanta of thermal vibration, a calculation of conductivity requires an estimate of the mean free path of phonons, the average distance traveled between the scattering events that randomize them, and there are several scattering mechanisms, some of which are difficult to quantify. In a hypothetical, perfect single crystal, scattering would arise only from interactions between phonons. This is the best understood of the scattering processes and so has received most attention in discussions of mantle conductivity. It is a consequence of anharmonicity, or nonlinearity in atomic bond forces. If these forces were perfectly linear, that is, if the forces on displaced atoms were simply proportional to their displacements, then their oscillations would be harmonic or sinusoidal, with no interaction between superimposed oscillations (phonons would not scatter one another). The anharmonicity of real materials is apparent as positive thermal expansion coefficients and is described theoretically in terms of the Grüneisen parameter,  $\gamma$  (q,v.). The fundamental physics of the process is discussed by Kittel (1971); Poirier (1991) summarized its application to geophysics, emphasizing an expression, due originally to A.W. Lawson, representing the variation of conductivity with temperature and pressure.

Phonon-phonon scattering, which leads to Lawson's formula, is observable only under highly idealized conditions. For common rocks Lawson's formula overestimates conductivity by a factor of order 10. In these materials, phonon scattering is due to their interactions with crystal imperfections and the random distribution of different elements, even including different isotopes of the same element. The temperature and pressure dependences of "impurity scattering" are not represented by the theory of phonon-phonon scattering. The extreme case of an "imperfect crystal" is a glass, in which the atomic arrangement resembles that of a liquid. Glasses have much lower thermal conductivities than the corresponding crystalline solids and both the temperature and pressure dependences are opposite to those of pure, simple solids. The result is a very confused picture of phonon scattering in chemically and crystallographically complicated materials, such as rocks, making it impossible to extrapolate reliably to the base of the mantle. It appears safest to assume that there is no dramatic variation in conductivity with depth in the mantle and to verify that this leads to no conflict with what we understand about the properties of D'' (see below).

## **Radiative heat transfer**

Materials that are transparent at infrared wavelengths may transmit heat radiatively, giving an additional component of thermal conductivity at high temperature. This is an important heat transport mechanism in the interiors of stars and was introduced to geophysics by S.P. Clark. In the simple case of a "gray body," a generalization of the ideal black body of radiation laws, in which the absorption of radiation with depth of penetration is the same for all wavelengths, the radiative conductivity is

$$\kappa_{\rm R} = \frac{16}{3} \frac{n^2}{\epsilon} \sigma T^3$$

where *n* is refractive index,  $\sigma = 5.67 \times 10^{-8}$  W m<sup>-2</sup> K<sup>-4</sup> is the Stefan-Boltzmann constant and  $\in$  is the opacity, the reciprocal of the average distance traveled by a photon before absorption. For an idea of how significant this may be we can calculate the value of  $\in$  required to give a radiative conductivity equal to a plausible lattice conductivity at a temperature of 2500 K (near to the base of the mantle). We find  $\epsilon \approx 2500$  m<sup>-1</sup>, corresponding to a penetration depth of 0.4 mm. Thus, a quite modest transparency would suffice to make this an important consideration.

The opacities of mantle minerals are controlled primarily by their iron contents, especially if the iron occurs as both  $Fe^{2+}$  and  $Fe^{3+}$  ions, providing an absorption mechanism by charge transfer. Electron energy bands are broadened by pressure, making this process easier by spreading the wavelength range of absorption. Lower mantle minerals are believed to be primarily (Mg,Fe)SiO<sub>3</sub> perovskite and (Mg,Fe)O magnesiowustite, both with substantial iron contents, so that, although the question is not conclusively resolved, it appears unlikely that radiative transfer is important in the lower mantle.

## Conduction of core heat into the D" layer

The structure of D" is complicated by compositional heterogeneity, making a direct interpretation of seismological observations in terms of temperature difficult, at best. However, we have a reasonable idea of the thickness of the D" zone and if this is accepted as representative of the thickness of the thermal boundary layer (see D" *as a boundary layer*) then we can use it to estimate the diffusivity and hence conductivity. D" is modelled as a 150 km thick layer in PREM (Dziewonski and Anderson, 1981) and this value is assumed here. An uncertainty of 50 km or so is of no consequence as we can only make a rough calculation.

The temperature at the core-mantle boundary, estimated as 3740 K from core properties (see *Core, thermal conduction*), is almost 1000 K higher than the lower mantle temperature estimated by extrapolating adiabatically from the 670 km deep phase transition zone (2760 K). We must, therefore, consider a 1000 K temperature increment across the boundary layer. This means that the mantle material in contact with

the core has a viscosity that is lower by a factor of at least  $10^4$  than that of the mantle a few hundred kilometers higher, concentrating convective flow in a very thin layer at the bottom. A theory of the mechanism by which this flow feeds narrow hot plumes is given by Stacey and Loper (1983), but a simple analog represents the essential features.

As the hot material is skimmed off into narrow buoyant plumes, there is a general collapse of the mantle on to the core to replace it. The analog is the ablation of materials from the surfaces of meteorites and spacecraft entering the atmosphere. A steady, exponential profile of temperature, T, is established, moving inward as surface material is removed, so that

$$T - T_0 = (T_S - T_0) \exp(-h/H)$$

where *h* is the distance from the heated surface, at temperature  $T_{\rm S}$ , and  $T_0$  is the temperature well removed from the ablating surface. Our interest is in the scale height, *H*, which we identify with the thickness of D"

$$H = \eta / v$$

 $\eta$  being thermal diffusivity and v is the speed of the collapse of the mantle on to the core. If the core to mantle heat flux is  $\dot{Q}/A$  (per square meter) then

$$\dot{Q}/A = v\rho C_P (T_{\rm S} - T_0)$$

and if we estimate this as 0.033 W m<sup>-2</sup> (5 × 10<sup>12</sup> W over the surface of the core-mantle boundary) then these relationships give  $\eta = 7.6 \times 10^{-7}$  m<sup>2</sup> s<sup>-1</sup>, in fortuitously close coincidence with the value for basalt at zero pressure.

Although this calculation is simplified and approximate, it encourages the view that thermal diffusivity does not vary greatly through the mantle. With the higher density at the core-mantle boundary the corresponding conductivity is  $\kappa \approx 5 \text{W m}^{-1} \text{ K}^{-1}$ , higher than for laboratory samples, but not dramatically so.

# A general conclusion

Thermal conductivity of the deep mantle is poorly constrained by either observation or theory, in spite of repeated efforts to understand it, but we have no evidence that it differs greatly from the conductivity of the uppermost mantle or laboratory samples of basic or ultrabasic rock. In this circumstance core heat is conducted into a boundary layer at the base of the mantle, 100 to 200 km thick, softening it and allowing for its removal in buoyant plumes. Convection, not conduction, is responsible for heat transport up the several thousand kilometer depth of the mantle.

# MATUYAMA, MOTONORI (1884–1958)

Born in Oita Prefecture, Japan, as a son of a Buddhist priest, he graduated from the physics department, Kyoto University, 1911. He became lecturer in 1913, associate professor in 1916, and then professor in the Department of Geology, Kyoto University, from 1922 to 1946. He studied at the University of Chicago between 1933 and 1935. After retirement from Kyoto University, he served as president of the Yamaguchi University, from 1949 to his death. For his contribution to paleomagnetism and gravity, Matuyama was elected to Member of Japan Academy in 1950.

In the 1920s, Matuyama conducted a systematic survey of the natural remanent magnetization (NRM) of Quaternary and late Tertiary volcanic rocks in Japan, Korea, and Northeast China (Manchuria at that time). The determination of the dipole moment was done by the method of Gauss (spherical harmonic analysis). In the results, he noted that the youngest rocks are always magnetized to directions similar to the present day field, while many of the early Quaternary and Tertiary rocks had NRMs almost oppositely directed. In all cases, there were not many rocks with the NRMs in the intermediate directions. On the basis of these observations, Matuyama concluded that the Earth's magnetic field was in the reversed state in the late Tertiary (Miocene) and again in the early Quaternary (Matuyama, 1929). This early report was later picked up by Allan Cox and Richard Doell, who named the reversed interval just before the current normal period (Brunhes epoch) after him (Matuyama epoch). "Matuyama" thus became one of the most often referred personal names of Japanese origin. "Matuyama chron" is often quoted in the studies such as magnetostratigraphy, seafloor spreading, sedimentology, geomagnetic reversal timescale, and so on.

Earlier in his career, Matuyama performed gravity survey of a coral reef in the Marshall Islands using an Eötvös deviatoric gravimeter. This was one of the earliest application of gravity methods to the study of the crustal structure, especially in the coral islands. Gravity continued to be one of his main research subjects and, inspired by the work of Vening Meinesz in the Indonesian Archipelago, he also measured the gravity near the Japan Trench in a submarine of the Japanese Navy (Matuyama, 1934). This led to the discovery of the westward offset of the center of the negative gravity belt from the trench axis, which later became an important factor for considering the origin of the great earthquakes in the Sanriku region. Other subjects he studied include the rheological properties of the ice, which was undertaken in collaboration with T.C. Chamberlin of the University of Chicago when he stayed in the United States

# MELTING TEMPERATURE OF IRON IN THE CORE, EXPERIMENTAL

## Introduction

There are two major techniques commonly used for ultrahigh pressure melting studies: shock wave experiments and the internally heated diamond anvil cell (DAC). In shock compression experiments, the sample is subjected to high pressures and high temperatures by dynamic processes (see *Shock wave experiments*). In DAC experiments, pressure is generated by pressing two opposing diamond anvils, while heating is applied resistively and/or using laser heating. Both techniques have been extensively applied to study high pressure melting of iron. However, accurate determination of melting is exceedingly difficult at extremely high pressure and temperature conditions. The associated weaknesses—the short timescale in shock compression and the small sample size in DAC—are reflected by the large uncertainties and the discrepancy among literature values on melting temperature of iron in the core.

In this section, we begin with a brief description of the generation of simultaneous high pressures and temperatures in the DAC, followed by a discussion on the observation of the onset of the melting transition and the determination of pressure-temperature conditions associated with the observation. A brief review is given on DAC experiments in studying the melting temperature of iron at high pressures. The effect of light elements on the melting temperature is discussed in the end.

For more details on this topic, the following review articles are suggested. See *Melting temperature of iron in the core, theory* for theoretical approaches in this area.

## Diamond cell technique

## Diamond as anvil and window

Diamond is a premier anvil material because it is the hardest material known, and it is transparent from infrared to hard X-rays, thus providing a window for probing samples by various methods and for heating samples by lasers. With the DAC technique, pressures beyond that at the center of the Earth have been reported (Xu *et al.*, 1986). The principal components of a DAC are two opposing diamond anvils with a gasket in between. A drilled hole in the center of the gasket serves as sample chamber. For melting experiments at very high pressures, typical dimensions of a sample chamber are 10–20 µm thick and ~50 µm in diameter.

## Heating diamond anvil cells

An easy way to provide heating is to heat the entire DAC externally. However, there is a temperature limit of  $\sim 1500$  K with this method. To generate extreme high temperatures to melt iron at high pressures, internal heating methods are generally employed. One is the resistive wire heating, in which iron is used as a conductor wire and heating is applied electrically (Boehler, 1986; Mao *et al.*, 1987). With this method, temperatures can go as high as its melting point, but pressures are limited because of deformation of the electrical leads as pressure increases. The other is the laser-heating technique, in which near- or mid-infrared lasers (Nd:YAG, Nd:YLF, CO<sub>2</sub>) are used for heating samples in DAC. There are, in principle, no pressure and temperature limitations associated with this technique. The challenge is to control pressure and temperature conditions, to measure them accurately, and to characterize the sample at defined conditions. A typical sample configuration is shown in Figure M186.

**Figure M186** A typical sample configuration in laser-heated diamond anvil cell experiment.

#### Pressure measurement

Pressures in the laser-heated DAC are often measured by the ruby fluorescence method (Mao *et al.*, 1986) before and after laser heating or during heating from unheated ruby chips away from the heating area. When the laser-heating experiment is coupled with synchrotron radiation, pressures are estimated by measuring unit cell volumes of samples whose pressure-temperature-volume equations of state are known. For pressures measured before and after laser heating, thermal pressure (caused by the material's thermal expansion) has to be considered in estimating pressures at high temperature. Thermal pressure may be minimized by choosing a hydrostatic pressure medium and a small sample-to-medium ratio, and/or characterized with the use of highly collimated synchrotron radiation.

### Temperature measurement

Temperature measurement is based on the collected radiation from thermal emission through the Planck radiation law:  $I_{\lambda} = c_1 \varepsilon(\lambda) \lambda^{-5/2}$  $[\exp(c_2/\lambda T)-1]$ , where  $I_{\lambda}$  is spectral intensity,  $\lambda$  is wavelength, T is temperature,  $c_1 = 2\pi hc^2 = 3.7418 \times 10^{-16} \text{ Wm}^2$ ,  $c_2 = hc/k =$ 0.014388 mK, and  $\varepsilon(\lambda)$  is emissivity with  $\varepsilon(\lambda) = 1$  for a black body. This method covering a range of wavelengths is often called spectral radiometry, as compared to the general pyrometry in which thermal radiation at only one wavelength is measured. One major advantage of spectral radiometry is that, assuming wavelength-independent emissivity, temperatures can be measured independently from the absolute emissivity. However, emissivity is often found to be wavelength dependent. Use of the available data on the wavelength-dependent emissivity at ambient pressure (de Vos, 1954) gives about a 5% temperature correction downward at 3000 K and about 12% downward at 5000 K when compared with the results from the assumption of wavelength-independent emissivity. Unfortunately, such a correction cannot be accurately made because the wavelength dependence of emissivity is not currently known at high pressures and high temperatures, and it can be strongly dependent on the surface finish of a DAC sample. This is the main limitation in the absolute accuracy of temperature measurement by the spectral radiometry method.

## Melting criteria

Melting is thermodynamically defined as equilibrium between a solid and a liquid. When materials melt, their physical properties, such as density, viscosity, absorption properties, and electrical resistance, undergo a sudden change. Such property changes are characteristic for a first-order phase transition and are often used for recognition of melting. Unlike other first-order phase transitions, melting is characterized by the loss of long-range order and resistance to shear. To definitively identify melting, both of these two characteristics should be documented. Visual optical observation is a common way to determine whether melting has taken place. It is obvious that fluid flow observation is a good measure of the loss of resistance to shear. Therefore it has been widely used by almost all groups in the world (Saxena *et al.*, 1994; Jeanloz and Kavner, 1996; Jephcoat and Besedin, 1996; Boehler, 2000). However, visual observation (fluid flow) is less obvious as pressure increases, making it difficult to unambiguously define the onset of melting. Synchrotron X-ray diffraction has been combined with laser-heated DAC and used for melting studies to document the loss of long-range order upon melting. Melting at high pressure was identified by the appearance of diffuse scattering from the melt with the simultaneous loss of crystalline diffraction signals (Shen *et al.*, 2004).

Synchrotron Mössbauer spectroscopy (SMS) provides another promising method to identify melting. SMS measures the atomic thermal displacement that can be used for documenting rigidity of a material. Upon melting the strong elastic resonance signal diminishes in SMS. The mean-square thermal displacement of atoms (Lamb-Mössbauer factor) can be measured as a function of temperature, providing a plot for determining the onset of melting. Since measurement of SMS takes only a few seconds to minutes, it holds a great potential for high pressure melting studies.

## Melting of core material at high pressures

## Iron

Iron is the major component of the core. Knowledge of the melting curve of iron can constrain the temperature of the inner core boundary and anchor the Earth's temperature profiles (see *Core temperature*). At pressures below 50 GPa, the phase diagram of iron is reasonably well known (Figure M187). At ambient pressure, the stable phase is  $\alpha$ -Fe with a body-centered-cubic (bcc) structure. At high pressure it transforms to *e*-Fe with hexagonal-close-packed (hcp) structure. At high

**Figure M187** Iron phase diagram. Shaded areas represent the range of literature values in recent years with static diamond anvil cell experiments. Symbols are shock-wave data: square, Ahrens *et al.* (2002); diamonds, Brown and McQueen (1986); circle, Nyuyen and Holmes (2004). Brown and McQueen's point at 200 GPa was interpreted as a solid-solid transition. All other points are referred as melting.

temperature there is a large stability field for y-Fe with face-centered-cubic (fcc) structure. Although a controversial new solid phase (called  $\beta$ -Fe) was reported (Saxena et al., 1995; Andrault et al., 1997; Dubrovinsky et al., 1998), the existence of this phase was not confirmed in later experiments (Shen et al., 1998; Kubo et al., 2003; Ma et al., 2004). For the melting curve, there is a converging consensus at pressures below 60 GPa, reflected by a narrow uncertainty range in Figure M187. As pressure increases, uncertainties in phase boundaries, including the melting curve, become large as shown by wide bands in Figure M187. The width of the bands represents the scatter in literature data from recent years. Factors causing these uncertainties include those in pressure determinations (neglecting thermal pressure, different equations of state, and/or different standard materials), in temperature determinations (large temperature gradient and temporal variation, chromatic aberration in optics), and in sample characterizations (different melting criteria, transition kinetics).

Uncertainties in the melting curve and the  $\gamma$ - $\varepsilon$  transition lead to significant variations in the location of  $\gamma$ - $\varepsilon$ -liquid triple point. Knowledge of its location is important because it is the starting point used for extrapolating the melting curve of  $\varepsilon$ -Fe to core pressures. As shown in Figure M187, the slope of  $\gamma$ - $\varepsilon$  transition ranges from 25 to 40 K GPa<sup>-1</sup>, placing the triple point between 60 and 100 GPa. Such large uncertainties in the slope of the  $\gamma$ - $\varepsilon$  transition mainly arise from the coexisting nature of these two phases in the pressure-temperature range, causing difficulties in identifying the boundary. The uncertainties are also contributed by the pressure-temperature determination associated with the use of different standard materials and/or different equations of state.

The melting data for iron above the triple point are scarce and scattered, reflecting the difficulty level of such experiment. It appears that the early DAC data (Boehler, 1993; Saxena *et al.*, 1994) represent a lower bound of the melting curve in this region. The later experimental data falls at higher melting temperatures (Shen *et al.*, 1998; Ma *et al.*, 2004). The shock wave data (Brown and McQueen, 1986; Nguyen and Holmes, 2004) lie close to the upper bound. Extrapolating the data to the inner core boundary, the melting temperature of iron is between 4800 and 6000 K at 330 GPa (see e.g., *Grüneisen's parameter for iron and Earth's core*).

## Effects of light elements

As shown by Birch (1952), the density of the Earth's outer core is about 10% too low to be pure iron, so the core must also contain some light elements. At present, there is no consensus on the dominant light element in the core (see *Core composition* and *Inner core composition*).

At ambient pressure, the addition of a small amount of light elements decreases the melting temperature of iron by up to a few hundred degrees. Data at high pressure are scarce and limited in the Fe-FeO-FeS system (Usselmann, 1975; Urakawa *et al.*, 1987; Ringwood and Hibberson, 1990; Knittle and Jeanloz, 1991; Williams *et al.*, 1991; Boehler, 1992; Fei *et al.*, 1997). Eutectic melting was found in the Fe-FeS system (Knittle and Jeanloz, 1991; Boehler, 1992). Boehler (1996) pointed out that the melting curves in the Fe-FeS-FeO system converge instead of diverge with increasing pressure to that of pure iron.

However, several difficulties need to be addressed and overcome in melting experiments of multicomponent systems using DAC. The laser-heating spot could be on a scale similar to nonuniform samples, which could cause large experimental errors. Large temperature gradients in radial and axial directions could lead to compositional gradients (e.g., Soret diffusion), causing incomplete mixing during heating and melting. Significant developments are thus needed for constraints of light element effects on the melting temperature of iron.

# MELTING TEMPERATURE OF IRON IN THE CORE, THEORY

An accurate knowledge of the melting properties of Fe is particularly important, as the temperature distribution in the core is relatively uncertain and a reliable estimate of the melting temperature of Fe at the pressure of the inner-core boundary (ICB) puts a constraint on core temperatures. However, there is much controversy over its high pressure melting behavior (e.g., see Shen and Heinz, 1998). Static compression measurements of the melting temperature ( $T_m$ ) with the diamond anvil cell (DAC) have been made up to ~200 GPa, but even at lower pressures results for  $T_m$  disagree by several hundred kelvins. Shock experiments are at present the only available method to determine melting at higher pressures, but their interpretation is not simple, and there is a scatter of at least 2000 K in the reported  $T_m$  of Fe at ICB pressures.

Since both quantum mechanics and experiments suggest that Fe melts from the hexagonal close-packed (hcp) structured phase in the pressure range immediately above 60 GPa, this entry will focus on the equilibrium between hcp Fe and liquid phases. Several approaches for determining  $T_{\rm m}$  from theory have been adopted, including quantum mechanically based methods (e.g., Alfè *et al.*, 2002a,b), and more empirical methods such as dislocation melting models (Poirier and Shankland, 1993), or those based on thermal physics (Stacey and Irvine, 1977).

The condition for two phases to be in thermal equilibrium at a given temperature, T, and pressure, P, is that their Gibbs free energies, G(P, T), are equal. To determine  $T_{\rm m}$  at any pressure from theory, it desirable to

**Figure M188** The calculated high pressure melting curve of Fe of Alfè *et al.* (line 2) passes through the shock wave datum (open circle) of Brown and McQueen. Other data shown includes: The melting curve of Alfè *et al.*, corrected for the GGA pressure error (line 3), Belonoshko's melting curve (line 6), Belonoshko's melting data corrected for errors in potential fitting (black dots), Laio *et al.*'s melting curve (line 4), Boehler's DAC curve (line 5), Shen's data (diamonds), Yoo's shock data (open squares), William's melting curve (line 1).

calculate *G* for the solid and liquid phases as a function of *T* and determine where they are equal. In fact, it is usual to calculate the Helmholtz free energy, F(V, T), as a function of volume, *V*, and hence obtain the pressure through the relation  $P = -(\partial F/\partial V)_T$  and *G* through its definition G = F + PV.

To obtain melting properties with useful accuracy, free energies must be calculated with high precision, because the free energy curves for liquid and solid cross at a shallow angle. It can readily be shown that to obtain  $T_{\rm m}$  with a technical precision of 100 K, noncanceling errors in G must be reduced below 10 meV. It has been shown that ab initio molecular dynamics can be used to determine the free energies of liquid and solid of Al and Cu with sufficient accuracy as to reproduce the known melting temperature to within 100 K. Alfè et al. (1999, 2002a) used this method to calculate the melting curve of Fe up to core pressures, and their results, shown in Figure M188, give the melting temperature of Fe at ICB pressures to be  $\sim$ 6200 K, with an error of  $\pm 300$  K. For pressures P < 200 GPa (the range covered by DAC experiments) their curve lies ~900 K above the values of Boehler (1993) and  $\sim$ 200 K above the more recent values of Shen et al. (1998). Their curve falls significantly below the shock-based estimates for the T<sub>m</sub> of Yoo et al. (1993), in whose experiments temperature was deduced by measuring optical emission (however, the difficulties of obtaining temperature by this method in shock experiments are well known), but accords almost exactly with the shock data value of Brown and McQueen (1986) and the new data of Nguyen and Holmes (1999). For melting at ICB pressure, Alfè et al. (1999, 2002a) calculate  $\Delta V_{\rm m}/V = 1.8\%$ ,  $\Delta S_{\rm m} = 1.05R$  J K<sup>-1</sup>mol<sup>-1</sup>, and so obtain a latent heat of fusion of 55 kJmol<sup>-1</sup>.

There are other ways of determining the melting temperature of a system by *ab initio* methods, including performing simulations that model coexisting liquid and crystal phases. The melting temperature of such a system can then be inferred by seeing which of the two phases grows during the course of a series of simulations at different temperatures. This approach has been used by Laio *et al.* (2000) and by Belonosko *et al.* (2000) to study the melting of Fe. In their studies they modeled Fe melting using interatomic potentials fitted to *ab initio* surfaces. Alfè *et al.* (2002b) discovered, however, that these fitted

potentials did not simultaneously describe the energy of the liquid and crystalline phases with the same precision, and so these simulations do not represent the true melting behavior of Fe, but rather that of the fitted potential. Alfè *et al.* (2002b) found a way to correct for these shortcomings, by calculating the free energy differences between the model and the *ab initio* system for both the liquid and solid phases. This difference in free energy between liquid and solid can then be transformed into an effective temperature correction. When this was done to Belonosko's data, there was excellent agreement (see Figure M188) with previously determined melting curve for Fe determined by Alfè *et al.* (2002a) using the technique based on direct determination of free energies.

Other more approximate theoretical approaches are also in accord with the inferences from more accurate quantum mechanical studies. Poirier and Shankland (1993) obtained a value of  $T_{\rm m}$  for Fe at 330 GPa of 6100  $\pm$  100 K by using a dislocation melting model, Stacey and Irvine (1977) estimated  $T_{\rm m} = 6\,050$  K from a Lindemann's lawbased analysis, Stixrude *et al.* (1997) estimated  $T_{\rm m}$  to be ~6150 K, and Anderson (2003) found a  $T_{\rm m}$  of 5900  $\pm$  300 K on the basis of thermodynamic analysis. Thus with *ab initio* calculations having been shown to be robust, there now seems to be an emerging consensus on the melting temperature Fe at ICB pressure to be between 6 000 and 6400 K. There is still scope for further work on the difficult problem of the modeling of melting, but for the high pressure melting of Fe at least, it now appears that there may be as many problems with reconciling divergent experimental data than there are in obtaining accurate predictions of  $T_{\rm m}$  from *ab initio* studies.

# MICROWAVE PALEOMAGNETIC TECHNIQUE

The microwave technique is used to determine the strength of the Earth's magnetic field in the past. It is usually applied to igneous rock such as lava and dike or the surrounding material that has been heated by them (baked contact), as well as heated archaeological material (ceramics, fireplaces, etc.). Samples are placed inside a resonant cavity and exposed to microwaves for a few seconds (typically 10 s). The microwave exposure is directly analogous to raising the temperature of the sample in the conventional Thellier technique, the main difference being that when the sample is exposed to microwaves most of the energy is absorbed by the magnetic system whereas in direct heating the entire sample absorbs energy.

By concentrating the energy in the magnetic system the bulk sample is not heated significantly. This reduces the probability of laboratory thermal alteration and provides a more accurate determination of the ancient magnetic field strength.

## Microwaves magnons and temperature

A simple model for ferromagnetic minerals is a large number of spinning electrons, one for each ion. Each spin has a magnetic moment  $\mathbf{M} = g\boldsymbol{\mu}_{\mathbf{b}} S$ , where g is the spectroscopic splitting factor,  $\boldsymbol{\mu}_{\mathbf{b}}$  is the Bohr magnetron, and S is the spin (Kittel, 1966).

In a ferromagnetic mineral there is a very strong force between neighboring spinning electrons that tries to align all of the spins (exchange coupling). At very low temperatures when the thermal energy is near to zero the spins align and the total magnetization of the mineral is greatest. This total magnetization is expressed as a strong internal field in the mineral. As the temperature increases the energy increases and the individual spin magnetic moments move away from perfect alignment. As the spin magnetic moments move away from perfect alignment they precess around the internal field of the mineral so that only a component ( $M_z$ ) remains aligned and the total magnetization of the mineral reduces (Figure M189).

All of the spins precess at the same frequency (H where is the gyromagnetic ratio and H is the magnetic field) but each is slightly out of phase with its neighbor. Looking along the field direction ( $M_z$  direction) the  $M_x$  components form a "spin wave" that passes through the mineral (Figure M189). The amplitude of the spin wave increases in quantized jumps equivalent to the complete reversal of one spin magnetic moment and so the total magnetization of the mineral changes by 2**M**. A spin wave that is quantized in this way is called a magnon. For each magnon that is excited the magnetic moment reduces by 2**M**. This is a simplified picture of spin wave generation in ferromagnetic minerals but it helps us to understand how the magnetic moment of a sample is reduced by the generation of magnons.

In the case of conventional thermal demagnetization, ferromagnetic magnetization decreases with increasing temperature until it is completely removed at the Curie temperature. Looking at this process in more detail, the external thermal energy (the high temperature in an oven, say) generates phonons (lattice vibrations) in order to equilibrate the external energy with the internal energy. The phonons in turn generate magnons in the magnetic system in order to equilibrate the energy in the magnetic system. When sufficient magnons are generated the sample is demagnetized and the equivalent external temperature that caused this is called the Curie temperature.

Using microwaves it is possible to excite the magnons directly by ferromagnetic resonance without applying heat to the sample (Walton *et al.*, 1992, 1993). If this can be done quickly the high-energy magnetic system will not have time to pass energy into the sample, generate phonons and raise its temperature. In theory microwaves can demagnetize a sample in the same way as heating a sample but without raising its temperature. In practice it takes a few seconds of microwave exposure to generate sufficient magnons to completely demagnetize a sample, the normal exposure time is 10 s and this means that some phonons are generated. Also, since most samples are good insulators, there is some dielectric heating of the sample in the microwave field. The combination of these two effects is to raise the temperature of the sample slightly, usually less than  $150^{\circ}C$  (Hill *et al.*, 2000).

Dielectric heating is frequency-dependent, the higher the frequency the more heat is generated. Magnon generation is also frequencydependent, higher frequency generates more magnons. The sample size is also frequency-dependent, higher frequency means a smaller resonant cavity and therefore smaller samples. Experiments at 8 and 14 GHz show clearly that at 14 GHz samples are more easily demagnetized and are heated less than at 8 GHz. Much above 14 GHz dielectric heating becomes dominant and the samples are heated more. For microwave demagnetization without heating the 14–16 GHz range seems optimal (Figure M190).

Recent experiments demonstrate that high (low) microwave power is equivalent to high (low) temperature (Hill *et al.*, 2002) and so microwave demagnetization may be used instead of thermal

**Figure M190** Orthogonal 18 GHz microwave demagnetization plot (*left*) and 18 GHz microwave Thellier paleointensity plot with PTRM checks and multidomain tail checks (*right*). The maximum microwave power used was 40 W for 10 s.  $H_{pal} = 51.9 \pm 0.4$  mT, q = 140.4.

demagnetization to determine paleomagnetic directions. Microwave demagnetization has the added advantage that it can be used on samples that undergo severe alteration on heating and are unsuitable for thermal analysis (i.e., sulfide-bearing rocks).

Demagnetization Depth to Curie temperature Magnetization, Thermoremanent (TRM) Paleointensity
# Ν

# NAGATA, TAKESI (1913–1991)

Born in Aichi Prefecture, Japan; graduated from the Physics Department, University of Tokyo, 1936; research associate, Earthquake Research Institute, University of Tokyo, 1937; associate professor, 1941 and professor in the Department of Geophysics, University of Tokyo, 1952–1974; director of the National Polar Research Institute, 1973–1984; adjunct professor of University of Pittsburgh, 1962–1977; Nagata was quite active in international cooperation and served as bureau member of the International Union of Geodesy and Geophysics (IUGG) for 1960–1963, president of the International Association of Geomagnetism and Aeronomy (IAGA) for 1967–1971, and vice-president of the Scientific Committee on Antarctic Research (SCAR) for 1972–1976.

His doctoral thesis was devoted to a systematic experimental study of the properties of the thermoremanent magnetization (TRM) in volcanic rocks (Nagata, 1943). This included, concurrent with the work of Emile Thellier in France, the discovery of proportionality of the TRM to the magnetizing field and additivity of partial TRM. In 1951, Nagata and his colleague, and students Syun-iti Akimoto and Seiya Uyeda made a great sensation in geophysics community, by the discovery of the self-reversal of the TRM in Haruna dacite. The field reversal vs self-reversal continued to be a topic of hot controversy through 1950s and 1960s until Allan Cox and others established the polarity reversal timescale. Nagata and his colleagues studied not only the TRM, but also various forms of remanent magnetization, which are found in nature as well as are produced in the laboratory. These included viscous remanent magnetization (VRM, with Yoshio Shimuzu), chemical remanent magnetization (CRM, with Kazuo Kobayashi), pressure-induced remanent magnetization (PRM, with Hajimu Kinoshita), and shock remanent magnetization (SRM). The textbook Rock Magnetism, which was first published in 1953 and then revised in 1961, summarized all these works in rock magnetism, and was very influential to the community till very recent times.

Nagata also took part in studying the magnetic properties of the lunar rocks collected by the Apollo project and meteorites of various types. Nagata's scientific interest covered all the aspects of geomagnetism and the newly developing space sciences. Besides rock magnetism and paleomagnetism, he studied the main magnetic field, secular variation, tectonomagnetic effects, ionosphere, magnetic storms, and aurorae. Nagata became a very famous scientist in Japan and was influential in Japanese scientific policy on developing the polar exploration, rocket and satellite experiments, and even on the earthquake prediction program. His popularity arose mostly because he was the leader of the Antarctic expeditions for three consecutive years (1956–1958). This project was started as a part of the Japanese contribution to the International Geophysical Year Program (1957). The expedition built the Syowa Base on the Ongul Island in Antarctica and started various scientific observations, which are continued to this day. One of the prominent achievements of these expeditions was the discovery of meteorites on the ice field in 1969. Nagata strongly promoted continued search in the following years, and more than 16000 meteorites were recovered from the Antarctic ice surfaces since then. For the scientific achievement and for public services, he was elected to Member of Japan Academy (1983), and was awarded the Japan Academy Prize (1951), the Order of Culture of Japan (1974), and the gold medal of the Royal Astronomical Society, UK (1984).

# NATURAL SOURCES FOR ELECTROMAGNETIC INDUCTION STUDIES

Time changes of the magnetic field, regardless whether they are of internal (core) or of external (in the atmosphere, ionosphere, and magnetosphere) origin, produce secondary currents in the Earth's interior. Observations of the superposition of the primary (inducing) and secondary (induced) electromagnetic field allows for a determination of the electrical conductivity of the Earth's interior.

Mantle conductivity can be probed "from below" using signals originating from the outer core. This method requires a precise determination of the field during rapid and isolated events, like *geomagnetic jerks* (q.v.), and some *a priori* assumptions about the kinematics of the fluid motion at the top of the core. Conductivity of mantle and crust can also be studied "from above" by the analysis of field changes of external origin, as the induced currents of these fluctuations modify the observed electromagnetic field. Both methods require good knowledge of the time-space structure of the inducing field. The first approach has its strength in estimating the conductivity of the deep mantle, whereas the second approach is suitable for probing the conductivity of the crust and upper mantle down to the depths of 1000 km or so. This article summarizes natural sources of external origin only.

Two approaches are in use: the *Geomagnetic Deep Sounding* (q.v.) (GDS) method utilizes time changes of the vertical and horizontal magnetic field components; whereas *Magnetotellurics* (q.v.) (MT) uses the horizontal components of magnetic and electric fields. GDS is used for global soundings and with natural sources in the period range between hours and years, whereas MT is mostly used for regional studies and with periods between milliseconds and a few hours due to the decrease of the electric field strength with decreasing frequency.

Natural geomagnetic variations in the period range between a few hours and a couple of days have been used for more than one century to infer the electrical conductivity of the Earth's mantle in the depth range of a few hundred kilometers. The dominant sources for these variations are the magnetospheric ring-current and the ionospheric current system generated by wind systems in the upper atmosphere. The latter produces periodic external field variations (periods of 24 h and harmonics), whereas the magnetospheric ring-current contributes to field variations in the whole period range between minutes and months. These two sources are still the most important ones for inferring mantle conductivity in the depth range of a few hundred kilometers.

#### Time-space structure of external sources

At the Earth's surface, temporal variations of the magnetic field of external origin,  $\mathbf{B}^{\text{ext}} = -\nabla V^{\text{ext}}$ , can be described by means of a scalar potential  $V^{\text{ext}}$ . For modeling its spatial dependency, the flat-Earth approximation may be used to study phenomena that have a spatial scale much smaller than the Earth's radius. Studying phenomena at longer scales requires a spherical approach in which  $V^{\text{ext}}$  is expanded in a series of *spherical harmonics* (*q.v.*)

$$V^{\text{ext}}(t,r,\theta,\phi) = a \sum_{n=1}^{N} \sum_{m=0}^{n} \left( q_n^m(t) \cos \phi + s_n^m(t) \sin \phi \right) \left( \frac{r}{a} \right)^n P_n^m(\cos \theta)$$
$$= a \text{Re} \left\{ \sum_{n=1}^{N} \sum_{m=0}^{n} \varepsilon_n^m(t) \left( \frac{r}{a} \right)^n P_n^m(\cos \theta) \exp \mathrm{im} \phi \right\}$$
(Eq. 1)

where  $(r, \theta, \phi)$  are radius, colatitude, and longitude of a spherical coordinate system, respectively, with *a* as the Earth's radius,  $P_n^m$  as the associated Legendre function of degree *n* and order *m*, and  $\varepsilon_n^m = q_n^m - is_n^m$  as the corresponding external expansion coefficients. A similar expansion holds for the internal (induced) magnetic field,  $\mathbf{B}^{\text{int}} = -\nabla V^{\text{int}}$ , with expansion coefficients  $t_n^m$  and radial dependence  $(a/r)^{n+1}$  instead of  $(r/a)^n$ . The horizontal scale-length of a mode of degree *n* is  $\lambda_n = 2\pi a/(n+1) \approx 40000/(n+1)$  km.

If conductivity depends only on depth (1D conductivity), each expansion coefficient of the external field induces only one internal coefficient of same degree *n* and order *m*, and the ratio of their Fourier components (time dependence  $e^{i\omega t}$ ),  $Q_n(\omega) = t_n^m(\omega)/\varepsilon_n^m(\omega)$ , depends only on degree *n*.

Transfer functions (q.v.) like  $Q_n$  or the C-response

$$C_n = \frac{a}{n+1} \frac{1 - [(n+1)/n]Q_n}{1 + Q_n}$$

depend on the frequency  $\omega$  as well as on the spatial scale  $\lambda_n$  (i.e., spherical harmonic degree *n*) of the source field, and on the electrical conductivity distribution. Dependence of the *C*-response on spatial scale

 $\lambda_n$  and period is shown in Figure N1 for a typical model of mantle conductivity. The horizontal parts of the curves present the range of  $\lambda_n$ , for which source effects (the dependence of  $C_n$  on  $\lambda_n$ ) are negligible and  $C_n$  converge to the zero wave number response  $C_0$ . For the given conductivity model, this is true for variations of period T < 1 min. In the limit of no induction for which  $|C_n| = \lambda_n/2\pi$ , the response (and hence the induced field) is determined by the geometry of the source rather than Earth's conductivity. Because  $|C_n| \leq \lambda_n/2\pi$ , the maximum depth for which conductivity can be determined is given by the spatial scale  $\lambda_n$  of the source; with the chosen conductivity model it is for instance not possible to probe the Earth's conductivity using measurements of the equatorial electrojet (EEJ) for periods >2 h.

GDS requires a precise description of the time-space structure of the potential  $V^{\text{ext}}$  of the external field, but knowledge of the location of the external sources (currents) is not required—provided they are external to a sphere including the observation point (i.e., external to Earth for ground observations). This means that the determination of the equivalent source is sufficient for induction studies. The following section focuses on the morphology rather than on the physical nature of the various geomagnetic variations that are used for EM induction studies.

#### Classification of geomagnetic variations

Table N1 presents a classification of magnetic variations in dependence on period and Figure N2 shows a typical spectrum of the north component of the geomagnetic field for a midlatitude site.

#### Magnetospheric ring-current

The *ring current* (q.v.) in the *magnetosphere* (q.v.) is probably the source that has been used for most studies of mantle conductivity. To first approximation, its spatial structure can be described by the single spherical harmonic  $P_1^0(\cos \theta_d)$ , where  $\theta_d$  is geomagnetic (dipole) colatitude. Hence only the expansion coefficient  $q_1^0 = \varepsilon_1^0$  of Eq. (1) is used. Although the spatial structure of individual magnetic storms is often more complicated and requires more coefficients, the validity of this  $P_1^0$ -assumption on average seems to be remarkably good, at least for periods longer than a few days. For a  $P_1^0$  source, and a 1D conductivity, only one internal coefficient,  $\iota_1^0$ , is induced, and the sum of external (inducing) and internal (induced) potential is

$$V = V^{\text{ext}} + V^{\text{int}} = \left[ \epsilon_1^0 + l_1^0 (r/a)^3 \right] \cos \theta_{\text{d}}$$
 (Eq. 2)

This allows for a determination of the *C*-response from magnetic data of an individual site from observations of  $B_r = (-\varepsilon_1^0 + 2t_1^0) \cos \theta_d$  and  $B_\theta = (\varepsilon_1^0 + t_1^0) \sin \theta_d$  at that site (r = a) according to

$$C_1(\omega) = -\frac{a \tan \theta_{\rm d}}{2} \frac{B_r(\omega)}{B_{\theta}(\omega)}$$
(Eq. 3)

This approach, known as Z/H-method, has been used by most researchers to infer mantle conductivity at a few hundred kilometer depths with periods between few days and several months.

#### Daily variations

*Periodic external field* (*q.v.*) variations at nonpolar latitudes (Sq variations) are caused by diurnal wind systems in the upper atmosphere, which produce electric currents in the E-layer of the *ionosphere* (*q.v.*) between 100 and 130 km altitude. Typical peak-to-peak amplitudes at midlatitudes are 20–50 nT; amplitudes during solar maximum are about twice as large as those during solar minimum. Sq variations are restricted to the sunlit (i.e., dayside) hemisphere, and thus depend mainly on local time  $T = t + \phi$  (*t* and  $\phi$  are UT and longitude expressed in radians). The external potential (see Eq. (1)) of such local

**Figure N1** Absolute value of the *C*-response for a typical conductivity model (shown in the inset) as a function of horizontal scale-length  $\lambda_n$  and period *T* of the source.

Table N1 Classification of geomagnetic variations (after Schmucker 1985, modified), with typical periods, amplitudes, and penetration depths

Type of variation	Symbol	Typical period	Typical amplitude	Typical penetration depth
Solar cycle variations		11 years	10–20 nT	>2000 km
Annual variation		12 months	5 nT	1500–2000 km
Semiannual variation		6 months	5 nT	
Storm-time variation	Dst	Hours to weeks	50–500 nT	300-1000 km
Regular daily variation				
At midlatitudes	Sq	24 h and harmonics	20-50 nT	300-600 km
At low latitudes	ĒĒJ		50–100 nT	
Substorms	DP	10 min to 2 h	100 nT (1000 nT at p.l.)	100-300 km
Pulsations (=Ultra low frequency waves)	ULF	0.2–600 s		20-100 km
regular continuous pulsations	pc	150-600 s (pc5) 45-150 s (pc4) 5-45 s (pc2,3) 0.2-5 s (pc1)	10 nT (100 nT at p.l.) 2 nT 0.5 nT 0.1 nT	
Irregular transient pulsations	pi	1–150 s	1 nT	
Extreme low-frequency waves Schumann resonance oscillations	ELF sferics	1/5–1/1000 s 1/8 s	<0.1 nT <0.1 nT	Tens of meters-kilometers
Very low-frequency waves, whistlers	VLF	$10^{-5} - 10^{-3}$ s		Few meters-tens of meters

Note: If amplitude depends significantly on latitude, values are also given for polar latitudes (p.l., dipole latitude >65°).

**Figure N2** *Top*: Amplitude of magnetic variations (north component) at a midlatitude site for periods between 1 ms and 30 years, estimated using data from the sites Niemegk/Germany (2 h–30 years), Kakioka/Japan (2 s–2 h), and Socorro/USA (1 ms–1 s). *Bottom*: Skin depth  $\delta = \sqrt{\rho T / \pi \mu_0}$  for a uniform half-space in dependence on resistivity  $\rho$  and period *T*.

time phenomena consists of elementary modes of the form  $\varepsilon_n^m(r/a)^n P_n^m \exp imT$ , with periods of 24/m h. Coefficients representing most of the power are those with n = m + 1, i.e.,  $\varepsilon_2^1, \varepsilon_3^2, \dots$  Typically, four Fourier terms, m = 1-4 (periods 24,...,8 h), are used, which results in a somewhat restricted period range of a factor of four; therefore Sq variations provide conductivity estimates only in a rather limited depth range between roughly 300 and 600 km. The earliest attempts (Schuster, 1889; *Chapman* (*q.v.*), 1919) to determine mantle conductivity have used Sq as the inducing source.

There is about a fivefold enhancement of the daily variation near the dip-equator, called EEJ. Its latitudinal width is about  $6^{\circ}-8^{\circ}$ , which requires spherical harmonics up to degree n = 20-30 or higher.

# Seasonal and solar cycle variation

The amplitudes of Sq variations depend on the season and on the 11-year cycle of solar activity, but because of vanishing ionospheric conductivity (due to vanishing solar radiation) ionospheric currents are almost zero at night. This requires ionospheric currents that vary with season and solar cycle (i.e., there exists a true long-period *variation* in addition to a *modulation* of the daily variation). In addition, there is also a pronounced seasonal (mainly semiannual) and solar cycle variation of the magnetospheric ring current. Induction studies using semiannual, annual, and 11-year signals provide information on the conductivity of the lower mantle. However, reliable estimates of transfer functions at such long periods are hampered by contamination by short-term secular variation of the core field. The main spherical coefficients are  $\varepsilon_1^0$  (semiannual, solar cycle variation) and  $\varepsilon_2^0$  (annual variation).

#### Magnetospheric substorms, DP variations

*Magnetic storms and substorms* (q.v.) are irregular variations caused by the interaction of the Earth's magnetic field with the solar wind. Ionospheric currents in the auroral regions, called polar electrojets (PEJ), are linked to the magnetosphere by field-aligned currents. Both currents are highly dependent on solar wind conditions. Their magnetic field variation, called disturbed polar (DP) variation, has a typical timescale of a few minutes to hours and a horizontal scale-length of a few hundred kilometers.

# Geomagnetic pulsations, ULF and ELF waves, sferics, and whistlers

*Geomagnetic pulsations (q.v.)*, i.e., ultralow-frequency (ULF) waves, cover roughly the period range from fractions of a second to a few minutes. On the basis of their waveform, pulsations are classified into *pulsations continuous* (pc) and *pulsations irregular* (pi). Their amplitudes range from 100 to 0.1 nT, with longer periods exhibiting larger amplitudes. Typical amplitudes are 1 nT at midlatitudes and 10 nT at polar latitudes for a period of 30 s. There are several mechanisms that produce pulsations; resonant oscillation of the Earth's main field in response to changes in the solar wind is one of them. The typical spatial size of pulsations at midlatitudes is a thousand kilometers and longer.

Extremely low-frequency (ELF) waves covering periods from milliseconds to seconds originate from thunderstorm lightnings and are called atmospherics of sferics. This part of the spectrum shows, in particular, Schumann resonance oscillations (with peaks at 8 Hz and multiples) caused by standing waves in the waveguide formed by the Earth's surface and the ionosphere. Whistlers are sferics that travel along Earth's magnetic field lines from one hemisphere to the other. As higher frequencies travel faster than the lower ones the lightning wave is dispersed into a whistler tone.

# NÉEL, LOUIS (1904–2000)

Louis Néel was born in Lyon, France. He followed the classic French academic path to excellence: starting from the "classes préparatoires Maths Sup" of Lycée du Parc in Lyon, he joined the Ecole Normale Supérieure de Paris and later obtained the "Agrégation de Physique." His early vocation for magnetism led him to defend a thesis under the supervision of Pierre Weiss in 1932 in Strasbourg, where he set up the theoretical basis that grounded his later discovery of antiferromagnetism (Néel, 1936; the term antiferromagnetism was later coined by Bitter). Mainly, his input was to introduce the concepts of quantum mechanics in magnetism (following Heisenberg exchange interaction concept), turning the uniform molecular field of Pierre Weiss into a local field. He became professor in Strasbourg in 1937 and gained

Nils Olsen

**Figure N3** Louis Néel (1904–2000).

international recognition soon after. During World War II, he moved to Grenoble where he spent the rest of his career. His central contribution to modern magnetism was quite lately acknowledged by a Nobel Prize, shared in 1970 with Hannes Halfven. Both of them, top physicists, have grounded a discipline of geophysics: rock magnetism for the former, magnetospheric and space plasma physics for the latter. One can appreciate his place in modern magnetism knowing that his scientific contributions are at the origin or central to the understanding of antiferromagnetism, ferrimagnetism, fine-grained magnetism, thermoremanence, viscosity theory in single- and multidomains, theories of the Rayleigh law and hysteresis cycle, domain walls, exchange and surface anisotropies, coupling interaction and self-reversal, for the most notable. To get a more detailed account of his scientific contributions one can refer to his Nobel lecture (Néel, 1970) as well as to Prévot and Dunlop (2001).

Closer to our concerns, Louis Néel gained interest in paleomagnetism very early mostly through its rapid passage as the director of Clermont-Ferrand Geophysical Observatory in 1931 (30 years after B. Brunhes). At that time the nature of natural remanent magnetization (NRM) was a full mystery and this may have triggered a good part of Louis Néel theoretical breakthroughs. His most prized contribution in rock magnetism concerns the single domain theory of relaxation time, thermoremanence, and viscous remanence (Néel, 1949). This theory turned paleomagnetism from magic to science. In the original paper the theory was validated using the experimental results of Thellier on baked clays, going against the often-observed reluctance of physicists to use natural samples as a valid model. Nicely, this rather exotic contribution for a physicist nowadays is the most cited paper of Louis Néel, mostly in the nongeophysics literature. This is a beautiful example of the input of Earth sciences into physics, balancing the more common backward input. On the other hand, Louis Néel and his coworkers were able to synthesize and measure the highly anisotropic magnetization of the predicted ordered form of Fe-Ni alloy (Néel et al., 1964). As this ordering appears only below 320°C, that is, at a temperature where atomic diffusion is negligible, they used a trick to enhance this diffusion: neutron bombardment. Much later, another trick was found-ultralow cooling rates-only available in meteorite parent bodies; the Fe-Ni ordered phase, tetrataenite, was "rediscovered" (e.g., Wasilewski, 1988).

A great lesson from Louis Néel's career (Néel, 1991) is that while being so sharp in his personal scientific work he was so broad in his interests and inspiration. His hobby was woodwork. It would be a large error to remember him mainly as a theoretician: he demonstrated great skills as an experimentator and as a man of action and organization. When the Nazi troops approached Strasbourg in 1939 he organized practically by himself the evacuation of the most sensitive equipments of the Strasbourg University in a train convoy. Soon after he was responsible for battleship demagnetization to avoid the triggering of magnetic mines moored at the entrance of French ports. It took him less than 6 months to set up original ship-size demagnetization systems in several major ports and efficiently "immunize" more than 500 ships. He was fully involved in practical and engineering magnetism, for example through military research or through the push of improving the magnetic materials used in recording or electromechanical devices. When he arrived in Grenoble, there were a handful of physicists in the university. When he retired from his leading position there 30 years after, thousands of people were involved in various fundamental and applied physics research institutes. As the leading builder of this top European center for solid-state physics, he early recognized that subdisciplines of theoretical and experimental physics have to work in close connection to solve the complex problems facing modern physics. As a result, it is nowhere else than in Grenoble, where it is possible to walk with the same sample from a neutron reactor to a synchrotron x-ray source via world record high-magnetic field facilities, finding all possible types of magnetic, spectroscopic, and other measuring devices in between. The Louis Néel scientific impetus is still visible today in the strong contribution of Grenoble laboratories-first

of all, the Louis Néel laboratory: http://lab-neel.grenoble.cnrs.fr—to the advancement of magnetism (du Trémolet de Lacheisserie *et al.*, 2002). These textbooks include a foreword by Louis Néel, acknowledging the fact that he was going on to actively participate in the science community until the term of his tremendously filled life.

# NONDIPOLE FIELD

The nondipole (ND) field is that part of the internal geomagnetic field remaining after the major geocentric dipole contribution has been removed. It is distinct from the nonaxial-dipole (NAD) field for which only the component of the geocentric dipole that is parallel to Earth's rotation axis is subtracted. Figure N4a/Plate 4a shows the strength of the total scalar field at Earth's surface, with the spatial variations dominated by the dipole field, while in Figure N4b/Plate 4b the dipole contribution has been subtracted to reveal the substantially more complex nondipole field. Two source regions contribute to the ND field: the dynamo in Earth's core that is also responsible for the dipole part of the geomagnetic field produces the largest part; the other source is Earth's lithosphere (see Crustal magnetic field). Nondipole field contributions are significant, but contribute only a small fraction of the average magnetic energy at the surface, as can be seen in Figure N5a, which shows  $\langle \vec{B}_l \cdot \vec{B}_l \rangle_{r=a}$ , the squared average value of the field strength over the Earth's surface, average radius r = a, as a function of spherical harmonic degree, l. This geomagnetic spatial power spectrum (q.v.) falls off rapidly with increasing l (decreasing wavelength), up to about degree 12, then flattens out and remains roughly constant out to the shortest resolvable wavelengths. The ND field between degrees 2 and 11 is dominated by sources in Earth's core, while above degree 15 the core contribution is overwhelmed by that from lithospheric magnetic anomalies (see Magnetic anomalies, modeling; Magnetic anomalies, long wavelength; and Magnetic anomalies, marine). Between degrees 11 and 15, it is difficult to isolate the primary source, although time variations (Figure N5b) in the core part at these spatial scales will be better characterized with new high-quality satellite data. Temporal variations in the lithospheric field occur on geological timescales, but direct measurements over the past few centuries will only sense changes in inducing fields. These are very small at timescales of the order of a year or longer.

**Figure N4/Plate 4a-d** (a) Geomagnetic field strength *B* in  $\mu$ T and (b) its secular variation d*B*/d*t* in nT/y, evaluated at Earth's surface (*r* = 6371.2 km) using the geomagnetic field model OSVM for the epoch 2000. Lower panels, (c) and (d) are the nondipole field strength, *B*<sub>nd</sub> in  $\mu$ T, and its rate of change, (nT/y). Note different scales for each panel.

**Figure N5** The spatial power spectrum of the geomagnetic field (a) and the spatial power spectrum of the secular variation (b) evaluated at Earth's surface (r = 6371.2 km). In (a) black dots are for a satellite field model for epoch 2000 as a function of degree *I*, solid line gives the crustal power spectrum derived from *Project MAGNET* (*q*,*v*.) aeromagnetic data after removal of core field contributions.

Inferences about the historical ND field rely on *time-dependent* models of the main magnetic field (q.v.), extending from 1590 to the present (the GUFM model of Jackson *et al.*, 2000). Recently developed paleofield models (Continuous Archeomagnetic and Lake Sediment, CALS7K.2, for 0–7 ka, version 2) model of Korte and Constable, 2005) extend to millennial timescales and are likely to improve as more data become available. The Oersted secular variation model (OSVM) for epoch 2000.0 of Figure N4/Plate 4a-d (Olsen, 2002) is based on recent satellite and observatory data with excellent spatial coverage, and has much higher resolution than historical or paleofield models.

For the year 2000, the ND field is lower in the Pacific than the Atlantic or Asian hemisphere (Figure N4b/Plate 4b). Major ND contributions are in the Central and South Atlantic, where the total field seems anomalously low (Figure N4a/Plate 4a), and beneath Australia and Eastern Asia, where it is on average rather high. The South Atlantic anomaly is of some concern since the relatively low-geomagnetic field results in diminished geomagnetic shielding from cosmic radiation, presenting a hazard to low-Earth-orbiting satellites.

Figure N4c,d show the geomagnetic secular variation (q.v.), the rate of change with time, in the total and nondipole parts of the scalar field for the year 2000. The ND field is increasing in some regions and decreasing in others, with the largest rates of change in the Atlantic or Asian hemisphere. At present the secular variation in the geomagnetic field is predominantly in the ND part of the field. Figure N5b shows the maximum power is at degree 2. In time-varying historical models, much of the secular variation is manifest by westward drift (q.v.) of features in the ND field, but the westward drift is confined to the Atlantic or Asian hemisphere, with features modified or dying away before reaching the Pacific region. Paleofield records from distant sites are uncorrelated, supporting the view that the longevity of drifting ND features is insufficient to carry them for a full global circuit. For the second half of the 20th century variations in the ND field are well fit by dynamical models that comprise steady fluid flow in the outer core, and torsional oscillations (q.v.): such models predict observed length of day variations (q.v., see also Jault, 2003), as well as the sudden changes known as geomagnetic jerks (q.v.). Westward drift of features in the ND field is well documented for the Atlantic or Asian hemisphere (Bloxham et al., 1989), but definitive identification of poleward propagation in the ND field has proved elusive, perhaps because longer timescales are involved and the quality as well as the temporal and spatial distribution of records deteriorates with increasing age.

The longevity of both static and drifting features in the ND field is poorly documented, but both paleofield records and global models derived from them indicate substantial variations on timescales of hundreds to several thousands of years and probably longer. These variations are large in spatial scale, exhibiting substantial coherence over continental size geographic regions.

A fundamental tenet of paleomagnetism, embodied in the *geocentric* axial dipole hypothesis (q.v.), is that when the geomagnetic field is averaged over long timescales, nonaxial-dipole contributions can be considered negligible. That this is approximately true can be seen in Figure N6/Plate 4e-h, where the vertical component of the nonaxial-dipole (NAD) field is shown for the year A.D. 2000, along with averages for the most recent 400 years, 7 ka and 5 Ma. The magnitude diminishes with increasing averaging interval, but there remain small (apparently time-varying) NAD field contributions on all time-scales. The spatial scale of the residual contributions increases with averaging interval, supporting the idea that short wavelength features are associated with shorter timescales. The short-term averages in

Figure N6a,b/Plate 4e,f exhibit a number of similarities to one another, which seem quite distinct from the similarities between the longer term averages in Figure N6c,d/Plate 4g,h.

The similarities in structure for the long-term averages are generally positive NAD radial fields at equatorial and low latitudes and generally negative NAD radial fields at high latitude. This overall latitudinal variation in NAD radial field contributes to the persistent "far-sided effect" in virtual geomagnetic poles derived from paleomagnetic directional observations and detected in early work that identified small departures from the geocentric axial dipole hypothesis. This reflects a (latitudinally varying) negative deviation of the inclination from that predicted by a geocentric axial dipole field (Merrill et al., 1996). For a several million year average such an effect can be largely explained by a persistent axial magnetic quadrupole with a moment of the order of a few percent of that of the axial dipole. The influence of any axial quadrupole on paleomagnetic directions is largest at the equator, generally visible at low- to midlatitudes, and basically so small as to be undetectable at high latitudes. The existence of a small but persistent geocentric axial quadrupole contribution in addition to the axial dipole is the only feature on which all magnetic field models for the interval 0-5 Ma agree: however, the size of the estimated contribution varies by about a factor of three (McElhinny, 2004).

Although it is often supposed that nonzonal (longitudinally varying) contributions to the field will average out on long timescales, this remains controversial. Small contributions persist in the model in Figure N6d/Plate 4h and statistical models of *paleomagnetic secular variation* for the time interval 0–5 Ma invoke significant variations attributed to nonzonal quadrupolar fields. Some researchers attribute all of the nonzonal structure to poor quality and spatial distribution of the data (McElhinny, 2004). Others (including the author) believe that the persistent quadrupole is overemphasized in many models because of the poor geographic coverage (see Gubbins, 1998, 2003; Gubbins and Gibbons, 2004), and that one might expect hemispheric differences arising from thermal *core-mantle coupling* (*q.v.*).

**Figure N6/Plate 4e-h** (a) Vertical component of the nonaxial dipole filed in  $\mu$ T evaluated at Earth's surface (r = 6371.2 km) using the geomagnetic field models OSVM for A.D. 2000, (b) GUFM averaged over 400 years, (c) CALS7K.2 averaged over 7 ka, and (d) LSN1 (Johnson and Constable, 1997), from normal polarity lava and marine sediment directions averaged over 5 Ma. Note scales for (c) and (d) differ by factor of 3 from (a) and (b).

704

It is notable that the persistent nonzonal structures in Figure N6c,d/ Plate 4g,h do have a number of similarities, despite the fact that they are derived from very different kinds of data. It is likely that much of the detail in Figure N6c,d will change as new modeling efforts take advantage of improved data sets. It remains unclear whether field behavior in the Pacific hemisphere is persistently different over thousands or millions of years: paleofield models for 0-7 ka indicate substantial secular variation, but they are not yet good enough to allow a definitive determination of whether the ND field is consistently anomalous there. The same holds true for longer time intervals. More effort needs to be invested in discriminating among the various data sets and viable models.

The temporal evolution of the South Atlantic anomaly from the historical to the present field has given rise to speculation that complex field structures in this region may be a sign of impending geomagnetic reversal. The longevity of this feature is unknown, making it an interesting target for future study. There is no evidence that the nondipole field is substantially increased or diminished during a reversal: most reversal records indicate field strengths around 10%–20% of the prereversal field at their lowest point. It is possible that the NAD field may differ for successive polarity chrons, but this remains at the limit of current data resolution. The possibility of larger nondipole field contributions in the ancient past is widely discussed (van der Voo and Torsvik, 2004; Courtillot and Besse, 2004), and for Precambrian times it cannot be ruled out with currently available data (Dunlop and Yu, 2004).

# NONDYNAMO THEORIES

The internal magnetic field of Earth or any planet is normally considered to have three components at most: A large, globally coherent field is attributed to a dynamo operating deep within the planet; a spatially complex, usually much smaller field is attributed to permanent magnetism of near-surface rocks, and a small time-varying magnetotelluric field is induced by the external time-varying field. For Earth at least, the separation of these three is not difficult because of their very different spatial and temporal characteristics. There are some bodies for which the last two fields dominate. For example, the Martian field appears to be dominated by permanent magnetism in the crust, and the change in field near Europe is dominated by an induced field, presumably caused by electrical currents induced in a salty ocean beneath an icy shell. see Dynamos, Planetary and Satellite for a discussion of the conventional explanations of observed fields. This section is concerned with other alternatives that do not easily fit into one of three categories of field defined above, with a particular emphasis on the possibility that a large global field might have a nondynamo origin.

There is at present strong acceptance of a dynamo origin for most of Earth's magnetic field. The same acceptance applies to fields of comparable magnitude in other planets or stars Parker (1979). Historically, this acceptance was slow to develop, even though the essential physical ideas (Faraday's law in particular) are over 150 years old and the concept of a dynamo existed long before general acceptance of its validity.

This slow acceptance can be attributed primarily to the difficulty of deriving the desired dynamo behavior from the governing equations. Without the advent of modern computers, beginning in the 1950s, it would still be difficult to convince oneself that a homogeneous dynamo really works. We now know that this difficulty is real, in the sense that many possible fluid flows do not create a dynamo, but that the flows that occur in convecting, rotating planetary cores are indeed suitable for field generation. During the long period of uncertainty about dynamos, many alternatives were considered and advocated. Alternatives are still advocated occasionally. These remain interesting for several reasons. First, they might be relevant for Earth or other planets as an increment to a dynamo field or where the total field is small. Second, the criteria for their presence or their failure might tell us about the conditions within planets. Last (but not least), the dynamo mechanism is still sufficiently poorly understood that one should be open to alternatives.

These nondynamo theories can be categorized in three groups: (1) Theories that invoke well-established physical principles (phenomena that are known to produce magnetic fields in the lab). (2) Theories that may have a physical basis but invoke properties or conditions far removed from those that are compatible with existing laboratory data or material properties. (3) Theories that go beyond established physical principles. We discuss these various ideas in roughly that order and define their specific failings. A summary is then provided for the common failings that these alternatives frequently share. Further details can be found in the bibliography.

# Primordial currents and fields

A current inside the core does not immediately disappear when the energy source for its generation is turned off. This raises the possibility that the present magnetic field is the consequence of a freely decaying current distribution of ancient or primordial origin. However, this is not an acceptable explanation because the free decay-time of the field is of order a few tens of thousand years at most (for Earth) and paleomagnetic evidence shows that the field has persisted throughout most of geologic time.

#### Unexpected or exotic permanent magnetism

In addition to the readily demonstrated permanent magnetism associated with some minerals (e.g., magnetite) in cold, near-surface crustal rocks, one should consider the possibility that some mineral deep within Earth (and perhaps the solid inner core) exhibits permanent magnetism. This cannot be excluded with certainty. Moreover, permanent magnetism (unlike most of the mechanisms discussed here) is in principle capable of providing a large field. However, neither is there any laboratory evidence of high-temperature permanent magnetism in any material of relevance to Earth's interior, nor is there any theoretical support for this idea from ab initio quantum mechanical calculations. Solid metallic iron loses its ferromagnetism at modest pressures relative to Earth's deep interior (and the temperatures are in any event high relative to any plausible Curie point). Moreover, any permanent magnet explanation would fail to explain the well-established temporal variation of the field. Rotating permanent magnets can also exhibit a dipole aligned with the rotation axis (the gyromagnetic effect Barnett, 1933) arising from the fundamental connection between angular momenta and magnetic moments for nuclei and atoms, but for the Earth's slow rotation rate this fails by ten orders of magnitude to explain Earth's field.

#### Off-diagonal condensed matter physics effects

Any disequilibrium or gradient in the electronic chemical potential can lead to currents and hence (through Ampere's law) to magnetic fields. Some of these effects are "off-diagonal" in the sense that they involve a relationship among vectors or components of vectors that one would normally treat as independent. The best known and most frequently invoked of these is the *thermoelectric effect*: An emf and electrical current that arises when both compositional and thermal differences are present. The most likely application of this would be that the emf arises at the boundary between a metallic core and a semiconducting mantle when there are temperature variations along that boundary. For reasonable parameter choices, an emf of order millivolts can arise. The associated currents are poloidal and the resulting field is accordingly toroidal. Despite the undisputed reality of this effect, two problems are immediately apparent in its application to explaining a large magnetic field: First, the likely emfs provided are typically two or more orders of magnitude less than dynamo emfs (which are of order 1-10 V typically). Second, the resulting field is toroidal rather than poloidal.

Other off-diagonal effects are even less attractive. The *thermomagnetic effect* (or equivalently the Nernst-Ettinghausen effect) provides a current and hence a field when there is a preexiting field and thermal gradient. In this case, one would hope to use this effect to amplify a seed magnetic field. The magnitude of the effect is too small by orders of magnitude and the proposed amplification is probably not possible, even in principle. The *Hall effect* is well known but offers no method of amplification: It merely changes the conductivity tensor.

# Rotating electric fields and charges

According to fundamental electricity and magnetism, magnetic fields can be related to moving charges. In everyday experience, this is usually associated with materials that are very close to electrically neutral on all scales much larger than atomic scale. However, a rotating body with net charge (or charge separation, i.e., macroscopic capacitor) could provide a magnetic field. There is no large net charge associated with Earth (though there can be localized large separation of charge in the atmosphere, e.g., as in thunderstorms) so this mechanism can have no relevance unless the Earth is a large, charged capacitor with the two "plates" at different mean distances from Earth's center. The problem is that one requires very large voltage differences in order to produce modest magnetic fields. In SI units, the electric field E (in V m<sup>-1</sup>) required to explain a field of strength B (in tesla) is  $\sim c^2 B/v$ , where v is the rotational velocity. This suggests  $E \sim 10^{11}$  V m<sup>-1</sup>, which is physically impossible (it will ionize atoms). This must not be confused with the sustained emf and voltage (only a few volts) that arise through induction during dynamo generation in an electrical conductor. The latter continually drives a current, whereas the former must be associated with a capacitor that never discharges. A "capacitor" (meaning any macroscopic charge separation) can in principle exist even in a conducting region. For example, the thermoelectric effect discussed above causes charge separation. However, the associated electric fields are totally insignificant.

An interesting but equally inadequate origin for an electric field is the differential effect of gravity on electrons and ions. This *compression effect* can create a voltage difference of a few volts in planets (and is actually important in the diffusion and gravitational settling within white dwarf stars) but it drives no sustained current (i.e., does not have an energy source) and is undetectable in Earth by many orders of magnitude.

#### Magnetic monopoles

Dirac postulated the possible existence of magnetic monopoles. From the perspective of modern elementary particle physics, the idea of a magnetic "charge" is still acceptable. They are predicted in some grand unified theories. However, they are also predicted to have immense masses by conventional elementary particle standards, suggesting that they are exceeding rare at best. There are a few claimed "sightings" of monopoles in laboratory experiments, but none of these has been confirmed. From the perspective of Earth and planets, the telltale signal of a net magnetic charge would be a field that decays as inverse square rather than inverse cube. There is no evidence for a contribution of this

#### Table N2 Nondynamo theories

Mechanism	Physical basis	Significance and possible magnitude
Primordial	Finite decay time of currents	Decay time is too short compared to age of the Earth
Unexpected (noncrustal) ferromagnetism permanent magnetism		No suitable candidate minerals exists
Gyromagnetism	Dipole associated with a rotating ferromagnet	Too small by at least 10 <sup>10</sup>
Thermoelectric effect	Differences in temperature and composition	Field too small and wrong geometry
Thermomagnetic effect	Currents arising in presence of thermal gradients and magnetic field	Amplification too small; no regeneration of field
Hall effect	Additional current in presence of magnetic field	Small change in existing field
Rotating electric fields	Current arising from rotating charged capacitor	Requires impossibly large charge or electric fields
Compression effect	Gravity acts differently on electrons and massive nuclei	Too small by ${\sim}10^{10}$
Magnetic monopoles	Permitted in some fundamental particle physics theories	Not observed
Magnetic "Bodes law" hypothesized fundamental connection between magnetic moment and angular momentum	No observational or theoretical basis	

form. One could in principle "hide" their presence by hypothesizing equal numbers of magnetic charges of each sign (i.e., equal numbers of South and North poles that are spatially separated within Earth) but in the absence of any laboratory evidence, this hypothesis has no support.

#### New physical theories associated with rotation

Since Earth's dipole is approximately aligned with the rotation axis, it is natural to think of some (unspecified) physical process that creates a magnetic dipole aligned with the angular momentum vector for any rotating body. This is in the sprit of the previously mentioned gyromagnetic effect, except that it would be different physics (i.e., would exist even for a nonmagnetic material) and would be important only for very large accumulations of material. One could hypothesize, for example, that  $M \propto J^n$ , where *M* is the magnetic moment, *J* is the angular momentum, and *n* is some exponent. This proposed proportionality has become known as the *Magnetic Bode's law* (in very crude analogy with the Titus-Bode geometric progression of planetary orbital spacings), except that the label is now more often used to describe some poorly understood scaling for the dynamo process rather than hypothesized new physics. (Note that the original "Bode's law" is not in fact a physical law.).

The basic idea that there is some universal linear relationship between angular momentum and magnetic moment sufficient to explain Earth's magnetic field was disproved in the laboratory by Blackett during his development of highly sensitive magnetometers in the 1950s. The strictly empirical claimed proportionality observed when one plots M and J for planets on a log-log plot (magnetic Bodes law) deserves to be in ill repute because it covers many orders of magnitude and most of the range is explained by the fact that dipole moments scale as planet radius cubed, while angular momenta scale as planet radius to the fifth power. (The other parameters in this hypothesized relationship vary by smaller amounts.) The magnetic Bodes "law" can be used as a pedagogical example of how to mislead oneself and others by plotting two quantities that have an underlying common factor and thereby falsely concluding a relationship.

#### Summary

Table N2 summarizes nondynamo theories, their basis (or otherwise) in fundamental physics, and their possible significance and magnitude.

With the exception of permanent magnetism, these proposals are either real effects that are too small (usually by many orders of magnitude) or effects that have no established reality. The bibliography includes reference to two papers on the planet Mercury, which illustrate the extent to which alternatives can continue to have some credibility in an instance where the field is much smaller than Earth and the data are limited.

Dynamos, Planetary and Satellite

# NORMAN, ROBERT (FLOURISHED 1560–1585)

Nothing is known of the birth and death dates, parentage, or precise marital status of Robert Norman. All that we have to go on, from information contained in his two published works and a few other scattered fragments, is that he served at sea for 18 or 20 years before settling in the seafaring district of Ratcliff, on the north bank of the Thames, London, as a maker of navigational instruments, and in particular of marine compasses. It was to be in this latter profession that he won both a contemporary and an enduring fame in the history of geomagnetism. In *The Newe Attractive* (London, 1581), Norman published the first serious study of the magnetic dip. For while the dip had been discovered by the German Georg Hartmann around 1544, Hartmann had only communicated his discovery in a private letter that was not to become known to the wider world until 1831, so that Robert Norman's discovery, announced in print in 1581, can be rightly credited as independent and original.

Although a working instrument maker, Norman clearly possessed all the right instincts for an original research scientist. He made a long-standing study of the behavior of the compass, and found that to make a ship's compass needle lie properly flat on its suspension pin in London, he had to weight the south end of the needle, for it invariably dipped down to the north. A small blob of wax was used to act as the counter weight. Trials and experiments led him to realize that, in London, the magnetic needle dips at an angle of 71°50'. This prompted him to next investigate how the needle behaved elsewhere, which in turn brought him to the understanding that the Earth's magnetic field seemed to act in more than just the horizontal plane. Norman realized that knowledge of the magnetic dip, when used in conjunction with the position of the usual horizontal compass needle, could be of great benefit to position-finding at sea. For if navigators and researchers could build up a detailed knowledge of the position of the horizontal and dip needles for different parts of the globe, then a sailor could derive a better knowledge of his position. (A similar logic was to lie behind William Gilbert's practical uses of magnetism and Edmond Halley's magnetic surveys of the Atlantic, over a century later.) Unlike Gilbert, however, Norman never developed a coherent theory about what magnetism was or how it occurred.

Robert Norman belonged to a class of men who were coming to play an increasingly significant role in the wider rise of science, especially in England: intelligent, ingenious craftsmen, sailors, and experienced travelers, who while not "learned" in the sense of having received a Latinate classical education, were to approach the study of natural phenomena from a refreshing and original angle. Unfettered as they were by classical cautions about the unreliability of senseknowledge, and outside the linguistic and philosophical games of the European universities, they formed that cadre of men whose praises were soon to be sung by Dr. William Gilbert, Sir Francis Bacon, and the early fellows of the Royal Society. It would be wrong, however, to see Norman, and enterprising men like him, as simple tradesmen who were fond of writing. For, although not classically educated, Norman seems to have had a good reading and even a translating knowledge of Dutch, and was encouraged in his magnetical researches by none other than William Borough, himself a student of magnetism and comptroller of the Royal Navy, to whom The Newe Attractive was dedicated. It is perhaps more appropriate to see Norman as a successful entrepreneur who financed his scientific researches on the

strength of a successful business: a pattern that would be very common in British science down to the late 19th century.

Geomagnetism, moreover, was in many ways a more challenging field of research for such men to become occupied with, for while mathematical-scale graduators and cross-staff makers became involved in astronomy and oceanography, the study of magnetism was more innately mysterious. This meant that it was much more "philosophical," or what we would call research-physics-based, in so far that it-like optics-involved wrestling with and discovering the mathematical behavior of invisible and seemingly intangible natural forces. Indeed, the essentially practical nature of physics research as conducted by men such as Norman, he explicitly contrasted with the approach of "learned" scholars, who preferred to remain in their studies and find answers to all things within their books. What is more, Norman, like contemporary navigation writers such as Edward Wright, was a pioneer of the English language as a medium of scientific and technical discourse. His The Safegarde of Saylers, or, Great Rutter (1584, 1590) used contemporary material, which Normon had translated from Dutch vernacular navigation manuals, often called "Rutters" (or Routers), and was, in fact, part of a vernacular technical and navigation book movement that included not only Dutch and English, but also French, Spanish, and Italian materials. Indeed, all the great sea powers of the age produced vernacular authors who wrote instruction books and tables for their non-Latinate sea captains who now faced, as a matter of course, long-haul oceanic voyages.

And what began as vernacular books for sailors became increasingly the norm for learned scientists by the 17th century, and by the 1660s the Royal Society and the French Académie regarded it as normal to publish the researches in their mother tongue. In this way, therefore, Norman and his magnetic researches played a role in the growth of a new intellectual tradition. Norman's published work also helped to stimulate wider English researches into geomagnetism. Edmund Gunter, Henry Gellibrand, and those early Gresham College, London, professors who began to monitor the westward drift of the compass variation at Limehouse between 1622 and 1634 (in the wake of William Borough's work in the same place 50 years earlier), *learned* men as they were, took at least part of their queue from Norman's example.

Norman's instruments were clearly prized, for Dr. Christopher Merret, an early fellow of the Royal Society, recorded taking one of Norman's "Clinatories" or dip-needles for repair by Henry Bond nearly a century after it had been made.

It is sad that the wider details of the life of a figure of such importance as Robert Norman in the early history of geomagnetism should have been lost.

## **OBSERVATORIES, OVERVIEW**

Geomagnetic observatories carry out continuous and accurate monitoring of the strength and direction of the Earth's magnetic field over many years, making measurements at least every minute. Observatory data reveal how the field is changing on a wide range of timescales from seconds to centuries, and this is important for understanding processes both inside and outside the Earth. It is estimated that there are approximately 180 observatories currently operating around the world (Figure O1) (for more information on observatories in particular countries or regions of the world see Observatories in ... and Figure O2/Plate 3). The distribution of observatories is largely determined by the location of habitable land and by the availability of local expertise, funds, and energy supply, and as result, it is uneven and a little sparse in some regions. Many observatories have had to move because of encroaching urbanization. However, the continuity of their data series is generally maintained by simultaneous observations at the old site and new site over a period of time to allow site differences to be established.

The distribution of data in time is shown in Figure O3. International scientific campaigns such as the first International Polar Year in 1882/1883, the second International Polar Year in 1932/1933, and the International Geophysical Year in 1957/1958 encouraged the opening of many observatories around the world. Geomagnetism is a crossdisciplinary science, and as a result, observatories are run by a wide variety of institutes whose interests range from geology, mapping, geophysics (including seismology and earthquake prediction), meteorology to solarterrestrial physics, and astronomy.

There are two main categories of instruments at an observatory. The first category comprises variometers that make continuous measurements of elements of the geomagnetic field vector but in arbitrary units, for example millimeters of photographic paper in the case of photographic systems or electrical voltage in the case of fluxgates (see *Observatories, instrumentation* and *Observatories, automation*). Both analog and digital variometers require temperature-controlled environments and installation on extremely stable platforms (though some modern systems are suspended and therefore compensate for platform tilt). Even with these precautions they can still be subject to drift. They operate with minimal manual intervention but the resulting data are not absolute.

The second category comprises absolute instruments that can make measurements of the magnetic field in terms of absolute physical basic

Figure O1 Locations of currently operating observatories.

Figure O2/Plate 3 Continued

**Figure O2/Plate 3** The Danish Meteorological Institute suspended triaxial fluxgate magnetometer being adjusted at Alibag observatory in India (a). This variometer can measure the magnetic field variations along the axes of three orthogonal sensors every second. Another instrument also run in continuous mode at observatories is a proton precession magnetometer. It is an absolute instrument and measures the strength of the magnetic field. In order to convert the variometer data into absolute data, manual observatory in Australia. The fluxgate theodolite, or DI-flux, is widely used. (b) Shows the fluxgate theodolite at Kakadu observatory in Australia. The fluxgate sensor is fixed to the telescope of the non-magnetic theodolite and is used to indicate when its axis is orthogonal to the magnetic field, and therefore the orientation of the field (see *Observatories, instrumentation* and *Observatory*, *Greenland*; (f) Tamanrasset observatory, Algeria; (g) Hartland observatory, UK; (h) Dumont D'Urville observatory, Antarctica; (i) Tihany observatory, Hungary. These buildings, some in the vernacular style, are made of non-magnetic material and can be maintained at stable temperatures if housing variometers.

Figure O3 Number of observatory annual means per year in the Northern (grey) and Southern (black) Hemispheres.

units or universal physical constants. The most common types of absolute instrument are the fluxgate theodolite for measuring declination and inclination and the proton precession magnetometer for measuring total intensity. In the former the basic unit is an angle. The fluxgate sensor mounted on the telescope of a non-magnetic theodolite is used to detect when it is perpendicular to the magnetic field vector. True north is determined by reference to a fixed mark of known azimuth. This can be determined astronomically or by using a gyro attachment. In a proton precession magnetometer, the universal physical constant is the gyromagnetic ratio of the proton and the basic unit is time (frequency). Measurements with a fluxgate theodolite can only be made manually while a proton magnetometer can operate automatically.

Final observatory data are produced by adjusting the variometer data by application of a baseline, so that they closely fit the absolute data. In this process any long-term drifts or steps in the variometer data and differences between the sites of the variometers and absolute instruments are effectively removed. Various other instrument effects may also be included in the baselines. These are scaling factors, offsets, sensor alignments, temperature responses, and timing errors. Many of these effects are insignificant with modern digital variometers. If there is a backup variometer, ideally housed in a different building on the observatory site, filling of gaps resulting from human-made noise and data loss may also be possible. Once a continuous clean time series of data reduced to the observatory reference location is obtained, final observatory products are produced and disseminated. These include 1-min means, hourly means, annual means, and *K*-indices.

There have been many efforts to standardize the operation of magnetic observatories and to expand the network. Current international efforts include the IAGA Observatory Workshops and INTERMAG-NET but there are also many efforts made by individual institutes (see *Observatories in* ...). The International Association of Geomagnetism and Aeronomy (see *IAGA, International Association of Geomagnetism and Aeronomy*) runs workshops every 2 years where information is exchanged on observatory practice and instrumentation. IAGA has also published a guide to observatory practice (Jankowski and Sucksdorff, 1996). Since the late 1980s INTERMAGNET (*International Real-time Magnetic observatory Network*) has contributed to the establishment of global standards in the measurement, recording and dissemination of digital geomagnetic data (see *Observatories, INTERMAGNET*). There are now about 100 observatories operating to INTERMAGNET standards.

The satellite magnetic survey missions of the International Decade of Geopotential Research, which started with the launch of the Ørsted satellite in 1999 (see Ørsted and CHAMP), along with increased appreciation of the effects of space weather on technological systems during magnetic storms (see Geomagnetic hazards) has fueled recent interest in geomagnetic observatory data. The many programs to replace analog systems with digital systems will also increase the utility of observatory data. The future for geomagnetic observatories is hopefully a bright one.

#### Introduction

The main task of a geomagnetic observatory is to observe the natural geomagnetic field for an extended period of time (at least 1 year) by performing continuous measurements of the three-dimensional geomagnetic vector. Observatory instrumentation is responsible for this measurement task. As we are dealing with a very wide-frequency spectrum of signals, whose characteristic times extend from centuries to subsecond intervals (see *Geomagnetic spectrum, temporal*), issues of

long-term instrument reliability, standardization of the instrumentation, continuity in data formats, as well as fast sampling capability are to be considered carefully. As only the natural geomagnetic field is of interest here, observatory instrumentation should be completely nonmagnetic: it should not modify the direction or amplitude of the geomagnetic vector in a measurable way. If, however, the sensors are magnetic, or produce magnetic fields for the sake of the measurement procedure, it must be ensured that those effects are eliminated by the measurement protocol and that no perturbation on neighboring instruments arises.

For the instrumentation to perform successfully, the observatory must answer to strict magnetic conditions: low magnetic gradient and identity of field changes over the area. Moreover, one is led to consider the whole observatory site as part of the observatory instrumentation; hence the quality of measurement depends on the magnetic hygiene of the surroundings and the buildings, on low magnetic noise conditions, as well as on the stability of the pillars bearing the field orientation in observatories can be found in Jankowski and Sucksdorff, 1996.

#### Short history

The first magnetic observatory instrument-the magnetic compasswas discovered in China already before the year A.D. 1000. Early observatories-starting in the 16th century-used an oversize compass needle so as to ensure sufficient resolution on the declination angle. The compass was later complemented by the dip circle for measuring the magnetic inclination. Still later, projected field components would be measured by using setups with current-carrying coils and calibrated magnets. A (virtual) visit to the Museum of the History of Science in Florence will allow you to see those early instruments. Continuous observations were performed by an observer making a reading every 2 h or so and writing the values down in a notebook. The photographic paper recorder appeared in the 19th century, allowing uninterrupted graphical registration of the field. The invention of the fluxgate in the early 1900s permitted the development of the triaxial electronic variometer and the DI-flux, which are in use today in most magnetic observatories. The introduction of the proton precession magnetometer (Packard and Varian, 1954) allowed an important operational simplification and improvement in the measurement accuracy of the magnetic induction (see Instrumentation, history of ).

#### Geomagnetic metrology

To completely describe the geomagnetic vector, each measurement must sample three independent vector components. The three most popular coordinate systems for describing the geomagnetic vector are:

Cartesian: X (North component), Y (East component), Z (vertical component, positive downward).

Cylindrical: D (magnetic declination angle, positive East), H (horizontal component).

CRLF: Z Spherical: D, I (magnetic inclination angle, positive downward), F (magnetic field induction intensity).

Component magnetometers will measure projections of the vector with a large constant part, like X and Z, while orientation magnetometers will be sensitive to the orientation of the field with respect to the sensor and measure small projections like D or Y. Component and orientation magnetometers are not yet capable of continuously measuring all the field components with the required absolute accuracy. Therefore, an observatory measurement setup uses:

- a variometer to measure the variation of the field components about baseline values in a continuous and unattended way at the required sampling rate, say 1 Hz and
- absolute measurements performed regularly (say 2 per week) by an observer with the adequate instrumentation (DI-flux, proton magnetometer; see Figure O4) to establish the values of the baselines.

**Figure O4** Instrumentation as used in most magnetic observatories of the world. The left panel represents a triaxial fluxgate variometer sensor. Right panel: the DI-flux magnetometer mounted on top of the pillar consists of a nonmagnetic theodolite with a fluxgate sensor on its telescope. In the foreground, an Overhauser proton magnetometer consisting of the cylindrical sensor and the electronic console.

This makes the observatory measurement essentially a two-step process, where the second part is performed manually. Postprocessing merges the two data sets to produce a final data record having the accuracy of the absolute instruments at the variometer's sampling rate. The expression "absolute measurement" means here that the observations must be fully traceable to metrological standards for the magnetic induction and that the orientation of the geomagnetic vector is measured with respect to the local vertical and to geographic north.

It is expected that in the future fully automatic observatories will be available (see *Observatories, automation*) where the absolute measurement part will be also unattended. Observers are striving to make absolute measurements with an accuracy of 0.1 nT for inductions and 1 s of arc for orientation. The INTERMAGNET consortium (see *Observatories, INTERMAGNET*) has laid down observatory instrumentation specifications for its members. This conveniently provides guidelines for observatories wishing to upgrade their instrumentation.

In less-modern observatories, variometers consist of suspended magnets and magnetic balances (Wienert, 1970). The continuous record of the field's components is recorded as curves on a piece of photographic paper, the magnetogram. Elongated axial magnets, suspended so as to rotate freely around the vertical, will orient their magnetic axis along the geomagnetic meridian, and will thus indicate its direction, providing a declination variometer. If an auxiliary stationary magnet creates a bias field so as to position the suspended magnet with its magnetic axis east-west, the suspended magnet's motion will follow the changes in the horizontal component, allowing it to be recorded. Magnetic balances compare the torque exerted by the vertical component on a magnet with the one exerted by gravity on a constant mass using a knife-edge balance. In all cases, the recording of the magnet's motion is ensured by a light beam falling on a mirror at the magnet's extremity. The horizontal beam, deflected by this mirror, will impress a time-dependent curve on a vertically streaming photographic paper. The streaming speed is usually about 20 mm  $h^{-1}$ , but for rapid run magnetographs it may go up to 200 mm  $h^{-1}$ .

In modern observatories, the most popular magnetometers are based on the proton precession effect and the fluxgate sensor. In former Soviet bloc countries, the Bobrov magnetometer, which consists of a magnet suspended by a taut quartz fiber, is successfully used in its servo version, where the magnet's orientation is kept fixed by the action of a coil. The coil current is easily fed to a digital data acquisition system to produce computer readable files.

#### The proton precession magnetometer

It is used in observatories for measuring the magnetic induction *B* in the range of  $10-100 \ \mu\text{T}$  with accuracy down to 0.1 nT. Here the free precession frequency *f* of protons is the observable and the formula

$$2\pi f = \gamma_p' B \tag{Eq. 1}$$

allows the measurement of the magnetic induction by way of the measurement of a frequency. The standard for the magnetic induction is thus conveniently converted to a frequency standard, which is widely available. The quantity  $\gamma'_p$  is the proton gyromagnetic ratio at low field for a spherical H<sub>2</sub>O sample at 25 °C. The recommended value given by CODATA and adopted by IAGA in 1992 is (Cohen and Taylor, 1987)

$$\gamma'_{p} = 2.67515255 \mathrm{T}^{-1} \mathrm{s}^{-1} \tag{Eq. 2}$$

The sensor consists of a bottle containing the proton-rich fluid and is surrounded by a coil, serving the dual purpose of applying periodically a polarizing field to the liquid and picking up the signal from the precessing protons after cutting off the polarizing field. An electronic console will amplify the precession signal and perform a frequency measurement of it with the required accuracy. This measurement is then scaled using  $\gamma'_p$  to give the field induction intensity in teslas.

This quite remarkable instrument is one of the few sensors able to measure directly the modulus of a vector without using computation from components or performing a leveling or tedious orientation procedure. This is of course due to the fact that the free protons have only the ambient magnetic field to orient themselves.

Modern proton magnetometers can be quite compact and have high resolution and sampling rate (0.01 nT and 3 Hz are typical). The Overhauser types (Sapunov *et al.*, 2001) in particular are responsible for this progress and have the additional benefit of low power operation. They are therefore a first choice in modern observatories instrumentation, providing automatic and continuous observation of the geomagnetic induction field intensity.

#### The optically pumped magnetometer

Optically pumped magnetometers (OPM) are based on the splitting of the energy levels of some alkali metal and helium atoms in a magnetic field. The optical pumping scheme allows measuring this energy splitting with very high resolution (Alexandrov and Bonch-Bruevich, 1992).

OPMs have been used at magnetic observatories, both for total field modulus measurement and, when complemented by a set of bias coils, for observing the geomagnetic field direction changes. One of the first digital observatories was based on a rubidium OPM (Alldredge and Saldukas, 1964).

Like proton magnetometers, the OPMs are scalar magnetometers but, to the contrary of the proton magnetometer, deliver a continuous stream of data, in the form of a frequency modulated by the value of the field. This frequency, with name of Zeeman, is linked to the measured magnetic induction by the Breit-Rabi polynomial formula. In a few cases, when the Zeeman peaks corresponding to the different energy-splits in the atoms are resolved, the polynomial coefficients can be calculated from fundamental physical constants, and the OPM has then absolute accuracy. This is the case of the OPMs based on potassium, <sup>3</sup>He, and <sup>4</sup>He vapor (Alexandrov and Bonch-Bruevich, 1992; Gilles *et al.*, 2001).

OPMs have a high sensitivity with some approaching the 0.1 pT  $Hz^{-1/2}$  noise level. This performance makes them attractive for prospection work, aeromagnetic survey, space-based observations, and field stabilizers. However their high initial and maintenance cost due to the short lifetime of the gas-discharge pumping lamp has limited their use in the observatory. It looks like this deficiency will be overcome in the future in view of quick progress in laser-pumping lamps (Gilles *et al.*, 2001).

#### Induction coil magnetometer

The induction coil (or search-coil) magnetometer's (ICM) operation principle is based on the Maxwell equation which can be written in integral form as

$$e = -\frac{\mathrm{d}\Phi}{\mathrm{d}t},$$

where e is the electromotive force (emf),  $\Phi$  is the magnetic flux, and t is the time. In its simplest form an ICM contains a coil with many turns of copper wire connected to the input of a voltage amplifier.

As it is seen from the equation, an ICM can be used only for the measurement of a time-varying magnetic flux. Its component collinear to the coil's axis intercepts the coil loops and generates an emf at the coil's terminals, which is further amplified to an easily measurable level.

To increase the ICM sensitivity, a high permeability ferromagnetic material is used as a core inside the multiturn winding. Due to their relative simplicity, ICMs are widely used for many applications, mainly in geophysics. In geomagnetic observatories they are used for the study of Earth's magnetic field pulsations.

Their operational frequency band covers from about  $10^{-4}$  till  $10^{+7}$  Hz and the measurement dynamic range covers the range from fractions of femtotesla till tens of tesla. In spite of an apparent simplicity, the creation of a high-class ICM needs complicated calculations to establish an optimal matching of the sensor coil with the amplifier (Korepanov *et al.*, 2001).

#### The fluxgate magnetometer

This instrument is used for measuring the component of the magnetic field vector along its sensor's axis. The fluxgate principle uses the nonlinear field/induction relationship of an easily saturable ferromagnetic core. The core, usually a rod or a ring, is subjected to both the DC field to be measured, and an auxiliary AC field produced by a coil and an electronic oscillator. This offset sinusoidal excitation will create a distorted AC signal, in a pick-up coil surrounding the core. The detection of its even harmonics provides a DC signal proportional to the field to be measured.

Fluxgate sensors work best in small axial fields, therefore they are often operated within a third current-carrying coil, which cancels off the main part of the DC field. This main part may be calculated by a servo scheme, or be constant. Otherwise, the fluxgate sensor is operated with the field essentially normal to the sensor, resulting in a small field component along the core axis. The fluxgate will then be sensitive to its orientation to the field.

Observatory fluxgate variometers will include three fluxgate sensors arranged orthogonally on a stable support made of marble or quartz. This trihedron is then oriented by the variometer frame according to the three components set one wishes to observe (see Figure O4).

#### Absolute measurements of declination and inclination

Measuring the orientation of the geomagnetic vector with respect to a coordinate frame pointing to the geographic north and to the local vertical represents a metrological challenge, especially if one wishes to attain 1" direction accuracy on this fluctuating vector. In fact, several measurements are taken so as to correct for systematic instrumental defects. Therefore the variometer of the observatory is used for taking into account any field changes during the measurement procedure. The state of the instrumentation art is now provided by a device called "DI-flux" or "DIM," which is assembled from a nonmagnetic theodolite and a fluxgate sensor mounted on the telescope. The magnetic axis of the fluxgate should be nearly parallel to the optical axis of the telescope (see Figure O4). With a DI-flux so configured, a measurement protocol suggested by Lauridsen (1985) allows the error-free determination of D and I.

# **OBSERVATORIES, AUTOMATION**

In 1847 magnetic recording by photography was introduced at the Royal Observatory at Greenwich. This early example of observatory automation was prompted by the difficulty and expense of maintaining a schedule of hourly observations coupled with the scientific desire to see a fuller spectrum of magnetic variations. Economics is a major factor behind the present-day move to automate as many observatory operations as possible. If Canada, for example, were to place a full-time observer at each of its 13 observatories, the cost of operating the network would roughly double. Fully automated observatories can be deployed in remote locations where staff is unavailable, including the ocean bottom. Automation is also a natural consequence of the necessity for observatories to meet the present-day scientific requirements for digital data. Digital magnetometer systems naturally lend themselves to automation.

All aspects of observatory operations are subject to full or partial automation: (1) data collection, (2) data telemetry, (3) data processing, (4) data dissemination, (5) error detection, and (6) absolute observations. The natural end point of the automation process is an automatic magnetic observatory (AMO). Not all aspects of observatory operations need to be completely automated for the observatory to be considered an AMO. However, (1), (2), and (6) must be fully automated and (3), (4), and (5) must be at least partially automated. Although

several systems previously or currently in use have been called "automatic observatories" none truly deserves the designation.

Observatories may be classified as fully staffed if there is an operator on duty everyday, unstaffed if the observatory is visited less than once per month, or partially staffed if visits to the observatory fall between these two extremes. A fully staffed observatory may be highly automated; an unstaffed observatory must be highly automated. Regardless of the level of staffing or the degree of automation, the quality of the data obtained from the observatory should meet accepted international standards such as those promulgated by INTERMAGNET. In particular, the final data disseminated by the observatory should have an absolute accuracy of better than 5 nT, so that data may be used to study secular variation and other long-period changes in the magnetic field. The requirement for absolute accuracy, as opposed to relative accuracy, distinguishes magnetic observatories from other magnetometer installations. To define absolute accuracy consider the difference between the true value of the magnetic field, B, and the reported value, Br; given by  $\delta = \epsilon + \sigma$  where  $\epsilon$  denotes a slowly varying or systematic error and  $\sigma$  denotes a random error. To achieve high absolute accuracy,  $\epsilon$  is treated as a parameter that can be determined through a series of calibration, or "absolute", observations that are used to correct the output values of the magnetometer. If data are only used to study short-period variations, relative accuracy, rather than absolute accuracy, is important. We assume that  $\epsilon$  remains constant over the time interval  $t_2-t_1$ , so that the difference  $Br(t_2)-Br(t_1)$  will accurately represent  $B(t_2)-B(t_1)$ , provided  $\sigma$  is small, even though  $\epsilon$ , and therefore  $B(t_1)$  and  $B(t_2)$  are not accurately known.

Alldredge (1962) designed a highly automated system, ASMO (Automatic Standard Magnetic Observatory) which was intended to produce outputs similar to those obtained by scaling standard magnetograms. However, since 1-min values were recorded to tape, it was obvious that many additional types of analyses could be carried out. ASMO consisted of a rubidium magnetometer located at the center of a two-axis Helmholtz coil system. This was oriented such that the total vector field would be biased to produce sequential changes in the angle of declination and inclination. When installed at Castle Rock, California, the system featured data transmission via telephone line to a receiving and recording center 160 km away (Blesch, 1965). Thus, it fulfilled several, but not all, of the requirements of an AMO.

The fluxgate magnetometer rapidly superceded the vector proton magnetometer as the primary instrument in automated systems. For example, AMOS, deployed in Canada in 1969 (Delaurier et al., 1974), consisted of a triaxial fluxgate sensor mounted inside a square Helmholtz coil system so that the sensor essentially operated in zero field. D, H, Z (and F) were sampled every minute and recorded on tape. By 1974, it was agreed that the system was at least as reliable as the photographic recorder it was intended to replace and could in fact record large, dynamic magnetic storms, which the photographic system was incapable of recording. AMOS featured an innovative telephone verification system (TVS) that permitted remote diagnosis of malfunctions. Given the lack of stability of fluxgate magnetometers of that era, the deployment of AMOS did not eliminate or reduce the need for absolute observations. There was no longer a need for full-time personnel at the observatories, but part-time contractors were still needed to perform absolute observations and other minor duties. Thus, of the six areas of automation, AMOS addressed only the areas (1) and (5).

Other early systems that incorporated fluxgate magnetometers include those installed at Erdmagnetisches Observatorium Wingst in 1980 (Schultz, 1983), at British observatories in 1979 (Forbes and Riddick, 1984) and at French high (southern) latitude observatories in 1972 and at Chambon-la-Forêt (Bitterly *et al.*, 1986).

By the mid-1980s advances in magnetometry, computers, and telemetry increased the possibilities for automation. Although developments took place in many countries, the UK and United States (quickly joined by France and Canada) spearheaded a movement to establish modern standards for digital magnetometers and data. The initiative, which evolved into INTERMAGNET, also promoted rapid telemetry and automatic dissemination of data. Any observatory that adopts INTERMAG-NET standards and specifications will possess a system capable of providing digital data that can be collected, processed, and distributed automatically. Such an observatory will typically possess a late generation fluxgate magnetometer system controlled by and recording data to a computer or other microprocessor-controlled data collection platform (DCP). Data will be filtered in the DCP to form 1-min values, which will be transmitted by satellite or phone line to the host institute and/ or an INTERMAGNET geomagnetic information node (GIN), where, after some basic error checking, they can be obtained automatically by users. Thus an INTERMAGNET observatory is likely to achieve complete automation of (1), almost complete automation of (2), and at least some automation of (3) and (4).

One of the first such systems was ARGOS (Automatic Remote Geomagnetic Observatory System), which became operational at the three UK observatories in 1987. ARGOS consisted of a threecomponent fluxgate and a proton precession magnetometer controlled by a computer, which also acted as the data logger. Data were transmitted to a central office by phone line. The US system was similar in concept; however, it used a ring core fluxgate and the (GOES) for transmission of data. The Canadian system, Canadian magnetic observatory system (CANMOS), used the same fluxgate magnetometer as the US system and also used the GOES for data transmission. It also included an improved remote diagnostic system. The French system included an improved magnetometer operating in feedback coils. Similar automated magnetometer systems are now (2005) in operation at approximately 100 observatories.

Subsequent improvements to magnetometers and data collection systems have been concerned with magnetometer stability and sampling rates. Efforts have been made to make the output of the fluxgate magnetometer as stable as possible, thus reducing the need for independent absolute observations. Tilt-reducing sensor suspensions are capable of eliminating the effects of pier movement. Temperature coefficients of fluxgate magnetometers typically range from 0.1 to 1 nT K<sup>-1</sup> (Rasson, 2001) leading to errors of up to 10 nT. Temperature coefficients can be determined for some systems but for others it is simpler to keep the system at a constant temperature. Most observatories recognize the need of the scientific community for data at a faster sampling rate than 1-min; many are now providing 1-s data.

Many observatories currently rely on GOES, Meteosat, or GMS for telemetering 1-min data to the host institute. However, this method of telemetry is incapable of coping with the increasing need for near-real time 1-Hz data. The Internet, which is increasingly accessible at even remote locations, is becoming the method of choice for many institutes, which operate networks with satellite and phone systems serving as backup.

It is unlikely that data processing will ever be carried out without at least some human intervention. There will always be instances when judgment is necessary to decide on the validity of a datum or series of data. A certain amount of data processing may be carried out in the DCP; the rest is normally carried out after the data are received at the host institute. Tasks that have been automated include removal of large spikes, plotting of magnetograms, production of indices, computation of hourly means, and computation and addition of preliminary baselines. More difficult and perhaps impossible to completely automate are such tasks as detection and removal of small spikes, especially at auroral latitudes; handling of offsets; and calculation of final baselines, including the detection and removal of spurious absolute observations.

Sodankylä and Tromsö were the first observatories to use the Internet to display and download data (Linthe, 2001). Today many observatories have taken advantage of the World Wide Web to provide access to their data and products such as magnetogram plots, minute data (and faster sampled data as well), hourly, monthly, and annual mean values, indices, and observatory and network descriptions.

Automated error detection and diagnosis is extremely important when an institute runs a network of unstaffed or partially staffed observatories. Frequently the part-time operator at the site can be instructed on how to fix a problem once the nature of the problem has been established. In addition, some problems can be corrected remotely without on site human intervention. Tasks that can be performed remotely include rebooting the computer, adjusting the time, changing temperature of an instrument enclosure, adjusting pier differences, removing spikes or periods of bad data, and erasing old files. Parameters that can be monitored include temperature, humidity, pier tilt, and  $\Delta F$ , the difference between F measured with a proton magnetometer and F calculated from the values of a vector magnetometer.

To be considered a true AMO an observatory must either automate its method of performing absolute observations or, alternatively, construct as system that is so stable that absolute observations need be carried out infrequently. With one notable exception, the vector proton magnetometer (VPM) has been the instrument of choice for either of these approaches. One of the most successful of these has been Kasmmer (Kakioka Automatic Standard Magnetometer), first installed at Kakioka Observatory in 1973. Both the British and US systems have employed VPMs, known as DIDD (delta I-delta D) as a means of providing baseline control for the fluxgate magnetometers. Recently the US Geological Survey and the Eötvös Loránd Geophysical Institute of Hungary have collaborated to produce a highly stable DIDD featuring a compact spherical coil design. Evaluations of the system have proved encouraging (Pankratz, 1998; Csontos et al., 2001; Schott et al., 2001). Nevertheless, the DIDD is still susceptible to pier tilt and other forms of misalignment and can therefore be considered only quasi-absolute. Independent absolute observations are still required to meet the standards mentioned earlier. However, in a region otherwise devoid of observatories, one equipped with a good quasiabsolute DIDD would certainly be better than no observatory at all. Meanwhile, efforts continue to improve VPMs. In France, a <sup>4</sup>He pumped magnetometer is being developed which will eliminate the need for a coil system (Gravrand et al., 2001); consideration is also being considered to developing a tilt-compensating suspension for the Hungarian or US system.

A totally different approach to automating absolute observations has been taken by Rasson (1996): the automation of a declinationinclination magnetometer (DIM). The DIM consists of a single-axis fluxgate sensor mounted on a nonmagnetic theodolite; by rotating and tumbling the telescope in a prescribed manner the angle of declination and inclination can be obtained. Rasson has been able to automate this process through the use of piezoelectric motors, digital readout of the circles, accurate recording of tilt and the use of an autocollimator for sighting the reference mark. Development is also underway of an alternative version using a north-seeking gyroscope to eliminate the need for a reference mark; this would potentially make it possible to install the device on an ocean bottom observatory magnetometer, thus fulfilling a long-standing dream of the observatory community.

Observatories, INTERMAGNET Observatories, Overview

# **OBSERVATORIES, INTERMAGNET**

INTERMAGNET (*International Real-time Magnetic* Observatory *Network*) was created in order to establish a worldwide network of cooperating digital magnetic observatories. Those observatories agree to adopt modern standard specifications for measuring and recording equipment and to exchange data in close to real time. Moreover, INTERMAGNET extends technical support for maintaining and upgrading existing magnetic observatories as well as for establishing new ones.

INTERMAGNET defines standards for the measurement and recording of the geomagnetic field, considering the state of the art (see *Observatories, instrumentation*). INTERMAGNET is constituted from existing groups whose task is geomagnetic observatory measurement. The abbreviation IMO is used to indicate an INTERMAGNET Magnetic Observatory (Green *et al.*, 1998).

#### Short history

The idea of a near real-time observatory network arose independently from discussions inside the Geological Survey of Canada and between US Geological Survey (USGS) and British Geological Survey in 1986 during an IAGA workshop in Ottawa (see *IAGA, International Association of Geomagnetism and Aeronomy*). The idea was expanded to a global concept at the International Union of Geophysics and Geodesy (IUGG) assembly in Vancouver in 1987 as Institut de Physique du Globe de Paris joined. The network was based on magnetic observatories communicating as meteorological data collecting platforms and transmitting

**Figure O5** INTERMAGNET magnetic observatories as full squares and Geomagnetic Information Nodes (GIN) as crossed circles representing the global coverage in 2005. Open squares indicate some possible future IMOs.

their data to the meteorological satellites GOES and METEOSAT. Geomagnetic Information Nodes (GINs) in Golden, Ottawa, Hartland, and Paris equipped with downlinks collected the data from the satellites for archiving and distribution. The first transatlantic transmissions took place in late 1988 and by early 1990, four USGS, two Canadian, three French, and one British observatory were operating in INTERMAGNET mode. The first CD-ROM with definitive data (see below) from 41 observatories in 11 countries was produced in 1991.

The network predictably evolved by increasing the amount of IMOs and GINs, reaching 100 and 6, respectively, in 2005. The Geostationary Meteorological Satellite (GMS) (Japan) was added in order to cover the Asian continent. Where possible, data transfers by e-mail from IMO to GIN replaced satellite transmission, for reasons of simplicity and cost.

In 1997 a Web site was created at www.intermagnet.org

#### INTERMAGNET management

The Executive Council (EXCON totaling four members) establishes policy for INTERMAGNET, deals with questions of international participation and data exchange and communicates with national agencies and international scientific and funding agencies. It is assisted and advised by the 14 members of the Operations Committee (OPSCOM).

The OPSCOM advises the Executive Council on the technical issues that arise within INTERMAGNET. This includes matters relating to instrumentation, data processing, and communications. The committee is also responsible for establishing and maintaining standards and formats for the global exchange of data under the INTERMAGNET program, for designing and publishing the INTERMAGNET Technical Manual and producing the annual CD-ROM.

EXCON and OPSCOM meet about once a year for a few days in order to manage the network and plan for the future.

# The data

INTERMAGNET data consists of time series of the geomagnetic vector, sampled at the round minute and carefully filtered to avoid aliasing effects. This data, collected at the IMOs represented on Figure O5 (full squares), is continuously available from the GINs within 72 h. The data come in different accuracies: reported (as recorded—near realtime), adjusted (corrected for artificial spikes and jumps), and definitive (reduced to baseline so that it has absolute accuracy). The latter is made available a few months after the end of each year at the earliest and surely with the production of the yearly CD-ROM.

People needing real-time will use the reported or adjusted data, available from the GINs in daily ASCII files either in INTERMAG-NET imfv1.22 or IAGA 2002 format (e-mail request or ftp).

Access to the recent definitive data is through the Web site. Older data is available on the CD-ROMs. Definitive data come in monthly files in binary code. Browsers are available for easy perusal and inspection.

The data is freely available for *bonafide* scientific users. If any commercial aspects are involved, the user should seek a financial arrangement with the IMO directly.

All practical details about the data and for accessing them are available from the Web site where the Technical Manual is also available for download.

# The future

A large part of the activities of INTERMAGNET is devoted to improve the global coverage of its network. Therefore future activities will be oriented toward filling gaps in the network, mainly in the former Soviet Union, Latin America, and the oceans (see Figure O5). Many oceanic island sites are still available for installing new IMOs but lack of staff may impose fully automatic IMOs there (see *Observatories, automation*). Open ocean sites are required to obtain the ultimate global coverage (Rasson, 2001) and INTERMAGNET is keen to support and advise groups contemplating the installation of ocean bottom magnetic observatories.

Another development is the introduction of data sampling at 1 Hz, which is in demand from the space weather community. In 2003, INTERMAGNET defined an internal data file format (based on IAGA 2002 format) for interchange of this type of data. In the next years, it is anticipated that 1 Hz data will progressively become the norm in IMOs and that GINs will start disseminating and archiving them.

OBSERVATORIES, PROGRAM IN AUSTRALIA

The first Australian magnetic observatory was "Rossbank" Observatory at Hobart, established in 1840 by the British Association with support of the Royal Society during an expedition led by Captain James Clark Ross in command of HMS Erebus and HMS Terror (Savours and McConnell, 1982). Regular magnetic observations continued there until the end of 1854. By the initiative of Dr. Georg Neumayer an observatory was established by the Government of Victoria in Melbourne in 1858 (Dooley, 1958), beginning one of the longest continuous series of magnetic observations in the world (Figure O6). The original site of the Melbourne Observatory was in the Flagstaff Gardens but it was moved in 1862 to the Botanical Gardens, the geologically more suitable site originally chosen. Subsequent encroachment of electric tramways and railways forced the move in 1919 to Toolangi, where the observatory operated until 1986, at which time it had been replaced by the Canberra Magnetic Observatory. The Carnegie Institute of Washington's Department of Terrestrial Magnetism established Watheroo Magnetic Observatory in 1919 (McGregor, 1979), beginning the continuous recording of geomagnetic variations on the western side of the continent. The Bureau of Mineral Resources, Geology and Geophysics (BMR) was formed in 1946 (renamed the Australian Geological Survey Organization in August 1992; then Geoscience Australia (GA) in August 2001) soon after which both the magnetic observatories operating in Australia at that time were transferred to its geophysical observatories program. A new magnetic observatory at Gnangara replaced the Watheroo Observatory in 1958. The analogue variometer that operated at Watheroo was moved to Gnangara and operated until mid-1990 when it was replaced with digital instrumentation. In recent years there have been numerous burglaries and vandalism on the site and there are plans to relocate to a less vulnerable site in the vicinity.

In the 1950s BMR established observatories in the Australian Antarctic Territory (AAT) and sub-Antarctic islands. Macquarie Island Observatory, established in 1952 is still in operation. Apart from the short-lived observatory at Cape Denison, Commonwealth Bay, the first permanent observatory in AAT (which still operates) is at Mawson, established in 1955. The original instruments and buildings at Mawson came from Heard Island Observatory. Observatories at Wilkes (established by the USA IGY program), Port Moresby in Papua New Guinea, and Darwin were completed in time for the 1957–1958 International Geophysical Year (IGY). Wilkes Observatory was transferred to the Australian Government after the IGY and operated by BMR until its closure in 1967. Observatory operations were are also maintained at Casey and Davis in collaboration with the Australian Antarctic Division (McGregor, 2000).

Absolute control at Davis ceased in 2001. The observatory at Port Moresby was established by BMR and operated from 1957 to

mid-1995. It was transferred to the Geological Survey of Papua New Guinea in 1978. Absolute control ceased when the absolute magnet-ometers were stolen in November 1993.

The observatory at Canberra was established in 1978 after the Observatories Group of the BMR was transferred from Melbourne to Canberra in the early 1970s. As Canberra was eventually to replace Toolangi Observatory, and so contribute to a number of global geomagnetic indices, it was important to operate both observatories for as long as possible to enable the *K*-indices from the observatories to be statistically compared and station differences to be established. Routine absolute observations at Toolangi ceased in 1979 although the variometers continued and *K*-indices were scaled until early 1986.

Before Canberra Observatory was commissioned, all BMR's magnetic observatories made analogue recordings on photographic paper, from which hourly mean values were scaled. Since its beginning in 1978 only digital instrumentation has operated at the Canberra Observatory. All observatories commissioned subsequently were equipped to digitally record variations in three orthogonal components as well as the total field, initially at 1-min intervals, but presently at 1-sec intervals.

In 1983, the first of a new generation of digital observatories in Australia was established at Charters Towers. The variometers are installed deep within a disused mine tunnel in the side of a hill on the site of the Seismograph Station. The Learmonth Magnetic Observatory was installed on the site of the Learmonth Solar Observatory (operated jointly by the Australian Ionospheric Prediction Service and the US Air Force) in late 1986. Small concrete vaults in the ground house the variometer and proton magnetometer sensors. In mid-1992 an observatory was established at Alice Springs on a compound of the CSIRO Arid Zone research. It remains the only Australian observatory further than 120 km from the sea and so free from oceanic induction effects. The variometers are housed in concrete vaults similar to those at Learmonth.

The most recently established observatory is that at Kakadu in the Northern Territory, located on the South Alligator Ranger Station of the Australian Nature Conservation Agency, where recording began in March 1995. Problems with lightning strikes have plagued the observatory, resulting in a number of long breaks in data acquisition and instrumentation changes.

All Australian observatories now have 1-sec digital computer-based data acquisition with data available in near real-time via either dial-up or network connections.

The main basis of the 5-yearly regional field models is the large collection of ground, airborne, marine, and satellite survey data. Observatory data, supplemented by repeat station data provide the main basis for the secular change part of the models. Together with the ongoing repeat station surveys comprising 15 super repeat stations that cover Australia, South-West Pacific Islands, and Papua New Guinea, it has been estimated that, together with the New Zealand and Indonesian observatories, GA's Geomagnetism program monitor variations of the Earth's magnetic field over approximately an eighth of the Earth's surface. Figure O7 shows the current Australian Observatory network and super repeat stations.

Calibration of observatory variometers is achieved by regular absolute observations with magnetometers that have been extensively intercompared. Final observatory data are thus consistent across the continent. Past calibrations of quartz horizontal magnetometers (QHMs) at the Danish Meteorological Institute and recent intercomparisons at IAGA Geomagnetism Workshops have ensured Australian absolute magnetometers are kept to international standards. Since the 1980s, classical absolute magnetometers have gradually been replaced by the declination and inclination magnetometer (DIM) together with the proton precession magnetometer (PPM) as the principal means of calibrating the observatory variometers. The accuracy of data produced by the Australian observatories has been enhanced by the availability of a magnetometer calibration facility at the Canberra Magnetic Observatory, in operation since 2000, providing highly accurate scale-values, relative sensor orientations, and temperature sensitivities of three-component observatory

**Figure O6** Annual mean values in magnetic declination, vertical intensity, and horizontal intensity from the succession of observatories at Melbourne, Toolangi, and Canberra adjusted to Canberra; and Watheroo and Gnangara adjusted to Gnangara.

variometers. These parameters were previously derived from sequences of absolute observations through baselines.

Although the emphasis of GA's program in geomagnetism is toward solid-earth geophysics, with a time resolution of 1 s and observational accuracy of the order of tenths of a nanotesla, information of relevance to upper-atmospheric, magnetospheric, and solar physics is available. One-minute vector data and hourly mean values are regularly provided to the world data centers in Boulder, USA and Copenhagen, Denmark. Data from most observatories are also transmitted by e-mail daily or more frequently to the Edinburgh GIN of the INTERMAGNET project.

Figure O7 Locations of magnetic observatories (named squares) and super repeat stations (round dots) operated by Geoscience Australia in 2005.

*K*-indices are is scaled from magnetogram records from the Canberra, Gnangara, and Mawson observatories, applying the classical method of hand-scaling until late 2002. As this index is still in demand, and as no computer algorithms has quite been able to emulate the results of manual scaling, a computer-assisted method of manual scaling has been developed at GA. Using the LRNS (Hattingh *et al.* 1989) algorithm to produce an estimate of the undisturbed daily (regular solar or SR) variation that overlays the daily magnetogram on a computer screen, the SR curve is manipulated on the screen into a form that would be applied if scaling manually. Australian observatories contribute toward the global Kp-index and its derivatives, the aa-index and the am-index.

GA maintains a corporate database that has been gradually populated with data and information from all projects undertaken by the organization. There is a long history of geomagnetic operations at GA as well as holdings of data acquired before the organization existed. Software has been developed that enables geomagnetic data to be loaded into the corporate database as soon as it is transmitted to headquarters. This, together with the steady population with historical data, has allowed access to Australian geomagnetic data via the Internet.

Detailed descriptions of the observatories, their operations, histories, and data summaries can be found in the *Australian Geomagnetism Report* series, especially from 1993 when the contents of the report was expanded beyond monthly summaries. The more recent issues are available on the GA Web site: http://www.ga.gov.au

# OBSERVATORIES, PROGRAM IN THE BRITISH ISLES

#### History

In his survey of magnetic observatories that have operated in the British Isles, Robinson (1982) lists 18 locations, including 11 in England, 4 in Scotland, 2 in the Republic of Ireland, and 1 on the island of Jersey. The earliest two observatories were both constructed in 1838: in the grounds of Trinity College, Dublin; and in Greenwich Park, London, where an astronomical observatory had been established following a warrant issued by King Charles II in 1675. The earliest known measurement of magnetic declination at Greenwich is that made by John Flamsteed in 1680, and declination measurements were made there regularly from 1816, to assist in the calibration of ships' compasses. The initial program of observations at Dublin and Greenwich consisted of two-hourly measurements. Both observatories, along with that at Makerstoun in Scotland, participated in the Göttingen Magnetic Union (1836-1841), which promoted simultaneous measurements at cooperating observatories, and certain days were designated "term days" when observations were made every 5 min. A British artillery officer, Edward Sabine, was a chief protagonist of the efforts by the Göttingen Magnetic Union to establish a global network of observatories, and through this, several observatories were set up by the British in its colonies at the time (see Gauss, Carl Friedrich; Humbolt, Alexander von; Sabine, Edward; and Geomagnetism, history of).

The laborious nature of meteorological and magnetic observations stimulated a drive to develop automatic recording devices, and Charles Brooke designed the photographic magnetographs that were brought into operation in Greenwich in 1847 (Brooke, 1847). Francis Ronalds, working at Kew Observatory, which had been built at Richmond, London, for King George III to observe the transit of Venus in 1769, also produced a photographic magnetograph at around the same time as Brooke's. Ronalds' instrument was later redesigned by John Welsh to produce the Kew-pattern magnetograph that was subsequently installed in many observatories around the world (Stewart, 1859). The instrumental developments by Brooke and Ronalds established the standard technique employed for magnetic observatory recording worldwide for more than a century (see *Instrumentation, history of*).

Observations at Dublin Observatory were short-lived, continuing only until 1850. A meteorological observatory was established on Valentia Island, Kerry, in 1867 and regular absolute magnetic observations commenced there in 1888. The observatory was moved to the mainland, close to the town of Cahirciveen, in 1892, but kept the name Valentia Observatory. Continuous recording instruments were first installed in 1953. Met Éireann, the Irish meteorological service, now runs the observatory.

Geomagnetic measurements in London were to become impossible because of electrification of the railway and tramway systems. Kew Observatory suffered disturbances from about 1900 and with compensation from the tramway company responsible, Eskdalemuir Observatory, in the Southern Uplands of Scotland, was built. Eskdalemuir was selected as one of very few places in Great Britain that was more than 10 miles from the then extensive rail network. Construction work at Eskdalemuir started in 1904 and a full program of magnetic observations began in 1908. Later, the geomagnetic work carried out at Greenwich was similarly affected and was transferred to Abinger Observatory, on Leith Hill, London, in 1924. Observations were made there until April 1957 when, once more, disturbances from electrified railways reached intolerable levels. A transfer of operations was planned and a magnetic observatory was constructed close to the village of Hartland, Devon. Hartland Observatory opened in 1957, in time for the observatory to participate in the International Geophysical Year (IGY). Overlapping measurements were made at the times of the Greenwich-Abinger and the Abinger-Hartland moves, establishing site differences and enabling the records from the three observatories to be combined.

Lerwick Observatory in the Shetland Isles was established as a meteorological station in 1919 and geomagnetic measurements began there in 1922. Lerwick, Eskdalemuir, and Hartland are the three magnetic observatories in operation in the UK in 2005. They are run by the British Geological Survey (BGS), a component body of the Natural Environment Research Council. Lerwick and Eskdalemuir continue to have roles as meteorological stations, and seismological equipment is operated at all the observatories.

#### **Observatory operations in 2005**

The main objective of a magnetic observatory is to record geomagnetic field variations continuously, over the long term, at a stable location, and to maintain the accuracy required to produce data of the quality needed for studies of the slow changes of the main geomagnetic field generated in the Earth's core, the secular variation. The combination of magnetographs, based on suspended magnet instruments and photographic recording, supported by regular absolute observations, enabled the UK observatories to achieve this objective over many decades. However, the observatory operations were labor-intensive, both in running the magnetographs and in processing the analog photographic recordings. By the 1970s, technical developments in fluxgate and proton precession magnetometers gave an alternative set of observatory instruments, and advances in digital data acquisition and computing presented new opportunities for observatory automation. The BGS began a development program, and automatic digital systems were adopted as the observatory standard recording equipment at the three UK observatories on January 1, 1983 (see Geomagnetic secular variation; Observatories, instrumentation).

Since 1983, technology has continued to develop, bringing significant improvements to magnetometer performance and data acquisition and communications. The latest generation systems used at the UK observatories were commissioned on January 1, 2003, again based on the combination of fluxgate and proton precession magnetometers. The fluxgate magnetometer output is sampled once per second and the data are transmitted to the BGS offices in Edinburgh within minutes. A fluxgatetheodolite combination is used to make regular (manual) absolute measurements of magnetic declination and inclination, with the proton magnetometer providing absolute values of total field strength.

Instruments similar to those at the UK observatories are used at Valentia Observatory. Efforts to improve the global coverage of observatories continue and to this end observatories were set up by the BGS on Ascension Island and at Port Stanley in the Falklands Islands in 1992 and 1994, respectively.

#### Uses of the observatory data

In 2005, the combination of data from magnetic survey satellites, such as Ørsted and CHAMP, and observatories worldwide, is providing a rich resource for research into core processes. The data also bring practical benefits through their use in the production of global and national magnetic field models and charts used for navigation. Here, observatory data are of great importance because of the information they give on the secular variation, providing the basis for estimation of future values of the geomagnetic field at a given location (see Ørsted; CHAMP; Main field maps; Main field modeling; and IGRF, International Geomagnetic Reference Field).

Observatories also provide data on the relatively rapidly varying magnetic fields of ionospheric and magnetospheric origin. These "disturbance fields," indicative of "space weather" conditions, are characterized by various geomagnetic activity indices (Mayaud, 1980). Each of the UK observatories has provided data for the computation of the Kp-index since its creation in 1932. Data from the Greenwich-Abinger-Hartland series, together with data from Australian observatories, have been used to construct the aa-index, which extends from 1868, providing valuable information on long-term changes in solar-terrestrial interactions. (Both the Kp- and the aa-indices are computed for 3-h intervals.) When space weather conditions are such that a major geomagnetic disturbance, a magnetic storm, is in progress, operations in space and on the ground can be at risk. Global geomagnetic activity indices, such as Kp, are used widely as measures of disturbance. Satellite management, assessment of propagation conditions for radio and GPS signals, and geophysical surveying are examples of applications where indices are used (see *Storms and substorms, magnetic* and *Geomagnetic hazards*).

By collecting 1-s samples, the UK observatories are producing data useful for research into external magnetic fields. Data at this time resolution are required for, and are applied to, modeling geomagnetically induced currents, which is of interest to the electricity distribution industry. A further modern-day application, important to hydrocarbons production around the UK, is the use of accurate magnetic reference data to correct wellbore survey measurements acquired using magnetic survey tools. Data from the UK magnetic observatories are used in the analysis of data collected in measurement-while-drilling operations, and this application demands the rapid access to the data that the UK observatory operations provide. This application has resulted in observatories being set up on Sable Island, offshore Nova Scotia, and at Prudhoe Bay in northern Alaska by Halliburton with the assistance of the BGS.

# Outlook

Lerwick, Eskdalemuir, Hartland, Valentia, Ascension, and Port Stanley are all INTERMAGNET observatories and hence are members of a coordinated global monitoring network operating to high modern standards (see *Observatories, INTERMAGNET*). This echoes the participation of observatories in the British Isles and Empire in the Göttingen Magnetic Union. These observatories are providing data for scientific research, for global data products, and are also finding local applications for the data they produce. The scientific and "real world" demands for the data are as strong today as at any time in the past.

# **OBSERVATORY PROGRAM IN FRANCE**

The French contribution to the history of measuring the Earth's magnetic field is a long one, which began at least as early as the 16th century, with the first declination measurement performed by Künstler Bellarmatus in 1541. In 1667, the Académie des Sciences decided to build an observatory in Paris and take declination measurements. Before beginning construction, an initial measurement was made on June 21, 1667 using a 5-in. needle. Subsequent measurements were performed from 1667 onward, sometimes continued as a family tradition (La Hire, Cassini, Maraldi). There are fewer measurements of inclination than declination at the Paris Observatory, owing mainly to its late discovery; but also, it was of less interest to navigators, and presented a greater problem for accurate measurements. More details about the observations of declination and inclination in the Paris region are given in Alexandrescu *et al.* (1996).

The study of geomagnetism in France has benefited from the centralized nature of the French governments through the last centuries, as only a few site changes are to be noted, and a long continuous measurement series is now available. Indeed, the Paris series for declination and inclination span more than four and three centuries, respectively. The available annual means of declination (1541–2004) and inclination (1671–2004), adjusted to the Chambon la Forêt Observatory are presented in Figure O8.

*Chambon la Forêt—the French National Magnetic Observatory.* The year 1883 marks the creation of the French National Magnetic Observatory. This was installed successively at Parc Saint-Maur (1883–1901), Val-Joyeux (1901–1936), and Chambon-la-Forêt (1936 to present day), as a consequence of the encroachment of urbanization in the Paris area and of the resulting electromagnetic pollution. From the beginning of the 1980s, absolute measurements have been made using the same fluxgate theodolite and consistent procedures. Three field components are recorded continuously by three different fluxgate variometer systems, and the total field is measured by two Overhauser proton magnetometers. From these continuous time series, 1-min values are produced. Longer series, for example, hourly means (since 1936) or monthly means (since 1883) are also available.

*Bureau Central de Magnétisme Terrestre* (in 2004). The Institut de Physique du Globe de Paris (IPGP)<sup>1</sup>, the Ecole et Observatoire des Sciences de la Terre de Strasbourg (EOST)<sup>2</sup>, and the Institut de Recherche pour le Développement de Bondy (IRD, ex-ORSTOM)<sup>3</sup> are responsible for the magnetic observatories located in French territories or maintained in cooperation with local institutes in foreign countries. The IPGP, EOST, and IRD consolidate their activities in a "Bureau Central de Magnétisme Terrestre" (BCMT),<sup>4</sup> and they contribute to running 16 observatories in total (Table O1). Many of these are in the Southern Hemisphere or in regions of the world with few other observatories.

Some of the main tasks of the BCMT are (1) gathering the observatory data and publishing them according to the IAGA/INTERMAG-NET recommendations; (2) controlling installation and function of magnetic observatory equipments; (3) specifying procedures for data acquisition and processing; (4) disseminating observatory data and results by year-books and CDs; (5) maintaining continuous cooperation programs with international associations and local institutes in the various countries where the observatories are located.

*Cooperation programs.* Cooperation programs between BCMT and different institutes have been established, mainly to run observatories in remote areas where local support is lacking (Algeria, Central African Republic, China, Ethiopia, Lebanon, Madagascar, Russia, Senegal, Vietnam). All French observatories or those run in cooperation have

full absolute control, providing 1-min magnetic field values measured by a vector magnetometer, and an optional scalar magnetometer, all with a resolution of 0.1 nT (see *Observatories, instrumentation*). More details about the instruments used through time are given in Bitterly *et al.* (1999).

All of these observatories are operated according to the principles and conditions necessary and desirable for maintaining a service of rapid magnetic observatory data exchange. The daily data quality control, the weekly absolute measurements, and the definitive data processing are done according to INTERMAGNET standards (see *Observatories, INTERMAGNET*). The observatory data are used for many specific uses, from characterizing the magnetic activity to modeling magnetic field contributions (see *Observatories, overview*).

# **OBSERVATORIES, PROGRAM IN USA**

The Geomagnetism Program of the US Geological Survey has, for over a century now, monitored the Earth's magnetic field through a network of magnetic observatories and conducted scientific analysis on the data collected. The program traces its origins to the Reorganization Act of 1843, in which Congress authorized the creation of a coastal survey agency, as part of the Treasury Department, that was responsible for, among other things, geomagnetic surveys. The 19th century saw the establishment of relatively short-lived magnetic stations, as well as the production of declination maps for the United

Figure O9 The geographic distribution of USGS geomagnetic observatories, identified by their three-letter IAGA codes.

States and territories. With the purchase of Alaska, coastal surveys became an increasingly higher priority, and in 1889 the Coast and Geodetic Survey, with a Division of Terrestrial Magnetism, was established. The first essentially permanent geomagnetic observatories were established under the Division's leadership of Dr. Louis A. Bauer and Dr. John A. Fleming: Cheltenham Maryland Observatory was established in 1900, subsequently moved to the Fredericksburg site in 1956; Sitka Alaska Observatory was established in 1901 and that of Honolulu Hawaii in 1902. Soon after these observatories became operational, it was found that the Sitka and Honolulu magnetometers were also sensitive to local earthquakes, and so seismometers were installed at the sites. In part, because of this colocation of instruments, the magnetic and seismological programs in the Coast and Geodetic Survey were united in 1925 under the Division of Geomagnetism and Seismology. Over the years, the Geomagnetism Program has evolved in response to the needs of the United States and in response to changes in the nation's various federal agencies. In 1903 the Coast and Geodetic Survey was transferred to the newly organized Department of Commerce, and in 1970 the survey became part of the National Oceanic and Atmospheric Administration (NOAA). In 1973, the US Geological Survey of the Department of the Interior assumed responsibility for the nation's Geomagnetism and Seismology programs.

Today, Geomagnetism is one of four programs, in addition to the National Earthquake Hazards, the Global Seismic Network, and the Landslides Programs, represented by the USGS Central Region Geohazards Team in Golden, Colorado. Unlike the Earthquake Hazards Program, which supports many different projects, based primarily in Menlo Park and in Golden, the National Geomagnetism Program is a self-contained entity within the USGS and the team. A major part of the program is concerned with operating and maintaining magnetic observatories located in the United States and its territories (see Figure O9). The observatories, which have modern digital acquisition systems, are designed to produce long time series of stable magnetometer data having high accuracy and resolution. The observatory data are collected, transported, and can be disseminated in near-real time. The program has made a considerable investment in computing technology to enable efficient processing and management of data. By necessity, the network, and everything associated with handling the data, is technologically elaborate; it consists of many finely tuned components, each of which need to be operated in careful synchronization. The USGS observatories form an important part of the INTERMAGNET network, within which the USGS has an important leadership role. The USGS Geomagnetism Program,

working in cooperation with other Federal Government departments and bureaus, most particularly the NOAAs Space Environment Center and the US Air Force Weather Agency, is an integral part of the Federal Government's National Space Weather Program. Further details about the USGS Geomagnetism Program are available at http://geomag. usgs.gov

# **OBSERVATORIES IN ANTARCTICA**

# Some historical landmarks

The history of magnetic measurements in Antarctica and the surrounding oceans can be traced back to the expeditions looking for the South Magnetic Pole (see Fogg, 1992 for a review). Until the turn of the 19th/ 20th century, all measurements were performed at sea, on ships including Gauss (E. Drygalski expedition, 1901-1903) and Discovery (first R.F. Scott expedition, 1901–1904), both being equipped with a magnetic observatory (Lüdecke, 2003). The first confirmed landing (although certainly not really the first one), can be credited to C. Borchgrevink's expedition (1893-1895), whose party reached Cape Adare and made some magnetic measurements there (Fogg, 1992). If we define the Antarctic region as that being south of 60° S the longest span of data is that collected at the observatory of Orcadas del Sur (South Orkneys, IAGA code ORC). This observatory was founded by R.C. Mossman in 1903 during the expedition led by W.S. Bruce, 1902-1904, (Moneta, 1951). Many annual means of the magnetic elements are available from this observatory from 1905 up to now. Other early observatories had a rather short or intermittent life, for example, Hut Point (Discovery Bay) set up by the first R.F. Scott expedition (1902-1903), Cape Evans (1911-1912) opened during the tragic second expedition headed by R.F. Scott, Cape Denison (1912-1913) opened by D. Mawson, and Little America (ran intermittently at various locations from 1929 to 1958). Things changed after World War II. It seems that P.N. Mayaud pioneered this new era with the observatory of Port Martin built in 1951 (Mayaud, 1953). Unfortunately, the station burned down 2 years later. Neither the first International Polar Year (1882-1883), which came too early for Antarctica, nor the second IPY (1932-1933) that was launched during an economically depressed time gave to scientific activities in Antarctica. However, the first gave Geophysical Year (1957–1958) boosted the opening of several observatories increasing the total number from around 4 to 14. All of the observatories recorded field variations on analog photographic magnetograms according to common practice in use before the advent of digital records in the 1970s. The first reported digital records were performed at Dumont d'Urville in 1969.

#### Situation at the beginning of the 21st century

At present, more or less permanent sites may be divided into three types: standard observatories with or without regular absolute measurements, unmanned magnetometer chains devoted to external field studies, and repeat stations, the latter two being beyond the scope of this review. According to J.L. Rasson (2001), there are a total of 44 observatories in the region with data for various time spans.

Figure O10 Location of the magnetic observatories in Antarctica. Large full triangles: open; stars: INTERMAGNET observatories; small open squares: closed. Dotted lines: geomagnetic coordinates according to the 2005 IGRF model.

Figure O10 displays the locations of all known observatories with respect to both geographic and geomagnetic coordinates. It shows that only a handful of the observatories were located on the ice cap. Vostok is the only survival of this on-land group, not taking into account the new base currently opening at DomeC (French-Italian Concordia station, DMC). ORC is the only observatory, opened before the first IPY that continues its activity today. The time spans of the observatories set up around the first IPY are highly variable, ranging from 1 year to nearly the full interval 1957-2004. In 2005, there are around a dozen observatories still running. To be termed as observatories it is necessary that they yield relative records complemented by baseline control afforded by absolute measurements. The quality of this control is variable. It ranges from episodical measurements performed during summer campaigns to measurements made regularly throughout the year at the staffed bases hosting qualified observers. There are currently three INTERMAGNET observatories (AIA, DRV, and SBA) in the region (see Observatories, INTERMAGNET).

The history of magnetic observatories in Antarctica closely reflects the history of the exploration of this mysterious and barely accessible continent. Their data are particularly useful for southern auroral and polar cap studies as well as tracking changes in the main field in this large region.

# **OBSERVATORIES IN BENELUX COUNTRIES**

#### Introduction

Benelux is a small geographical entity, which encompasses the countries Belgium, the Netherlands, and The Grand Duchy of Luxembourg. Although the Benelux countries cover a small area, there has been interest there for magnetic observations since early on. As a result, many observatories have been created by the Benelux countries at home and abroad. Luxembourg has no observatory of its own, only field geomagnetic measurements have ever been made (Flick and Stomp, 2002).

# Short history

The Dutch scientist Pieter van Musschenbroek was the first to continuously observe the magnetic declination starting 1728 in Utrecht and later Leiden until 1758. These measurements initiated a long series of observations in the Netherlands, with additional observatory locations in De Bilt (1898) and Witteveen (1938). However, in 1988 the management of the Dutch Meteorological Institute KNMI decided to stop funding magnetic observations in the Netherlands. This effectively ended the 260-year data series in the Netherlands (Schreutelkamp, 2001).

It was also the Dutch who decided in 1826 to build a magnetic observatory in Brussels. This was masterminded by the scientist Adolphe Quetelet and the institution was created almost at the time of the birth of the Belgian state. The location of the observatory changed three times within Brussels, because of the presence of local anomalies. In 1888 the observatory was located in Uccle at the outskirts of the Belgian capital. The century long series in Brussels had to be interrupted completely in 1952 due to cultural noise, while a new observatory was being constructed in the Namur province. This became the Dourbes (DOU) magnetic observatory in use today. It joined the INTERMAGNET consortium in 2002 (see *Observatories, INTERMAGNET*).

The University of Liège recorded the geomagnetic field in Cointe starting 1880, but its first full-size observatory was built in Manhay (MAB) for the International Polar Year (IPY) of 1932–1933 by Marcel Dehalu. DOU staff took over MAB operation in 1990.

# Worldwide dissemination

The founding of the Dutch Royal Magnetical and Meteorological Observatory at Batavia, Indonesia, starts the dissemination of worldwide observatories from the Benelux countries, with the first "exotic" magnetic data being recorded in 1884. Magnetic observations are still being made near Jakarta today, although the site of the observatory had to be moved first to Kuyper and finally to Tangerang to avoid cultural magnetic noise (see *Bemmelen, Willem van*).

Binza was installed in Belgian Congo and started delivering data in 1953. Many magnetic observatories were created during the International Geophysical Year of 1957–1958: the observatories of Lwiro and Elizabethville were created by Belgium in Congo as well as the Base Roi Baudouin (RBD) in Antarctica. The Netherlands installed Hollandia and Paramaribo in Indonesia and Dutch Guyana, respectively (see Figure O11).

#### Present situation

From the 14 observatories indicated on Figure O11, only three remain today: DOU, MAB, both in Belgium, and Tangerang (TNG) in Indonesia. Unfortunately, cultural magnetic noise is on the rise in all of them, so that short period signals smaller than 1 nT, especially in the vertical component, are increasingly difficult to study.

Figure O11 Timelines for the life of the observatories in and installed by the Benelux countries. The insert shows their location.

Dutch customers involved in aeronautical and topographic mapping continued to request declination information over the Netherlands after the closure of the Dutch magnetic service so that from 1999 onward, the team from DOU performs yearly repeat measurements at several Dutch stations, including former Witteveen Observatory, for producing the isogonal maps.

# **Future perspectives**

The Belgian observatories DOU and MAB will remain open for the foreseeable future—especially as there is demand from the socioeconomic sector for magnetic products and services in the Benelux. There is a search going on for a new site in Belgium with reduced noise, especially as space weather research and forecasts needs clean short period signals.

There are no plans in the Netherlands to resume the operation of Witteveen Observatory. The TNG Observatory is in need of a better observation site and improved instrumentation; international collaboration with the Indonesian Meteorological and Geophysical Agency is attempting this now.

There are talks between the Democratic Republic of Congo and Belgium to resume operation in Binza, whose magnetic pavilions are reported to be in good condition. A new Belgian Antarctic base might also host a magnetic observatory 200 km south of RBD as part of a contribution to the IPY in 2007–2008.

# **OBSERVATORIES IN CANADA**

The origin of the Canadian Magnetic Observatory Network (CANMON) can be traced back to the founding of the Toronto Magnetic Observatory in 1839. Except for a few temporary magnetic observatories, such as those established during the First International Polar Year (1882–1883), Toronto (later Agincourt) was the only magnetic observatory operating in Canada until 1916, when Meanook was established. The network grew substantially during the years preceding and following the International Geophysical Year (1957–1958) and now consists of 13 observatories, operated by the Geological Survey of Canada, Natural Resources Canada (GSC).

#### Distribution of observatories

The CANMON extends over  $40^{\circ}$  of magnetic latitude, from  $54.3^{\circ}$  N to  $86.4^{\circ}$  N, and includes three zones of differing magnetic activity: subauroral, auroral, and polar cap. The distribution of observatories relative to the three zones is shown in Figure O12. All observatories,

Figure O12 Distribution of Canadian observatories: currently operating (large squares); closed (circles); planned (triangle).

including those that are no longer in operation, are listed in Table O2. Inuvik should be in operation by 2007.

Although the stations shown in Figure O12 are the only true magnetic observatories in Canada, several other magnetic variometer networks have been established to measure the unusual magnetic conditions that result from the presence of the polar cap and auroral zone. These include the CANOPUS (now CARISMA) network, the MACCS network, and the THEMIS network, as well as several other minor networks and single stations. In all, more than 80 permanent or semipermanent magnetometers are currently operating in Canada.

#### Instrumentation

All magnetic observatories in the CANMON except Alert are part of INTERMAGNET and are operated to INTERMAGNET standards (see Observatories, INTERMAGNET). Each observatory is equipped with CANMOS (Canadian Magnetic Observatory System), a modular system whose various components are controlled by a desktop PC, which also serves as the data-acquisition system. The system is equipped with two magnetometers: a three-component ring-core fluxgate for recording variations in the X (north), Y (east), and Z (vertical) components, and an Overhauser magnetometer for recording total intensity. The sensor of the three-component magnetometer is mounted on a novel tilt-compensating suspension (Trigg and Olson, 1990), and both sensor and electronics are housed in a temperature-controlled enclosure to minimize drift. The system transmits 1-min data via the GOES satellite to downlinks located at Ottawa and Golden, Colorado. At some observatories, 1-s data are transmitted in real time via the Internet. The system is also accessible via telephone modem, allowing remote monitoring and diagnosis of any problems.

Each observatory is also equipped with a declination-inclination magnetometer (DIM), consisting of a steel-free theodolite equipped with a single-axis fluxgate sensor used for weekly absolute observations.

#### Data availability

Both preliminary and definitive data are available, filtered over the following intervals: 1 s, 5 s, and 1 min. Definitive data undergo rigorous quality control and are calibrated using information derived from the DIM and Overhauser magnetometers. Preliminary data are checked for major spikes only. Preliminary 1-min data are available within 24 min. For those observatories that transmit data via the Internet, the delay

is at most a few minutes. Minute data may be plotted and downloaded from either the GSC Geomagnetic Laboratory's Web site (www.gsc.nrcan.gc.ca/geomag/) or from the INTERMAGNET site (http://www.intermagnet.org).

One- and 5-s data that are transferred in real time are available almost instantly from the geomagnetic laboratory site. They are also available from the Canadian Geospace Monitoring Program data portal (ssdp.ca). Definitive data are normally available about 3 months after year's end. They replace the preliminary data at all sampling intervals on all the above-mentioned Web sites. In addition, 1-min definitive data are available on the INTERMAGNET CD and from World Data Center Web sites.

#### Innovation

Magnetic observatories must evolve and adapt to meet the needs of the scientific community that they serve. In addition to this scientific imperative, development of the CANMON has been influenced by the logistical, environmental, and economic challenges brought about by the remoteness of many sites in this vast network. The presence of the auroral zone and the proximity of the north magnetic pole also present challenges in instrument design. These factors have provided impetus for innovation. Many instrumental and procedural developments that are now considered common place were pioneered or quickly adopted for use in CANMON. Most notable were the use of the DIM as an absolute instrument, which began in the mid-1950s (Serson and Hannaford, 1956; Loomer, 1961) and the development of a semiautomated, digital network, which began in 1969 with the installation of the AMOS system at St. John's (Delaurier *et al.*, 1974).

# **OBSERVATORIES IN CHINA**

At present, there are 43 magnetic observatories in China's mainland. Forty of them are sponsored by the China Earthquake Administration (CEA), formally China Seismological Bureau (CSB) and State Seismological Bureau (SSB). Three others are sponsored by the Institute of Geology and Geophysics, Chinese Academy of Sciences (IGGCAS), formally the Institute of Geophysics, Chinese Academy of Sciences (IGCAS). Among the 40 sponsored by the CEA, 3 new ones are under construction and are expected to operate in 2007. All of the CEA observatories will be equipped with at least two sets of triaxial fluxgate magnetometers, one fluxgate theodolite, and one proton precession magnetometer in 2007. For the most important observatories, an additional fluxgate theodolite and continuous recording of total field by the Overhauser effect magnetometer will also be deployed.

#### History

There were four major periods for the development of the magnetic observatories in China's mainland.

728

# Before the International Geophysical Year (IGY) 1957–1958

The first magnetic observatory in China was constructed in Beijing in 1870 by Russia. It ceased working in 1882. There had been other six magnetic observatories with different periods of operation but all of them had ceased working before 1944. One exception was Sheshan (SSH) Observatory which was constructed in 1874 by French missionaries and is still in operation now.

#### During the IGY

During the IGY, construction of seven magnetic observatories including Beijing (BJI), Changchun (CNH), Wuhan (WHN), Guangzhou (GZH), Lanzhou (LZH), Lhasa (LSA) and Urumqi (WMQ) observatories was initiated. Together with SSH, these eight observatories became the backbone of the Chinese magnetic network.

#### From 1966 to 1979

The 1966 Xingtai Earthquakes triggered the beginning of the Chinese research on earthquake prediction. Various observation methods were utilized including magnetic observation. More than 200 magnetic stations were set up around the country in the following years. These stations were sponsored by different organizations and/or institutions with a variety of observational procedures and quality controls.

#### After 1979

In 1979, all of the magnetic observatories and stations were put under the administration of the SSB. An organization (now the Geomagnetic Network of China) in the Institute of Geophysics, SSB (IGSSB, now IGCEA) was responsible for the technical support and data management of the magnetic network. The network was readjusted several times taking into account the distribution and the observational environment of the stations. Half of the stations ceased working. Meanwhile, instrumentation at 29 of the stations was improved to make them operate as observatories. Later on, three other observatories were set up in Mohe (1989), Beijing Mingtomb (BMT, 1993), and Sanya (1995) by the IGCAS (now the IGGCAS).

# Activities

All of the existing observatories have been producing yearbooks, *K*-indices, and catalogs of magnetic storms. The Geomagnetic Network of China is in charge of the quality control and dissemination of the data from the CEA observatories. These magnetic observations have been widely used in research work and applications related to geomagnetic field.

The relatively short distances among the observatories have had advantages. For example, the detection of errors in data by using the method of interobservatory comparison is justifiable if the observatories are close together. It also helps the scientists in research work on earthquake prediction and regional characteristics of the magnetic field.

Data from more than 15 observatories have been archived in the World Data Center system. Some of the observatories have been participating in international projects such as the Sino-American, Sino-Japanese, and Sino-French projects. Three observatories have participated in INTER-MAGNET (see *Observatories, INTERMAGNET*). With the improvement of the instrumentation at the observatories, it is believed that there will be more INTERMAGNET magnetic observatories from China's mainland in the near future.

# OBSERVATORIES IN EAST AND CENTRAL EUROPE

The first systematic magnetic observations in Central and Eastern Europe were made in Prague in 1839 by Karl Kreil (1798–1862), who was assistant director, and from 1845 director of the Prague Observatory and professor of astronomy at the Prague University. Measurements of declination started in 1830. Kreil constructed and improved magnetic instruments (using, among others, Gauss's method of measuring the horizontal component) and organized a rational system of magnetic observations. From 1843 he also carried out a magnetic survey of the Austrian Empire. In 1851, he was appointed the first Director of the Central Institute of Meteorology and Geomagnetism (ZAMG) in Vienna. The geomagnetic observatory started operating there in 1852.

The first Hungarian magnetic observatory was founded in Buda in 1871, but had to be closed in 1889 due to increased industrial activity, which rendered the measurements unreliable. The magnetic observations continued in O'Gyalla under the auspices of the Royal Hungarian Meteorological Institute. The geomagnetic observatory at O'Gyalla was officially opened in 1900. The observatory was a witness of the turbulent political development in Central Europe. Whereas many observatories had to change their locations due to industrial noise, O'Gyalla, having kept its original location, changed its name twice (Stará Ďala in 1924 and Hurbanovo in 1948) and the country it belonged to five times. In spite of this, Hurbanovo (IAGA code HRB) is the oldest operating observatory in Central and Eastern Europe.

Another geomagnetic observatory was established in 1880 in Pola (Istria Peninsula) under the auspices of the Hydrographical Institute of the Austro-Hungarian Imperial and Royal Navy. The data were also used for reducing Italian magnetic surveys. The observatory was in operation till 1925.

Before World War I, magnetic observations were made at several other places, but the operation was usually short (less then 10 years) and the only measured element was declination. Five observatories were founded between the wars: Swider near Warsaw (1920, SWI) and Hel (1932, HLP) in Poland, Wien Auhof (1929, WIA) in Austria, Jassy (1931, JSS) in Romania, and Panagyurishte (1937, PAG) in Bulgaria. On the other hand, Prague Observatory, located in the city center since 1839, was finally closed down in 1926.

The present shape of the observatory network was formed after World War II in a climate of increased interest in geosciences, also supported by the International Geophysical Year in 1957/1958. Due to the growth of industrial and urban magnetic noise more attention was paid to the choice of the sites. Of course, it was not easy to foresee future development. As regards the older observatories, only Hel, Hurbanovo, and Panagyurishte were able to keep their original sites.

The Vienna Observatory was moved in 1955 from Auhof to Wien Kobenzl (WIK). As this location is also not perfect, transfer to a quieter place is being considered. The Prague Observatory was replaced in 1946 by Pruhonice near Prague (PRU) but rapid expansion of the city and construction of DC-powered railways resulted in a deterioration of this location. The observatory was moved to Budkov (BDV) in south Bohemia, to a sparsely populated area, in 1967. Two observatories were built in Hungary. The Tihany (THY) Observatory was founded in 1953 in a protected area on the northern shore of Lake Balaton. The tourism boom brought more traffic to this area than had been expected; nevertheless, the conditions are still satisfactory. Another observatory was built in 1956-1957 in Nagycenk (NCK) near Sopron. Although the primary aim of the observatory was for the study of the Earth's electromagnetic field of external origin, it produces standard geomagnetic data. The Swider Observatory was affected by magnetic noise from Warsaw. An appropriate location was found in a rural region about 50 km south of Warsaw in Belsk (BEL) and regular measurements started in 1965. The Institute of Geophysics of the Polish Academy of Sciences has also been operating the Hornsund (HRN) Observatory in Spitsbergen since 1978. The Romanian observatory,

Surlari (SUA), was established in 1943 north-east of Bucharest. The Serbian observatory, Grocka (GCK), began its operations during the International Geophysical Year in 1957.

Most of the observatories joined the INTERMAGNET network (number in brackets shows the first year the data were presented on INTERMAGNET CD-ROM): Tihany (1991), Belsk (1993), Nagycenk (1993), Budkov (1994), Hurbanovo (1997), Hel (1998), Surlari (1999), and Hornsund (2002).

Two research groups are active in geomagnetic instrumentation development. Torsion photoelectric magnetometers (TPM), based on Bobrov-system quartz variometers, are being constructed in Belsk since 1977. In these magnetometers, angular deflections of variometer magnet mirrors are converted, by means of photoelectric convertors, into electric voltage changes in a system with a strong negative feedback. The Tihany Observatory is developing digital data acquisition systems DIMARS and DIMARK. They are designed for geomagnetic observatories to measure and process output signals of vector fluxgate and Overhauser proton precession magnetometers according to INTERMAGNET standards.

INTERMAGNET

# **OBSERVATORIES IN GERMANY**

#### Introduction

The tradition of geomagnetic observations in Germany spans back to the 16th century. In the early beginning, only the declination was observed for the purposes of navigation and mining by means of compasses. During the 19th century the theories and measurement methods of geomagnetic intensities were developed in Germany by Gauss and Weber.

The first "real" magnetic observatories in Germany were established by Gauss and Weber in Göttingen; by Alexander von Humboldt in Berlin and by Johann von Lamont in Munich. Today, three geomagnetic observatories are in operation in Germany: Fürstenfeldbruck, Niemegk, and Wingst, which all participate in the worldwide INTERMAGNET network. Table O3 includes essential information about the German observatories.

#### Development and international contribution

Early time series may be reconstructed from the notations by mining engineers or sailors, inscriptions in old instruments and maps, and by correcting these series with more recent observations. In Knothe (1987), the declination observation series of Krakau (today Krakow, Poland), Danzig (today Gdansk, Poland), Freiburg, Munich, and Clausthal are plotted together with those of Prague, Böckstein (Austria), Copenhagen, Paris, and London. Of course, these series are affected with large uncertainties, but they are the earliest certificates of magnetic observations in Germany.

The German universal scientist Alexander von Humboldt (1769– 1859) initiated from 1827 onward with own studies and by inspiring others progress in terrestrial magnetism in Germany. The mathematician Carl Friedrich Gauss (1777–1855), inspired by Humboldt, formulated the general theory of earth magnetism, developed the measurement method for the absolute determination of the intensity and introduced a system of physical units for geomagnetism from 1829 onward. When Wilhelm Weber (1804–1891) came to Göttingen in 1831, one of the most fruitful collaborations devoting to science started. In 1833, they initiated the construction of a nonmagnetic house for geomagnetic measurements in Göttingen. This magnetic observatory soon became

Observatory	Latitude (North)	Longitude (East)	Existence
Berlin	52.515°	13.393°	1836-1872
Fürstenfeldbruck	48.165°	11.277°	1939-
Göttingen	51.533°	9.950°	1833-1902
Maisach	48.200°	11.260°	1927-1937
Munich	48.147°	11.608°	1841-1925
Niemegk	52.070°	12.680°	1930-
Potsdam	52.380°	13.060°	1890-1931
Seddin	52.280°	13.010°	1907-1931
Wilhelmshaven	53.530°	8.150°	1878–1919,
			1931-1936
Wingst	53.750°	9.070°	1938-

the center of the "Göttinger Magnetischer Verein (Göttingen Magnetic Union)." This union, initiated by Humboldt, Gauss, and Weber, was the first worldwide geomagnetic observatory network, which existed from 1836 to 1841 and included 53 observatories, 18 of them non-European ones. All observatories took readings from their magnetometers all 5 min during appointed days. The results were published by Gauss and Weber together with scientific articles.

#### Observatories

Table O3 includes those German observatories that were in operation for long periods, and which provided vector data of the Earth magnetic induction vector. Table O4 shows general information about these observatories, while Table O5 contains the used main instruments.

# Summary and outlook

The German scientists Alexander von Humboldt, Carl Friedrich Gauss, and Wilhelm Weber initiated the establishment of the first magnetic observatories in Germany during the 1930s. They created the scientific basements of the measurement and mathematical description of terrestrial magnetism and developed suitable instruments. Further essential theoretical and instrumental contributions were performed by Johann von Lamont (1805–1879) and Adolf Schmidt (1860–1944). The "Göttinger Magnetischer Verein" (Göttingen Magnetic Union), initiated by Humboldt, Gauss, and Weber was the first worldwide geomagnetic observatory network.

Due to several reasons, the first magnetic observatories (Göttingen, Berlin, and Munich) that were established in the frame of the Göttingen Magnetic Union do not exist any more. Industrial and urban disturbances forced the movement of the observatories from their first locations within the cities to places far away from scientific centers. Today there are three observatories Fürstenfeldbruck (successor of Munich and Maisach), Niemegk (successor of Potsdam and Seddin), and Wingst (successor of Wilhelmshaven). The time series span back to 1840 (Munich-Maisach-Fürstenfeldbruck), 1890 (Potsdam-Seddin-Niemegk), and 1878 (Wilhelmshaven-Wingst). The observatories cooperate closely, though they are sponsored by different scientific institutions: Fürstenfeldbruck by the Institute of General and Applied Geophysics of Munich University, Niemegk by the GeoForschungsZentrum Potsdam, and Wingst by the GeoForschungsZentrum Potsdam and the Bundesamt für Seeschifffahrt und Hydrographie Hamburg (German maritime authority).

All three observatories produce minute, hourly, daily, monthly, and annual mean values and *K*-indices. They send reported data in quasi real-time and definitive data to INTERMAGNET. The observations contribute in the frame of the worldwide network of magnetic observatories to the database for scientific research of the Earth interior and the

Table O3 German geomagnetic observatories

Table O4 General i	nformation about Germ	nan observatories			
Observatory	Previous station	Observation period	Observers in charge	Buildings	Other observations
Berlin	I	1836–1872	J.F. Encke (1836–1865) and J.G. Galle (1836–1872)	One nonmagnetic house at the Berlin Astronomical Observatory	1
Fürstenfeldbruck	Munich, Maisach	Operated continuously since 1937	F. Burmeister (1937–1957), K. Wienert (1957–1978), M. Beblo (1978–2003), and J. Matzka (2003–)	Five nonmagnetic, five others	Seismological, telluric currents, and air electricity
Göttingen	1	1833–1902	C.F. Gauss (1833–1855), W. Weber (1833–1867), E. Schering (1867–1897), and E. Wiechert (1897–1902)	One nonmagnetic house at the Göttingen Astronomical Observatory	Seismological
Maisach	Munich	1927–1937	F. Burmeister (1927–1937)	One nonmagnetic hut and use of brewery basement	Seismological, telluric currents, and air electricity
Munich	1	1836–1925; observing gaps of several years	<ul> <li>J. v. Lamont (1836–1879), C. Feldkirchner (1879–1886), F. Schwarz (1898–1902),</li> <li>J.B. Messerschmitt (1902–1912),</li> <li>F. Bidlingmaier (1912–1914),</li> <li>Lutz (1914–1919), and F. Burmeister (1919–1925)</li> </ul>	Three nonmagnetic houses at the Munich Astronomical Observatory	Seismological, telluric currents, and air electricity
Adolf Schmidt Observatory Niemegk	Potsdam, Seddin	Operated continuously since 1930, with a short break of nine months 1945/1946	<ul> <li>A. Nippoldt (1930–1936), R. Bock (1936–1939),</li> <li>G. Fanselau (1939–1968), H. Schmidt (1969–1979), K. Lengning (1980–1982),</li> <li>A. Best (1983–1998), and HJ. Linthe (1999–)</li> </ul>	Seven nonmagnetic houses and 10 others	Telluric currents
Potsdam	I	1890–1931	M. Eschenhagen (1890–1901), A. Schmidt (1901–1927), and A. Nippoldt (1927–1931)	Two nonmagnetic houses	I
Seddin	Potsdam	1907–1931	A. Schmidt (1901–1927) and A. Nippoldt (1927–1931)	Two nonmagnetic houses, one other	I
Wilhelmshaven	I	1878–1919; 1931–1936	C. Börgen (1878–1909), F. Bidlingmaier (1909–1912), and P. Meier (1931–1936)	One nonmagnetic house	Meteorological and hydrographical observations
Wingst	Wilhelmshaven	1938-	O. Meyer (1938–1954), D. Voppel (1954–1974), G. Schulz (1974–2004), and HJ. Linthe (2004–)		

# OBSERVATORIES IN GERMANY

in the German observatories	

Observatory	Absolute instruments	Variometers
Berlin	Magnetometer for intensity determination by Meyerstein, Göttingen; inclinometer by Gambey; declinometer by Baumann	-
Fürstenfeldbruck	Magnetic theodolite (D, H) and oscillation box (H) and earth inductor by Schulze, Potsdam; proton vector magnetometer after Nelson (F, H, Z; 1964; Wienert); DI-flux theodolite Zeiss 010B/Bartington MAG010H (D, I; 1992); Overhauser proton magnetometer GSM19 (F; 1996)	Two sets of variometers with photographic recording (H, D, Z) by Schulze, Potsdam, and Edelmann, Munich; three-component fluxgate variometers by FGE and MAGSON (H, D, Z; 1996)
Göttingen	Declinometer (D), and magnetometer for intensity (H) after Gauß by Meyerstein, Göttingen; inclinometers (I) by Robinson (1840) and Meyerstein (1847); earth inductor (I) after Weber by Meyerstein (1868)	_
Maisach	Two magnetic theodolites (D, H) by Bamberg, Berlin and Tesdorpf, Stuttgart; earth inductors by Schulze, Potsdam and Edelmann, Munich	One set of variometers with photographic recording (H, D, Z) by Edelmann
Munich	Meyerstein (Göttingen), declinometer (D), and intensity instrument (H); magnetic theodolite (D, H, Z; 1841) by Lamont; magnetic theodolite (D, H) and inclinometer (I) by Bamberg, Berlin (1899); earth inductor (I) by Edelmann, Munich (1908)	Magnetograph (1847) by Lamont
Adolf Schmidt observatory Niemegk	Magnetic theodolites by Wanschaff, Berlin and after A. Schmidt (D and H); oscillation box by Schulze, Potsdam (H); earth inductor by Schulze, Potsdam (I); self-made proton magnetometers (H. Schmidt, 1968); DI-flux theodolite Zeiss 010B/Bartington MAG01H (D, I; 1996)	Four sets of classical variometers (H, D, Z) by Schulze, Potsdam and Mating and Wiesenberg, Potsdam; three-component fluxgate variometers FGE and MAGSON (H, D, Z; 1996)
Potsdam	Magnetic theodolite by Edelmann, Munich (D, H); inclinometer by Bamberg, Berlin and earth inductor by L. Weber (I); magnetic theodolite by Wanschaff (D, H; 1893); earth inductor by Schulze, Potsdam (I; 1901); oscillation box (H) and theodolite after A. Schmidt (D, H; 1923)	One set of variometers (H, D, Z) by Carpentier, Paris, with photographic recording equipment by Wanschaff, Berlin (main system); one set of variometers (H, D, Z) by Wild-Edelmann, Munich with visual reading (auxiliary system)
Seddin	_	One set of variometers (X, Y, Z) by Schulze, Potsdam
Wilhelmshaven	Declinometer after Neumayer by Bamberg, Berlin (D); magnetic survey theodolite by Lamont, Munich (H); earth inductor after Weber and inclinometer by Dover (I)	One set of variometers (H, D, Z), visually readable, by Lamont, Munich; one set of variometers (H, D, Z) with photographic recording of Kew type by Adie, London
Wingst	Magnetic theodolite (D, H), oscillation box (H), earth inductor (I) by Schulze, Potsdam; proton vector magnetometer after Voppel (F, H, Z; 1969); DI-flux theodolite Zeiss 010B/Bartington MAG01H (D, I; 1992) and Overhauser proton magnetometer GSM19 (F; 1992)	One set of variometers with photographic recording by Schulze, Potsdam (H, D, Z); 2 three-component fluxgate variometers FGE (H, D, Z; 1993)

solar terrestrial relations. The Adolf Schmidt Observatory, Niemegk is further responsible for the repeat station measurements and the construction of magnetic maps of Germany. Niemegk Observatory further carries out the Kp service for the International Service of Geomagnetic Indices of the IAGA. Niemegk and Wingst are Kp stations.

# **OBSERVATORIES IN INDIA**

Magnetic observatories have been running in India for more than 180 years. Three of the oldest observatories, namely Madras Observatory (1822–1881), Shimla Observatory (1841–1845), and Trivandrum Observatory (1841–1871) participated in the international collaboration venture involving simultaneous magnetic measurements at 50 observatories all over the globe organized by the Göttingen Magnetic
Union 1836-1841. The Colaba Observatory (Geographic latitude 18°53'36"N; longitude 72°48'54"E) was started in 1823 by the East India Company. Initially it was undertaking mainly meteorological observations to support the function of the Bombay Harbor. The first regular magnetic field observations from Colaba were started in the year 1841. In view of the proposed introduction of electric trams running on direct current in Bombay city in the year 1900, the then Director Dr. Nanabhai A.F. Moos could envisage its deleterious effect on the accuracy of magnetic measurements at Colaba Observatory. He made enormous efforts to choose an alternate site at Alibag (Geographic latitude 18°38'17"N; longitude 72°52'21"E), free from possible electromagnetic noises and in proximity to Colaba. The location of Alibag Observatory is at about 30 km south-south east of Bombay facing the Arabian Sea. The two historic nonmagnetic buildings, built completely with nonmagnetic Porbunder sandstone, brass, or copper fittings at Alibag, are still in good condition. Alibag Magnetic Observatory became operational from April 1904. These records overlapped with the Colaba records for a period of two years (1904–1906) and subsequently recordings at Colaba were stopped. Thus at present, Colaba-Alibag magnetic observatory data form a long series of more

than 160 years. At present there are 13 permanent magnetic observatories in India (Figure 013), and the Indian Institute of Geomagnetism (IIG), Mumbai, operates nine of these. The Alibag Magnetic Observatory joined the INTERMAGNET in 1993 when a Narod Ring Core Fluxgate magnetometer from USGS was installed there. Recently, analog variation magnetometers have been supplemented with digital fluxgate magnetometers manufactured by Dannish Meteorological Institute (DMI) at Tirunelveli, Pondicherry, Nagpur, Vishakhapatnam, and Jaipur observatories operated by IIG. Modern absolute instruments, such as declination inclination magnetometer (DIM), have been installed at most of the observatories, to record and maintain the stability in the baseline, which is a crucial parameter in computing the final absolute values from variation data. A brief description of the magnetic

Figure O13 Map showing the locations of permanent magnetic observatories in India.

observatories currently operational is given below. Also included is a map showing the locations of the magnetic observatories in India.

*Alibag Magnetic Observatory: ABG* (Operated by IIG, Mumbai), Geographic (18.63°N, 72.87°E), Geomagnetic (at 2000.0 10.03°N, 145.97°E).

This is the prime magnetic observatory of India. It was established in April 1904 as a successor to Colaba Magnetic Observatory, Bombay. The absolute instruments are vector proton precession magnetometer (VPPM), quartz horizontal magnetometer (QHM), zero balance magnetometer (BMZ), Kew No. 7 Magnetometer, and a DIM. The variometers used are Kew magnetometer, Askania magnetometer, La Cour variometer, and Izmiran II variometer.

*Ettaiyapuram Magnetic Observatory: ETT* (Operated by National Geophysical Research Institute, NGRI, Hyderabad), Geographic (9.00° N, 78.00° E), Geomagnetic (0.04° S, 149.99° E).

The Ettaiyapuram Magnetic Observatory was established in October 1979. The setup includes VPPM, QHM, BMZ, DIM, and a La Cour variometer.

*Gulmarg Magnetic Observatory: GUL* (Operated by IIG, Mumbai), Geographic (34.25°N, 74.41°E), Geomagnetic (25.56°N, 149.35°E).

Gulmarg Magnetic Observatory started functioning in September 1977. It has QHM, VPPM, DIM, and an Izmiran II variometer.

*Hyderabad Magnetic Observatory: HYB* (Operated by NGRI, Hyderabad), Geographic (17.42°N, 78.55°E), Geomagnetic (8.29°N, 151.29°E).

Hyderabad Magnetic Observatory was established in December 1964. The setup has VPPM, QHM, BMZ, DIM, and a La Cour variometer.

Jaipur Magnetic Observatory: JAI (Operated by IIG, Mumbai), Geographic (26.91°N, 75.80°E), Geomagnetic (17.98°N, 149.64°E).

The Jaipur Observatory was initially established in the year 1975 in the Malvia Regional Engineering College Campus. The observatory operations were discontinued from the year 1988. This observatory was restarted in September 2002. The absolute instruments are VPPM, QHM, BMZ, and DIM. The variation instrument is an Izmiran IV variometer.

*Kodaikanal Magnetic Observatory: KOD* (Indian Institute of Astrophysics, IIA, Bangalore), Geographic (10.23°N, 77.47°E), Geomagnetic (1.23°N, 149.58°E).

Kodaikanal Magnetic Observatory was started in January 1949. The setup includes Kew Magnetometer No. 3, galvanometer, Earth inductor, La Cour variometer, and Watson's variometer.

*Nagpur Magnetic Observatory: NGP* (Operated by IIG, Mumbai), Geographic (21.15°N, 79.08°E), Geomagnetic (11.96°N, 152.14°E). Nagpur Magnetic Observatory was commissioned in June 1991.

The setup has VPPM, DIM, and an Izmiran II variometer.

*Pondicherry Magnetic Observatory: PON* (Operated by IIG, Mumbai), Geographic (11.92°N, 79.92°E), Geomagnetic (2.70°N, 152.13°E).

Pondicherry Magnetic Observatory was established in January 1993 as a replacement for the Annamalainagar Observatory, Geographic (11.40°N, 79.68°E), which operated from 1957 to 1993. Its location is on the edge of the equatorial electrojet belt, which is a region under the influence of ionospheric current systems associated with the dip equator. The absolute instruments are DIM, PPM, VPPM, QHM, and BMZ. The variometer is an Izmiran II variometer.

Sabhawala Magnetic Observatory: SAB (Operated by Survey of India, SOI, Dehra Dun), Geographic (30.33°N, 77.80°E), Geomagnetic (21.21°N, 151.86°E).

Sabhawala Magnetic Observatory was commissioned in January 1964. The setup includes QHM, BMZ, La Cour variometer, and Askania variometer.

Silchar Magnetic Observatory: SIL (Operated by IIG, Mumbai), Geographic (24.93°N, 92.82°E), Geomagnetic (14.83°N, 165.38°E).

Silchar Magnetic Observatory was commissioned in November 1998. The setup has instruments DIM, PPM, VPPM, QHM, and Izmiran II variometer.

*Shillong Magnetic Observatory: SHL* (Operated by IIG, New Panvel), Geographic (25.56°N, 91.88°E), Geomagnetic (15.69°N, 164.72°E).

Shillong Magnetic Observatory started functioning from the middle of the year 1975. It operates QHM, BMZ, VPPM, DIM, and Izmiran II variometer.

*Tirunelveli Magnetic Observatory: TIR* (Operated by IIG, Mumbai), Geographic (8.42° N, 77.48° E), Geomagnetic (0.57° S, 149.42° E).

The Tirunelveli Observatory started in March 1996 as successor to IIGs Trivandrum Magnetic Observatory (Geographic:  $8.48^{\circ}$ N, 76.95°E), which was in operation from 1957 to 1999. The absolute instruments are DIM, PPM, BMZ, and QHM. The variation instrument is an Izmiran II variometer.

Vishakhapatnam Magnetic Observatory: VSK (Operated by IIG, Mumbai), Geographic (17.68°N, 83.32°E), Geomagnetic (8.17°N, 155.89°E).

Vishakhapatnam Magnetic Observatory started functioning from July 1994. The setup includes DIM, VPPM, QHM, and Izmiran II variometer.

The observatory network in India is ideal for studying equatorial, low- and midlatitude geomagnetic phenomena and space weather. The Indian magnetic data is published by IIG. It is planned to preserve the entire Colaba-Alibag unique data series by scanning and digitizing the old magnetograms. In addition, IIG is operating World Data Center for Geomagnetism, Mumbai. For more details, one can visit the Web site of the Indian Institute of Geomagnetism, Mumbai, at iigs.iigm.res.in.

# **OBSERVATORIES IN ITALY**

Monitoring the Earth's magnetic field is carried out by geomagnetic observatories all over the world. In Italy, the first observatory was founded in 1880, when Pietro Tacchini, the director of the Central Meteorological Institute (Ufficio Centrale di Meteorologia), launched an initiative to study the distribution of the Earth's magnetic field over the Italian territory. Prior to this, an initial attempt had been made by Father Francesco Denza (1834-1894). In 1881, Tacchini proposed to build an observatory in Rome, envisaging a nonmagnetic facility on the Palatino hill. However this effort was hampered by administrative difficulties. At the end of the 19th century, electromagnetic noise, generated mainly by the development of electrified transportation, affected Rome as well as other Italian cities. Meanwhile the International Commission for Terrestrial Magnetism was urging the Italian scientific community to establish a magnetic observatory in southern regions to facilitate the southern extension of the European network. The geophysical observatories in Catanzaro and in Messina, both located in Southern Italy, were then proposed. However the strong earthquake of 1905 in Sicily, which had dramatic consequences in Messina, scuppered plans to establish the magnetic observatory in the area.

In the meantime, repeat station measurements have been conducted by Luigi Palazzo in several locations of the Italian territory. These surveys indicated that satisfactory data reduction was achievable using the magnetic data of the observatory of Pola, operating since 1881 in the Istria Peninsula (Latitude 44.87°N, Longitude 13.85°S). At that time, Istria belonged to the Austro-Hungarian Empire. When World War I ended, Istria became part of Italy. Unfortunately, due to the electromagnetic disturbances caused again by the city tramways, geomagnetic recordings of the vertical component of the field were suspended. With a further increase of the noise, in 1923, Pola was closed.

It was then in 1932 that a section of the Italian Navy, the *Istituto Idrografico della Marina*, initiated regular absolute geomagnetic measurements at Castellaccio (near Genova, Latitude 44.83°N, Longitude 8.93°E) along with variational recording using Pola Observatory's equipment. Castellaccio Observatory operated regularly and published annual bulletins until 1962.

In the early fifties, the National Geophysical Institute (*Istituto Nazionale di Geofisica—ING*) undertook the task to identify a suitable location, from a geological and an environmental standpoint, for a national geomagnetic observatory. Accurate surveys conducted in the area of Preturo (Latitude 42.38°N, Longitude 13.32°E) near the city of L'Aquila in central Italy, indicated an appropriate site. Funding was secured in 1958 from Franco Molina. Preturo had been working for two years as a variometer station. In 1960, absolute measurements started to be carried out on a regular basis allowing the calculation of the absolute values of the Earth's magnetic field. This observatory is known internationally as L'Aquila.

Although in different epochs, the three geomagnetic observatories (Pola, Castellaccio, and L'Aquila) operated regularly during the last century for a number of years, allowing the secular variation of declination and the horizontal component in Italy to be determined since 1881.

Another magnetic observatory was then installed by ING in the north of the country, at Castello Tesino (Latitude  $46.05^{\circ}$ N, Longitude 11.65°E), and fitted with automatic recording equipment. Qualified personnel perform absolute measurements regularly on a monthly basis, guaranteeing the quality of the data.

Both L'Aquila and Castello Tesino are currently operating and recording field values every minute, with regular transmission of data to the data center at Rome.

Under the auspices of the Italian National Antarctic Research Program, ING built and currently operate the Antarctic Italian Geomagnetic Observatory Terra Nova Bay (Latitude 74.69°S, Longitude 164.12°E) located on the coast of the Ross Sea.

# **OBSERVATORIES IN JAPAN AND ASIA**

#### Magnetic observations in Japan

Modern geomagnetic observation in Japan began on March 15, 1883, in Tokyo, as an initiative of the Japanese government to join the First Polar Year. In conjunction, a geomagnetic survey over all Japanese islands was conducted. A well-equipped observatory in Tokyo was started in 1897 by the meteorological agency and continued until 1917. Unfortunately, most of the records were burnt during the 1923 Tokyo earthquake. Because of the magnetic noise due to the construction of a DC train system in Tokyo, the observatory was moved. A standard magnetic observatory in Kakioka, near Tokyo, was established in 1913 and the observations are continuing.

There are currently four agencies conducting geomagnetic observations in Japan.

 The Meteorological Agency of Japan operates three magnetic observatories: Kakioka, Kanoya, and Memambetsu. These observatories provide continuous geomagnetic data with precise absolute measurements. There is also one unmanned observatory, Chichijima. The main purpose of these observatories is for monitoring volcanic or earthquake activity, and it also deploys instruments for temporary observations during a volcanic eruption or strong earthquake. The observations are also used for research.

Table O6 Listing of magnetic observatories, operated by the government in Japan

- The Geographical Survey Institute of Japan operates three magnetic observatories—Kanozan, Mizusawa, and Esashi—and 11 unmanned continuous observation sites. They conduct magnetic surveys at repeat stations and publish magnetic charts of Japan every 10 years.
- The Hydrographic and Oceanographic Department has one observatory, Hatizyo. They conduct surveys by ship or airplane over the sea around the Islands of Japan and publish magnetic charts.
- The National Institute of Advanced Industrial Science and Technology (AIST) conducts Aeromagnetic surveys over the Islands of Japan and publishes magnetic charts.

Other than the observatories mentioned above (see also Table O6), there are many observation sites for scientific research that mainly belong to universities or national institutions.

#### Magnetic observation in Indonesia

The Indonesian Meteorological and Geophysical Agency (IMGA) operates three geomagnetic observatories: Tondano Geomagnetic Observatory (TND,  $1.29^{\circ}$ N,  $124.95^{\circ}$ E) in North Sulawesi, Tangerang Geomagnetic Observatory (TNG,  $6.17^{\circ}$ S,  $106.63^{\circ}$ E) in Jakarta, and Tuntungan Geomagnetic Observatory (TTG,  $3.50^{\circ}$ N,  $98.56^{\circ}$ E) in North Sumatra. Geomagnetic observatory (TTG,  $3.50^{\circ}$ N,  $98.56^{\circ}$ E) in North Sumatra. Geomagnetic observatory TNG started in 1964 using the Ruska type photographic paper variograph. TNG was upgraded in 1991 with a digital magnetometers. The observatory Tondano began collecting observations in 1991 with digital fluxgate and proton magnetometer. Tuntungan Geomagnetic Observatory (TTG) has been observing the geomagnetic field since 1980 using a La Cour photographic variograph, and after 2003 was equipped with a digital magnetometer.

#### Magnetic observation in Vietnam

The Hanoi Institute of Geophysics, National Centre for Natural Science and Technology of Vietnam currently operates four geomagnetic observatories in Vietnam; Cha Pa (CPA, 22.35°N, 103.83°E), Bac Lieu (BCL, 9.3°N, 105.7°E), Phu Thuy (PHU, 21.03°N, 105.95°E), and Dalat (DLT, 11.93°N, 108.48°E). The magnetic observations at CPA and PHU began in 1957 and 1978, respectively.

Toshihiko Iyemori and Heather McCreadie

# **OBSERVATORIES IN LATIN AMERICA**

### Introduction

During colonial times, geomagnetism in Latin American countries was restricted to declination measurements for cartography and the definition of borders. A large survey was performed by E. Halley (see *Halley, Edmond*), in 1700, when he prepared his famous magnetic chart of the South Atlantic. Following Halley's work, it was not until 1880 that a large field survey was made by the Dutch scientist Van Rickjervosel in the Brazilian coastal area. That observational work was completed by the publication of the first Brazilian magnetic chart. Since no observatories existed in those times, they could be considered as the prehistoric phase of geomagnetism in Latin America.

# Birth and development of Latin American magnetic observatories

In the first half of the 20th century a considerable effort was made by the Carnegie Institution of Washington (see *Carnegie Institution of Washington, Department of Terrestrial Magnetism*) to improve geomagnetism in South America. Observatories were installed in Peru and Argentina. Local efforts were made in various countries, sometimes with the assistance of the Inter-American Geodetic Survey, and the Pan-American Institute of Geography and History (PAIGH), to install other observatories. This phase lasted from 1920 to 1960. Chiripa Magnetic Observatory in Costa Rica is a good example of that international cooperation.

Lately, Peruvian observatories (Huancayo and Ancón) received considerable assistance from Japanese institutions, mainly from Tokyo University. In spite of a good beginning, some observatories lost their initial quality and some of them were closed.

In 1980, PAIGH started a campaign, under the leadership of the National Observatory of Brazil, to reorganize and modernize all observatories in Latin America. The most important part of that campaign was a series of Latin American geomagnetic schools, where the training of technicians and also the installation of modern instruments transformed old and unproductive observatories into operational ones. Important international contribution for these improvements came from the action of two IAGA Divisions, Division V (observatories, instruments, surveys, and analyses) and the Interdivision Commission on Developing Countries (see *IAGA, International Association of Geomagnetism and Aeronomy*). From this, the observatories of Trelew (Argentina) and La Habana (Cuba) received new magnetic instruments, such as digital fluxgate variometers and modern absolute instruments.

Besides the observatories mentioned above and others included in the summary below, there are some variation stations (where no absolute observations are carried out) that are operated for specific research projects. Among these stations the most important are located in Brazil, Peru, and Mexico.

It is interesting to note the importance and responsibility of Latin American magnetic observatories, not only for the great latitude range of the group (66°), but also for the occurrence of two important geomagnetic phenomena in the region—the equatorial electrojet and the South Atlantic magnetic anomaly.

Table O7 gives data for all observatories in the region.

#### Table O7 Summary

Country	Name of	Geographic coordinates		Year of installation	Actual status	
	observatory	Latitude	Longitude			
Argentina	Trelew	$48.2^{\circ}\mathrm{S}$	204.7° W	1957	Normal operation

# OBSERVATORIES IN NEW ZEALAND AND THE SOUTH PACIFIC

New Zealand has been involved in five magnetic observatories over the last century. In New Zealand, there has been a succession of three observatories located at Christ-church, Amberley, and Eyrewell. The others are Apia in Samoa and Scott Base in the Antarctic. The Apia and Scott Base observatories were only intended to operate for limited durations, but Apia has continued for over 100 years and Scott Base for nearly 50 years.

#### **Observatories in New Zealand**

Dr. Schmidt had drawn attention to the desirability of an observatory in New Zealand (Schmidt, 1897), and referring to this paper in his presidential address to Section A of the Australasian Association for the Advancement of Science Mr. Barrachi said, "The establishment of a magnetic observatory in New Zealand seems to be a duty that colony owes to the Scientific world" (Farr, 1916). With support from the commander in chief of the Australian Naval Station and the Shipmasters' Association of New Zealand, government funding was obtained for both a survey and the establishment of a magnetic observatory.

The observatory was established in the botanic gardens in Christchurch using Adie magnetographs and a new Kew magnetometer (No. 1C.Sc.I.Co) and Dip Circle No.147 for absolute observations. Christ-church soon became magnetically disturbed by electric trams. A substation, which eventually replaced Christ-church, was established at Amberley 43 km north of Christ-church using Eschenhagen magnetographs. In 1957, a set of La Cour variometers was installed at Amberley (J. A. Lawrie, personal communication).

In the mid-1960s a DC power line was erected to transfer power between the North and South Islands of New Zealand. It consists of two independent conductors (mounted on the same pylons where the line is over land) with a common earth return. Each conductor was capable of independently carrying up to 1200 A (since increased to 1800 A). At the observatory, this produced a vertical field proportional to the net current flowing in the two conductors. The maximum disturbance was 12 nT. A sensor was installed under the lines to measure the net current flowing in the conductors and provide a correction field around the Z variometer.

In 1977, development around Amberley forced the establishment of a new observatory at Eyrewell, about 22 km northwest of the original Christ-church Observatory. Digital recording instruments designed and built by the author were introduced in June 1990 allowing it to become an INTERMAGNET observatory in 1994. In February 2005, a new Danish Meteorological Institute suspended fluxgate magnetometer and a Gem GSM-90 Overhauser magnetometers were installed. These will become the prime recording instruments after a suitable period of comparison with the existing instruments.

#### Apia observatory

In November 1899 at a meeting of the council entrusted with the preparation of the German South-Polar Expedition, Adolf Schmidt proposed that a magnetic observatory should be set up in Samoa at the same time when the stations were to be set up by the expedition in Antarctica, to enable simultaneous records. Dr. Otto Tetens sailed to Samoa taking with him two Eschenhagen variometers, a Z-balance and a magnetic theodolite for absolute measurements. He arrived in June 1902 (Angenheister, 1974).

When World War I broke out, Samoa was occupied by 1500 soldiers from New Zealand. Dr. Gustav Heinrich Angenheister, who was serving as director, managed to convince the English commander that the observatory was a scientific institution and needed to be continued. He remained at the observatory during and after the war until 1920, working under conditions of extreme hardship and financial difficulties. At the end of the war, the League of Nations mandated control of the German Samoan Islands to New Zealand.

Funding for the observatory was provided by the New Zealand government and the Carnegie Institution, assisted by an annual grant form the British Admiralty (Sommerville, 1923). Eventually, the observatory came under the control of the New Zealand Department of Scientific and Industrial Research (DSIR). New La Cour variometers were installed by Lawrie in 1958.

Control of the observatory remained with the DSIR until a few years after independence in 1962 and was then handed over to the Samoan government. The DSIR still provided some support by way of technical advice and with the processing and publication of the data.

In 1990, Samoa was devastated by tropical cyclone Ofa which removed the roof from the variometer house. This turned out to be a blessing in disguise because repairs to the roof would have cost more than a new digital system. As part of New Zealand's aid program, the New Zealand Department of Foreign Affairs and Trade commissioned the DSIR to supply and install a digital system as used at Eyrewell. The installation of the digital system in December 1991 allowed Apia to become an INTERMAGNET observatory in 1998.

#### Scott base observatory

Originally Scott Base was to be at Butter Point on the western side of McMurdo Sound, but it was considered unsuitable for the Trans-Antarctic Expedition. The present site on the eastern side of Hut Point Peninsula on Ross Island was chosen instead. It is not a good site for a magnetic observatory as Ross Island is composed of highly magnetic basalt scoria (Cullington, 1961). However there was no alternative.

Two prefabricated buildings were erected in 1957, one each for absolute observations and the La Cour variometer systems. Most buildings have been replaced over the years but these two buildings are still used for their original purpose.

A digital fluxgate magnetometer was installed at Scott Base in December 1990 and it became an INTERMAGNET observatory in 1996. The instruments will be upgraded at the end of 2005 as has been done at Eyrewell.

Lester A. Tomlinson

# **OBSERVATORIES IN NORDIC COUNTRIES**

The Nordic countries comprise Denmark, the Faeroe Islands, Finland, Greenland, Iceland, Norway, and Sweden. All but the Faeroe Island houses one or more geomagnetic observatories. The observatories in operation as of 2005 are listed in Table O8.

They are all equipped with modern fluxgate magnetometers—the majority with the suspended Danish FGE type—for the continuous recording, and are using standard D/I-flux theodolite along with proton precession magnetometer for absolute calibration (see *Observatories, instrumentation*). Digital recording was introduced during the 1980s and 1990s at all of them.

#### **Denmark and Greenland**

The geomagnetic observatories in Denmark and Greenland have been part of the Danish Meteorological Institute in Copenhagen ever since the Copenhagen Observatory was established in 1891. Already in 1907 the Copenhagen Observatory was moved to Rude Skov 20 km to the north due to increasing magnetic disturbance in the city. The observatory remained here until 1984 when relocation to its present site at Brorfelde 40 km west of Copenhagen took place.

The first magnetic observatory at Greenland was established in Godhavn (today Qeqertarsuaq), at Greenland's west coast in 1926, where it is still found. The history of the North Greenland Observatory dates back to the Second International Polar Year (IPY) 1932/1933, when a magnetic observatory was operated in Thule. A permanent observatory was set up there in 1947, but had to be abandoned after only a few years due to the establishment of the US Air Force base at Thule. Finally, operation was resumed in 1956 at its present site of Qaanaaq (previously called Thule) 100 km to the north. The South Greenland Observatory of Narsarsuaq was added in 1967.

#### Finland

The history of geomagnetic observatories in Finland dates back to Göttingen Magnetic Union (see *Geomagnetism, history of*) when an observatory was set up in Helsinki by the University of Helsinki. Regular operation commenced in 1844 (Nevanlinna, 2004). In 1912 it was relocated within Helsinki, and finally in 1953 it was replaced by the present observatory at Nurmijärvi 40 km north of Helsinki. It is operated by the Finnish Meteorological Institute.

The observatory of northern Finland in Sodanlylä has a precursor in the First IPY station of 1882/1983. In 1914, the Finish Academy of Science and Letters set up a permanent geophysical observatory, a magnetic observatory being part of it (Kataja, 1973). Today the Sodankylä Geophysical Observatory is organized as a branch of the University of Oulu.

#### Iceland

The magnetic observatory at Iceland started recording in 1957. It is located at Leirvogur 12 km ENE of Reykjavik, and is maintained by the University of Iceland.

#### Norway

Similar to Finland, the first Norwegian magnetic observatory originated in the activities of the Göttingen Magnetic Union. The astronomical

Observatory name	IAGA code	Country	Geographic latitude	Geographic longitude	First annual mean

Table O8 Magnetic observatories in the Nordic countries operating in 2005

observatory in Oslo was then furnished also as a magnetic observatory and began regular observations in 1842. The University of Oslo kept it running until 1932 (Wasserfall, 1950). In the meantime, a magnetic station had been set up at Dombås 300 km north of Oslo in 1916, but not until 1950 was this station upgraded to a magnetic observatory. It is today run jointly by the universities in Bergen and Tromsø. The magnetic observatory in Tromsø was established in 1930 as part of the newly founded Auroral Observatory. From 1972 it is part of the University of Tromsø.

Bear Island was the site of a Polish research station including a magnetic observatory during the Second IPY 1932/1933. The magnetic observations were continued by the Auroral Observatory in Tromsø, but not until 1951 were the calibration and stability good enough to produce reliable annual means. Today it is run by the University of Tromsø. Hornsund is a Polish research station maintained since the International Geophysical Year in 1957/1958 by the Polish Academy of Science in the southern part of Svalbard. From 1978 the station has been manned all year and includes a magnetic observatory.

#### Sweden

The observatory of southern Sweden dates back to 1928 when the Lovø Observatory in Stockholm was built. A new observatory near Uppsala is replacing Lovø and is effective from 2005. In northern Sweden, the magnetic station at Abisko was set up by the Swedish Academy of Science in 1921, but before 1945 absolute calibrations were quite scarce. Both are operated today by the Swedish Geological Survey.

# Magnetic yearbooks

Descriptions of the observatories, their results, instruments, and methods are found in the so-called magnetic yearbook. Over the years they have been issued under changing forms and titles. Below the most recent issues are listed. Today the distribution of magnetic data by the Internet is important and this is done through INTERMAGNET (see *Observatories, INTERMAGNET*) and the World Data Centers as well as through the institutes' own Web sites.

# **OBSERVATORIES IN RUSSIA**

The first regular measurements of the geomagnetic field in Russia were started in St. Petersburg in 1829. Over the course of the next century geomagnetic observatories equipped with the most modern, by contemporary standards, instruments, were established in Ekaterinburg (1836), Tiflis (1844), Pavlovsk (1878), Irkutsk (1886), and Kazan (1909). The first polar observatory in the world was open in 1924 in

Table O9 List of Russian geomagnetic observatories (GO) and stations (S)

strait Matochkin Shar (close to modern Amderma). The next step, aimed at economic development of the Russian Arctic, was made in connection with the Second Polar Year (1932–1933). The observatories Yakutsk, Srednekan (Magadan), Dixon, Tikhaya Bay, Cape Chelyuskin, and Wellen, were set up in this period. The International Geophysical Year (1957–1958) and the subsequent beginning of the period of space research played a crucial role in building the present network of geomagnetic observations. About 50 magnetic observatories and stations were operated on the territory of former Soviet Union by 1985 (we define an observatory or a station by availability or absence of absolute geomagnetic measurements, respectively). The situation changed dramatically in connection with the disintegration of the Soviet Union and economic problems after 1991.

At present geomagnetic observations in Russia are carried out by about 30 observatories and stations, but quality of observations, determined by the type of instruments, is quite variable. Some observatories, equipped with modern instruments, provide digital data of high resolution, whereas others, using outdated devices, continue to record the magnetic variations in analog format or with insufficiently precise absolute measurements. In Table O9 we list only those geomagnetic observatories (GO) and stations (S), which provide the geomagnetic data in digital form. The table contains the name of observatory, abbreviation, geographical coordinates, the data resolution (in nT) and sampling rate (in s), and years covered by digital data. The observatories and stations are operated by various institutions of the Russian Hydrometeorological Service and Russian Academy of Science. These institutions are listed below and the last column of the table (Aff.) corresponds to the appropriate number in the list of affiliations. Letter R indicates that the data are presented in real time at the institution Web sites:

Observations at stations KTN, TIX, CHD, ZYK, PTK, MGD, and PPI are carried out in the framework of the Australian-Japan-Russian project "Circum-pan Pacific Magnetometer Network" (CPMN). Data from stations PBK, TIK, CCS, NOR, and DIK form the basis for calculation of the AE index, characterizing the intensity of magnetic disturbances in the auroral zone.

# **OBSERVATORIES IN SOUTHERN AFRICA**

#### The Early history of 1600 till 1932

This overview of geomagnetism and its historical development in southern Africa covers a period of approximately 400 years till present. During the era of exploration between 1600 and 1700, visiting seamen from Europe have been responsible for the early magnetic observations in South Africa. In fact, the earliest recorded observation of magnetic declination on land was made at Mosselbay in 1595 by Cornelis Houtman (Beattie, 1909), commander of a Dutch fleet on its way to India, who obtained a value of 0°. The first systematic observations in South Africa resulted from the establishment, in 1841, of a worldwide network of observation stations. One of these stations was built in the grounds of the Royal Observatory at the Cape of Good Hope, with the Royal Artillery detachment responsible for all measurements. After the magnetic observatory was destroyed by fire in 1852, a period of 80 years elapsed before a magnetic observatory worthy of name was again established in South Africa. During that period, observations of magnetic declination had been made by surveyors in different parts of the interior of the country. The first magnetic survey of the Union of South Africa, comparable with that of developed countries in the Northern Hemisphere, was carried out by Beattie (1909), assisted by Prof. J.T. Morrison of the University of Stellenbosch between 1898 and 1906.

#### The Period 1932 till present

The Polar Year of 1932–1933 prompted the establishment of a magnetic observatory at the University of Cape Town in 1932 under the leadership of Prof. Alexander Ogg (Trigonometrical Survey Office, 1939). International organizations provided grants for buildings and the loan of instruments for standard observations. The subsequent electrification of the suburban railway network however created a disturbing influence, to the extent that accurate observations became almost impossible. A new site was identified in Hermanus, because it was sufficiently remote from electric railway disturbances and had been proven by a magnetic survey to be suitable in other respects. The Hermanus Magnetic Observatory officially commenced operation on January 1, 1941. One of the most recent major contributions to geomagnetism in southern Africa was the institution of a long-term magnetic secular variation program in 1938-1939. The program consisted initially of 44 permanent field stations covering, with a fairly uniform distribution, the whole of South Africa, Namibia, and Botswana, but has since been expanded to Zimbabwe as well, with a total of 75 stations. To ensure exact reoccupation during subsequent surveys, concrete beacons were erected at each field station to mark the position of the instruments during observations.

A major undertaking during the period 1960–1975 was the establishment of other magnetic observatories in southern Africa. In 1964, an opportunity arose to establish a magnetic observatory on the premises of the "Forschungsstation Jonathan Zenneck," a permanent ionospheric observation station of the Max Planck Institut für Aeronomie outside Tsumeb in Namibia. Two more recording stations were also established in South Africa—one at Hartebeesthoek in 1972, and the other at Grahamstown in 1974. Problems at Grahamstown eventually led to the closure of the station in 1980. Since then both Hermanus and Hartebeesthoek became INTERMAGNET Observatories, with Tsumeb obtaining the same status in November 2004. The data from Hermanus are used together with those of Honolulu, San Juan, and Kakioka to derive the Dst index, with Hermanus being the only Southern Hemisphere magnetic Observatory of these four stations.

Since the first observatory was founded in Cape Town in 1841, geomagnetism has grown in stature where it is now part of a research program at the Hermanus Magnetic Observatory, exploiting ground observations as well as data from low-earth orbit satellites like Ørsted and CHAMP to investigate the peculiar behavior of the field over southern Africa.

# **OBSERVATORIES IN SPAIN**

#### History

The history of magnetic observatories in Spain, as elsewhere in the world, started in the last quarter of the 19th century. Some measurements of the geomagnetic field at earlier times have been recorded, for example the geomagnetic chart of the Iberian Peninsula made by Lamont in 1868, but nothing indicates continuous observations.

San Fernando Observatory (astronomical and geophysical observatory maintained up to the present time by the Spanish Navy; SFS—36°27.7′N, 6°12.3′W) received a set of instruments for absolute measurements around 1842. But the first records of regular measurements at this place were not till 1877. An Adie variometer was received on 1875, but continuous recording did not start till 1891.

The Madrid Astronomical Observatory (today named Observatorio Astronómico Nacional;  $40^{\circ}24.5'$ N,  $3^{\circ}41.2'$ W) started the publication of daily measurements of the geomagnetic field in 1879. They were stopped in 1901 due to the installation of electric tramways in Madrid.

At the same time, Jesuits founded magnetic sections in two meteorological observatories in Spanish colonies, Belen (from 1862— 23°8.24'N, 82°21.30'W), in Havana (Cuba), and Manila (from 1889—14°34.7'N, 120°58.5'E) in the Philippine Islands. Both continued after the independence of these countries in 1898.

At the beginning of the 20th century, in 1904, the Jesuits founded Ebre (or Ebro) Observatory (EBR-40°49.2'N, 0°29.6'E). The observation program was extensive, including telluric currents, solar activity, seismology, and atmospheric electricity. It was used as the reference observatory for the first Spanish geomagnetic chart completed in 1927.

In 1934, the state founded Toledo Observatory (TOL—39°53.0'N, 4°2.8'W). It was designated as the new central geophysical observatory in Spain. Geomagnetic measurements started in 1934, but the Spanish Civil War delayed the final set-up of the instruments, and regular observations were not undertaken till 1947.

As a contribution to the International Geophysical Year in 1957–1958, Spain decided to install some new geomagnetic observatories. Two were placed in the Iberian Peninsula: Almeria (1955– 1989; ALM; 36°51.2'N, 2°27.6'W) and Logroño (1957–1980; LOG; 42°27.5'N, 2°30.3'W); another, Las Mesas (1961–1992; TEN; 28°28.6'N, 16°15.7'W), in Tenerife Island and the last one, Moca (1958–1971; MOC; 3°20.6'N, 8°39.6'E), in Equatorial Guinea, at that time a Spanish colony.

#### Present status

As elsewhere in the world, magnetic perturbations due to human activity have forced magnetic observatories to move or to shut down. Present status is as follows:

#### San Fernando observatory (SFS)

Toward the end of the 1970s (1978), the electrification of the Sevilla-Cádiz railway forced the movement of the station 8 km northeast of the original location. Present instrumentation consists of a variometric 740

station with feedback torsion photoelectric sensors, a declinometer/ inclinometer (YOM MG2KP), and a Geometrics G-856 proton magnetometer. Since April 1998, to minimize the scatter, observations are restricted to periods when the railway is nonelectric. Two nighttime absolute measurements are made per week.

Although averaged data are not affected, new anthropogenic high frequency (some 2 nT rms) interferences are detected in the records. Thus, since 1997, tests have been made at different sites in order to select a new location. This has been chosen at 40 km distance from the present one. Works have already started. The new instrumentation envisaged for deployment there, consists of a fluxgate triaxial tilt-compensated variometer (model FGE) plus an Overhauser scalar magnetometer. For the absolute instrument the previously mentioned YOM MG2KP declinometer/inclinometer will be used.

Bulletins from this observatory have been published for the period 1891–1978 and from 1991 onward.

#### San Pablo observatory (SPT)

Located at 50 km southwest of Toledo, in 10 ha grounds free from disturbances, close to San Pablo de los Montes town, at 922 m above sea level (39°32.8'N, 4°20.9'W), it started operations in 1981. This was when Toledo Observatory closed due to the railway electrification. The variometric instrumentation consists of a tilt-compensated FGE station and a Geomag M390, both equipped with Overhauser GSM90 scalar magnetometers. As backup equipment there is also a vector magnetometer equipped with Geometrics G856AX sensors and there is a plan to incorporate a new dIdD sensor recently acquired from Gem Systems. Absolute observations are performed weekly with a couple of declinometer/inclinometer 010B Zeiss theodolites with Bartington fluxgate sensors. Bulletins from Toledo were published from 1947 to 1981 and those from San Pablo from 1982 onward.

#### Güimar observatory (GUI)

This observatory is located at 27 km south of Santa Cruz de Tenerife (Canary Islands) and at 4 km from Güimar town, at 868 m above sea level (28°19.3'N, 16°26.4'W). It has been operating since February 1993 after the closure of Las Mesas due to contamination from Santa Cruz city, located only 1 km away. Its pavilions are located in a 20 ha area of public mountain, free from human-made disturbances. The volcanic character of the terrain means that there is a large crustal bias for this observatory and that large gradients are present across the site. It is equipped with two tilt-compensated FGE stations with Overhauser GSM90 and GSM19 scalar magnetometers. The absolute instruments and the observation program are the same as at SPT. Published bulletins from Las Mesas cover the period from 1961 to 1992 and those of Güimar from 1992 onward.

#### Ebre observatory (EBR)

Ebre observatory started operation in 1904 but since 1973 the records have been disturbed because of the electrification of the railway. As a result, the rapid run magnetograph recordings had to be abandoned. Recently, a new location away from the disturbance has been selected and new instrumentation deployed. This comprises a tilt-compensated FGE and an Overhauser GSM90 scalar magnetometer. Continuous data are downloaded regularly via telephone and the site is visited once per week for the absolute measurements. These are done with a declinometer/inclinometer 015B Zeiss theodolite with an ELSEC 810A fluxgate sensor. For backup equipment there is a fluxgate triaxial tilt-compensated Geomag M390 station (also equipped with an Overhauser GSM90 scalar magnetometer) and an ARGO system, developed by the British Geological Survey (BGS), all located at the old site. The ARGO system comprises a dDdI semiabsolute vector magnetometer and a triaxial fluxgate sensor. Absolute measurements are also performed 5 days a week at the old site using another ELSEC 810A DI-flux, but with a 010B Zeiss theodolite.

This observatory has developed a procedure to semiautomatically digitize old classic records on photographic paper. Bulletins are available from the period 1910–1937 and from 1995 onward.

#### Livingston Island observatory (LIV)

Recently Ebre Observatory started a research program in the Antarctic that included the installation of a new geomagnetic observatory (LIV) at the Spanish Antarctic Station, Juan Carlos I (Livingston Island, South Shetland Islands, 62°39.7'S, 60°23.7'W). The main instrument is again a BGS dDdI vector magnetometer running all year round, although absolute measurements (with 015B Zeiss theodolite and an ELSEC 810A sensor) are only made during the 3 months of the summer survey. Data have been transmitted via the METEOSAT data collection system to the Edinburgh INTERMAGNET GIN, and presently through GOES-E to the Ottawa GIN. Data have been published since December 1996.

Crustal Magnetic Field Jesuits, Role in Geomagnetism Observatories in Antartica

# **OCEAN, ELECTROMAGNETIC EFFECTS**

The oceans play a special role in electromagnetic induction, due to their relatively high conductivity and the dynamo effect of ocean currents. Typical crystalline rocks of the Earth's crust have electrical conductivities in the range of  $10^{-6}-10^{-2}$  S m<sup>-1</sup>, (Siemen [1/ $\Omega$ ]). In comparison, seawater, with 2.5–6 S m<sup>-1</sup>, is a very good conductor. Electrical currents are induced in the oceans by two different effects: Induction by time-varying external fields and induction by motion of the seawater through the Earth's main field (see *Main field*).

### Ocean conductivity

While fresh water has a very low conductivity, a salt concentration of about 35 g  $L^{-1}$  turns the oceans into good conductors. In contrast to the electron and electron-hole conductivity of solid-Earth materials, the carriers of charge in the oceans are the hydrated ions of the dissolved salts. Positive ions are called anions and negative ions are called cations. The conductivity of seawater depends on the number of dissolved ions per volume (i.e., salinity) and the mobility of the ions (i.e., temperature and pressure). Conductivity increases by the same amount with a salinity increase of 1 g  $L^{-1}$ , a temperature increase of 1°C, and a depth (i.e., pressure) increase of 2000 m. The change in conductivity is dominated by temperature, with a range of about 2.5 S m<sup>-1</sup> for cold, deep water to about 6 S m<sup>-1</sup> for warm surface water.

# Motional induction

When the ions are carried by ocean flow through the Earth's magnetic field, they are deflected by the electromagnetic Lorentz force. The direction of the Lorentz force on the anions is given by the right-hand rule: thumb pointing in the direction of ocean flow, index finger in the direction of the magnetic field, then the middle finger indicates the direction of the deflection of the anions. The cations are deflected into the opposite direction. This separation of charge sets up large-scale electric fields. Depending on the conductivity structure of the ocean and solid Earth, these fields drive electric currents, which in turn generate secondary magnetic fields.

#### Governing equations

Motional induction is governed by the following equations: The local current density J in a conductor moving with velocity u is given by

$$\mathbf{J} = \sigma(\mathbf{E} + \mathbf{u} \times \mathbf{B}_{\text{main}}), \tag{Eq. 1}$$

where  $\sigma$  is the local conductivity and  $\mathbf{B}_{main}$  is the ambient main magnetic field (see *Main field*). The  $\mathbf{u} \times \mathbf{B}_{main}$  term is the driver of the motionally induced electric current, while the induced electric field  $\mathbf{E}$  counteracts this driver and results in the actual current  $\mathbf{J}$ . This current generates a magnetic field  $\mathbf{B}_{ocean}$  as

$$\nabla \times \mathbf{B}_{\text{ocean}} = \mu_0 \mathbf{J}.$$
 (Eq. 2)

Combining Eqs. (1) and (2), and rearranging, yields an equation for the induced electric field:

$$\mathbf{E} = \frac{1}{\mu_0 \sigma} \nabla \times \mathbf{B}_{\text{ocean}} - \mathbf{u} \times \mathbf{B}_{\text{main}}.$$
 (Eq. 3)

While the irrotational (divergent) part of this electric field is maintained by an induced charge, the rotational part is induced by the temporal variations of the ocean magnetic signal as

$$\partial_t \mathbf{B}_{\text{ocean}} = -\nabla \times \mathbf{E}. \tag{Eq. 4}$$

Taking the curl of Eq. (3) and combining with Eq. (4) gives the motional induction equation:

$$\partial_{t} \mathbf{B}_{\text{ocean}} = \nabla \times \left( \mathbf{u} \times \mathbf{B}_{\text{main}} - \frac{1}{\mu_{0} \sigma} \nabla \times \mathbf{B}_{\text{ocean}} \right),$$
 (Eq. 5)

which is valid inside the oceans and the solid Earth. The fields above the surface are then determined by Laplace's equation  $\nabla^2 V = 0$  for the scalar potential V of the magnetic field  $\mathbf{B}_{\text{ocean}} = -\nabla V$  in the current-free region outside of the Earth.

#### Electric fields of motional induction

Already in 1832, Faraday predicted a motionally induced electric field for the river Thames but failed to detect it, due to a lack of adequate instrumentation. Such fields were then observed in 1851 by Wollaston in a telegraphic cable across the English Channel. Young demonstrated in 1920 the recording of electric fields in the oceans by shiptowed electrodes. Submarine cables and towed electrodes are still the principal methods of measuring ocean flow by electromagnetic methods. Overviews of the theory and instrumentation are given by Sanford (1971) and by Filloux (1973).

#### Magnetic fields of motional induction

Motionally induced magnetic fields can be divided into toroidal (strictly horizontal) and poloidal (both horizontal and vertical) parts. The toroidal magnetic field is generated by electric currents closing in vertical planes and is estimated to reach 100 nT in amplitude. It is confined to the oceans and solid Earth and is therefore only observable by subsurface measurements, for example by ship-towed or ocean-bottom magnetometers. Indeed, Lilley *et al.* (2001) showed that a magnetometer lowered by a cable from a ship can be used to determine vertical profiles of the ocean velocity.

The much weaker poloidal field, with amplitudes up to 10 nT, results from electric currents closing horizontally. It has a significant vertical component and reaches remote land and satellite locations. Much attention has been given to the periodic magnetic signals of ocean flow, which is driven by the lunar tides. In interpreting tidal magnetic signals one has to take into account that lunar tidally driven winds in the upper atmosphere induce tidal electric fields and currents

**Figure O14** Predicted amplitude of the vertical component of the magnetic field at the Earth's surface generated by ocean flow due to the lunar M2 tide. (Reproduced from Kuvshinov and Olsen, 2005b.)

in the ionosphere that also contribute to the magnetic signal at these periods. However, the strength of the ionospheric currents depends on the conductivity of the ionosphere, which varies with the time of the day. This additional solar-time modulation of the ionospheric lunar tidal fields can be used to separate them from the oceanic lunar tidal signals (Malin, 1970). The dominant M2 lunar tidal ocean flow magnetic signal has also been identified in CHAMP (see *CHAMP*) satellite data (Tyler *et al.*, 2003). A map of this signal at surface level is displayed in Figure O14.

Using high-resolution ocean circulation models predictions of the magnetic signal of nontidal ocean flow have been made by several authors. Amplitudes at surface level are predicted to be comparable to those of tidal ocean flow signals. However, the magnetic signal of the steady ocean circulation is impossible to distinguish from the crustal magnetic field (see *Crustal magnetic field*). Observations must therefore concentrate on the much weaker time-varying part of the signal. For example, the annual variation in the Indian Ocean is predicted to generate a signal with only about 0.3 nT at satellite altitude. It is a great challenge to separate this weak ocean signal from ionospheric fields, which have similar periodicities and may even share some of the atmospheric driving forces. At this point of time, nontidal ocean currents have not yet been convincingly identified in land observatory or satellite magnetic measurements.

#### Induction by time-varying magnetic fields

External magnetic fields, generated in the ionosphere (see *Ionosphere*) and the magnetosphere (see *Magnetosphere of the Earth*), vary strongly in time, exhibiting regular daily variations (see *Geomagnetic spectrum, temporal*) and occasional strong magnetic storms (see *Storms and substorms*) caused by coronal mass ejections from the sun. These time-varying magnetic fields induce electric fields and currents in the oceans, generating secondary, induced magnetic fields.

#### Governing equations

A time-varying magnetic field induces an electric field  ${\bf E}$  in the oceans, given by

$$\partial_t \mathbf{B} = -\nabla \times \mathbf{E},\tag{Eq. 6}$$

where  $\mathbf{B}$  is the sum of the inducing and the secondary induced magnetic field. The induced electric field drives electric currents

$$\mathbf{J} = \sigma \mathbf{E},\tag{Eq. 7}$$

generating a secondary-induced magnetic field:

$$\mu_0 \mathbf{J} = \nabla \times \mathbf{B}_{\text{induced}}.\tag{Eq. 8}$$

Combining Eqs. (6), (7), and (8) yields

$$\partial_t \mathbf{B} = -\nabla \times \frac{1}{\mu_0 \sigma} \nabla \times \mathbf{B}_{\text{induced}},$$
 (Eq. 9)

which is the equation for induction by time-varying magnetic fields inside the oceans. In contrast to the motional induction discussed above, the oceans are assumed here to be stationary in the Earth-fixed reference frame. The field in the source-free region above the Earth's surface and below the external current systems is again given by Laplace's equation.

# Skin depth

Low-frequency electromagnetic waves penetrate deeper into an electrical conductor than high-frequency waves. For a periodic external field with frequency v, Eq. (9) demands that the amplitude in a uniform conductor decays exponentially with depth. The depth at which the amplitude is reduced to 1/e is called the skin depth  $\delta$ , given by

$$\delta = \sqrt{\frac{1}{\pi\mu_0 \sigma v}} \approx \frac{270 \text{m}}{\sqrt{v}} \tag{Eq. 10}$$

where the frequency v is given in hertz and a seawater conductivity of  $3.5 \text{ S} \text{ m}^{-1}$  is assumed. Thus, to effectively penetrate through a seawater column of 5 km, magnetic disturbances have to have periods longer than about 6 min. However, even up to periods of several days, induced fields are strongly influenced by the highly conducting oceans.

# Ocean induction by magnetic storms

While daily variations during solar quiet conditions generate significant induction in the oceans, a much stronger effect is caused by magnetic storms. Strong magnetic storms generate ocean-induced magnetic fields reaching magnitudes of more than 100 nT. An overview of induction in the oceans by solar quiet and storm time fields is given by Fainberg (1980). The induced currents are concentrated near the coasts, the horizontal boundaries of the conductor. Their magnetic signal is also known as the coast effect (see *Coast effect of induced currents*). The ocean-induced fields can be predicted for a given external storm signature using a 3D conductivity model of the oceans, crust, and mantle. The induction equation (9) is solved either directly in the time domain, or separately for all contributing frequencies with a subsequent inverse Fourier transform to the time domain. The result

**Figure O15** Magnetic field induced in the oceans by the Bastille-day magnetic storm of July 15, 2000. Shown is the vertical component of the induced magnetic field at 21:30 universal time at the Earth's surface. (Reproduced from Kuvshinov and Olsen, 2005a.)

of a simulation using the latter approach (Kuvshinov and Olsen, 2005a) for a strong magnetic storm is shown in Figure O15.

Storms and Substorms

# OLDHAM, RICHARD DIXON (1858–1936)

A British geologist and seismologist, born on July 31, 1858 in Dublin and died on July 15, 1936 in Llandrindod Wells. He was the third son of Thomas Oldham (1816-1878), Prof. of Geology at Trinity College, Dublin, and director of the Geological Surveys of Ireland and India. Richard Dixon Oldham was educated in England at first in Rugby, later at the Royal School of Mines. In 1879, he followed his father's footsteps by moving to India and working at the Geological Survey of India. During his time in India he wrote over 40 publications related to geology and tectonics of India, many of them about earthquakes and their observations in India. After moving back to England in 1903, he worked for sometime together with John Milne (1850-1913) on the Isle of Wight. Later, because of his ill health, he spent the winters in Southern France studying the history of the Rhône delta and the summers in Llandrindod Wells working on seismological problems. In 1908, he was honored with the Lyell Medal by the Geological Society and in 1911 he was elected a Fellow of the Royal Society. In geomagnetism. Oldham is known for his establishment of the Earth's core.

Oldham started his career in India with the publication of his father's collection of macroseismical and geological observations in the context of the large 1869 earthquake in Silchar (Assam). With this background, he was predestined for a similar investigation of the huge Assam earthquake of June 12, 1897. The results of his study are published in a famous monograph of 1899 and numerous additional

smaller publications. Since the first teleseismic observations of seismic waves by Ernst von Rebeur-Paschwitz (1861–1895), surface and body waves were known not only to exist but also to have different propagation velocities (e.g., Rebeur-Paschwitz, 1895). Oldham's most important result for modern seismology was that he for the first time could identify onsets in seismograms belonging to both body-wave types as proposed by the theory of elastic waves, which propagate with different velocities through the Earth: compressional waves (later named P-waves) are faster than shear waves (later named S-waves) (Oldham, 1899, 1900).

In the last decade of the 19th century, Emil Wiechert (1861-1928) deduced from moment of inertia, ellipticity, and mean density of the Earth the need for dividing the Earth in two principle parts: a less dense mantle of rock material and a much denser core of compressed iron (Wiechert, 1896, 1897; Brush, 1980, 1982). However, the seismological proof could not be given in these early days of seismology. During his first years back in England, Oldham analyzed and compiled teleseismic observations from the collection available at Shide, Milne's Observatory on the Isle of Wright. In 1906, he published a paper in which he claimed to have observed and modelled the Earth's core by delayed P- and S-phase observations due to lower seismic velocities inside the core. Oldham himself was not very convinced by his delayed P observations because of their scatter (Oldham, 1906). More important for his argumentation was the delay of S onsets at distances beyond 120° epicentral distance. From these data, Oldham concluded that the Earth's core has a size of about 0.4 of the Earth's radius and that both P- and S-wave velocities are much smaller than in the Earth's mantle. As Wiechert (1907) pointed out, Oldham's delayed S-phase observations are mostly SS phases, that is, the reflections of S phases at the Earth's surface, an interpretation later accepted also by Oldham (Oldham, 1919).

The correct deciphering of the main structural elements of the Earth's interior was then the work of the next generation of seismologists: Beno Gutenberg (1889–1960) could estimate the depth of the *core-mantle boundary* (q.v.) at 2890 km, calculate travel-time curves for core phases, and correctly identify in seismograms the P phases, which had been reflected from, or which had traversed the core (Gutenberg, 1913, 1914). Harold Jeffreys (1891–1989) showed that the Earth's core must have the rheological behavior of a fluid, and that therefore no S phases can pass it (Jeffreys, 1926) and in 1936 Inge Lehmann (1888–1993) discovered the inner core of the Earth (Lehmann, 1936, 1987).

However, Oldham was the first who discovered and published about the shadow effect of the Earth's core due to lower seismic velocities. Together with his work on seismic phase types, Oldham is one of the pioneers for the application of seismic-wave phenomena to investigate the structure of the Earth's interior.

# ØRSTED

This geomagnetic research satellite (Figure O16/Plate 5b), named after the Danish scientist Hans Christian Ørsted (1777-1851), is the first satellite mission after Magsat (q.v.) (1979-1980) for high-precision mapping of the Earth's magnetic field. It was launched with a Delta-II rocket from Vandenberg Air Force Base (California) on February 23, 1999 into a near polar orbit. Being the first satellite of the International Decade of Geopotential Research (IAGA, 1997), it has been a model for other missions, like CHAMP (q.v.) and Swarm (Friis-Christensen et al., 2006). Since optimal utilization of magnetic data for improved field modeling requires firm knowledge of all contributing sources, there was an endeavor to bring together experts in internal sources (core and crustal field, electromagnetic induction) and in external sources (current systems in the ionosphere (q.v.) and magnetosphere (q.v.)) in the Ørsted International Science Team (OIST) very early in the planning phase of the project (Friis-Christensen and Skøtt, 1997). Sixtyfour research groups from 14 countries joined the OIST, giving impetus to the mission (Stauning et al., 2003). Ørsted has also had an impact on the collection of ground data, as is evident from the significantly increased number of geomagnetic observatories that deliver data to the World Data Centers in support of the mission. Ørsted external field science is coordinated by the Danish Meteorological Institute (DMI), internal field science is coordinated by the Danish National Space Center (DNSC, formerly Danish Research Institute, DSRI). Satellite control is managed by the industrial company Terma A/S (Birkerød, Denmark).

744

Figure O16/Plate 5b The Ørsted satellite.

#### Satellite and orbit

Ørsted was built in a joint effort of various Danish research institutions and companies with significant contribution from space agencies in the United States and Europe. The satellite weighs 62 kg, measures  $34 \times 45 \times 72$  cm and contains an 8 m long boom, deployed shortly after launch, carrying two magnetometers (q.v.). The satellite is gravity gradient stabilized; attitude maneuvers are performed using magnetic torquers. The orbit has an inclination of 96.5°, a period of 100.0 min, a perigee at 643 km and an apogee at 881 km (decreased to respectively 99.7 min, 632 km, and 860 km after 7 years in space). The orbit plane is slowly drifting, the local time of the equator crossing decreases by 0.91 min day<sup>-1</sup>, starting from an initial local time of 1426 on February 23, 1999 for the north-going track, cf. the upper part of Figure O17. Nominal lifetime of the mission was 14 months (2 months commissioning phase + 12 months science phase), but after almost 8 years in space the satellite is still healthy and provides high-precision magnetic data.

#### Instrumentation

A proton precession Overhauser magnetometer (OVH), measuring the magnetic field intensity with a sampling rate of 1 Hz, is mounted at the top of the deployable 8 m long boom. This instrument, developed by LETI (Grenoble/F), has an absolute accuracy better than 0.5 nT. Two meters away, at a distance of 6 m from the satellite body, is the optical bench with the compact spherical coil (CSC) fluxgate vector magnetometer mounted closely together with the *star imager* (SIM); these instruments were developed by the Danish Technical University and DNSC. The CSC samples the magnetic field at 100 Hz (burst mode, at polar latitudes) or 25 Hz (normal mode) with a resolution better than 0.1 nT and is calibrated using the field intensity measured by the OVH (Olsen *et al.*, 2003). After calibration, the agreement between the two magnetometers is better than 0.33 nT rms.

A copy of the Ørsted boom and payload (but with a scalar helium magnetometer provided by NASA/JPL instead of the Overhauser

magnetometer), called Ørsted-2, was launched in November 2000 onboard the Argentinean satellite SAC-C. However, due to a broken connection in a coaxial cable, no high-precision attitude data (and hence no reliable vector data) are available.

# Data accuracy and availability

Ørsted data are available at the Ørsted Science Data Centre (http:// www.dmi.dk/projects/oersted/SDC) and at www.spacecenter.dk/data/ magnetic-satellites. Scalar measurements (from the OVH if available, and from the CSC otherwise) are provided at 1 Hz sampling rate in the MAG-F files. The overall accuracy of the scalar data is estimated to be better than 0.5 nT. Vector data (at the sampling rate of 1.135 s of the SIM) are distributed as MAG-L files. The biggest limitation of the vector data is the star imager attitude accuracy. It is highly anisotropic: determination of the SIM bore-sight direction (pointing) is more accurate than determination of the rotation around bore-sight (rotation), resulting in a relatively higher noise of the SIM rotation angle. In addition, the rotation angle is more sensitive to distorting effects like instrument blinding (for instance by the moon). This attitude anisotropy results in correlated errors between the magnetic components, which have to be taken into account when deriving field models, as demonstrated by Holme (2000). Let n be the unit vector of the SIM bore-sight, and let **B** be the observed magnetic field vector. The magnetic residual vector (observation minus model field)  $\delta \mathbf{B} =$  $(\delta B_{\rm B}, \delta B_{\perp}, \delta B_3)$  can be transformed such that the first component,  $\delta B_{\rm B}$ , is in the direction of **B** (and therefore to first order is equal to the scalar residual), the second component,  $\delta B_{\perp}$ , is aligned with  $\mathbf{n} \times \mathbf{B}$ , and the third component,  $\delta B_3$ , is aligned with  $\mathbf{B} \times (\mathbf{n} \times \mathbf{B})$ . The last two components are perpendicular to the magnetic field. Attitude noise may result in significant noise in the magnetic vector components: since the nominal bore-sight direction is almost East-West, typical rotational attitude noise will result in noise in  $B_r$  of up to 10 nT amplitude at low latitudes. Whenever possible, the user should be aware of this effect and use data in the  $(\delta B_{\rm B}, \delta B_{\perp}, \delta B_{3})$ -frame rather than  $(B_r, B_{\theta}, B_{\phi})$ .

The boom experiences occasional jerks associated with thermal expansion/contraction, especially near the terminator. The resulting boom oscillations, mainly around the boom axis, have a frequency close to 0.5 Hz and are seen in the magnetic vector components as occasional damped oscillations with amplitudes of a few nanoteslas. These technically induced signals should not be confused with geomagnetic pulsations of natural origin.

Accuracy of  $\delta B_{\rm B}$ ,  $\delta B_{\perp}$ , and  $\delta B_{3}$  is estimated to be better than 1, 2, and 8 nT, respectively. Vector data in an Earth-Centered-Earth-Fixed frame  $(B_r, B_{\theta}, B_{\phi})$  and the SIM bore-sight direction **n** are available together with time and position in the MAG-L files. Data at higher sampling rates are available upon request. The lower part of Figure O17 shows the availability of scalar data (MAG-F, black) and of vector data (MAG-L, light grey). Since attitude data (dark grey) are essential for providing vector data, drop outs of the SIM (for instance due to thermal problems, or due to blinding of the instrument by the Sun, Moon, or Earth) limit the availability of Ørsted vector data. The satellite was fully illuminated by the Sun from July to November 2000, from August 2002 to February 2003, and from January to May 2005 (shaded area in Figure O17 top). Since the satellite was not designed for this situation (nominal lifetime of 14 months ended in April 2000), thermal problems resulted in decreased data availability during these periods, as shown in the bottom panel of Figure O17.

As secondary data products, magnetic field models that have been derived using Ørsted data are provided at www.spacecenter.dk/ projects/oersted/models/.

#### Scientific results

After almost 8 years of operation, about 150 scientific papers using Ørsted data have been published. The satellite and first science results were presented in an overview article in EOS (Neubert *et al.*, 2001).

Figure O17 Local time evolution of the Ørsted orbit (top) and data availability (bottom), as of July 2006.

A parade of *magnetic field* (q.v.) models of increasing complexity and accuracy have been derived from Ørsted observations, starting from models that describe a snapshot of the field at a specific epoch, like the *IGRF, International Geomagnetic Reference Field* (q.v.) 2000 or the Ørsted Initial Field Model *OIFM* (Olsen *et al.*, 2000) to models that include the temporal changes of the field (Olsen, 2002, Oslen *et al.*, 2006). Spherical harmonic coefficients estimated using more than 6 years of Ørsted observations are robust up to degree n = 40for the static terms, and up to at least n = 15 for the linear time terms (see *Secular variation models*). Comparing two models estimated from Ørsted data (epoch 2000) and Magsat data (epoch 1980), respectively, Hulot *et al.* (2002) derived core-flow models from the observed mean secular variation, down to length scales previously inaccessible.

Ørsted's altitude makes an investigation of the *crustal magnetic* field (q.v.) difficult, but combination with other satellite (*POGO* (q.v.), *Magsat* (q.v.), *CHAMP* (q.v.)) and ground data allows for an improved separation of internal and external sources, and thereby better crustal field determination. This was shown by Sabaka *et al.* (2004) in their *Comprehensive Model*, *CM4*, which determined crustal field contributions that are reliable at least up to degree n = 50.

Although the main objective of Ørsted is the precise mapping of Earth's internal field, the satellite has contributed to improved understanding of ionospheric and magnetospheric current systems. A much more detailed determination of their variability with season and local time is possible due to the greatly improved data distribution compared to previous missions. By taking the curl of the magnetic field residual (observation minus field model), Christiansen et al. (2002) derived mean field-aligned currents (FAC) in dependence on season, local time, and interplanetary magnetic field (solar wind) conditions and found that the entire polar caps are filled with currents even during very quiet solar wind conditions. The influence of these quiet time polar cap currents on core and crustal field models is still an unsolved problem. Embedded in the large-scale average current systems are small-scale (few hundreds of meters) current structures (filaments), especially in the cusp region, as found by Neubert and Christiansen (2003).

Figure O18 Torsional oscillations in the core. The direction of the azimuthal cylindrical flow indicated by the black arrows oscillates in time. The Earth's axis of rotation points in the direction of  $\Omega$ .

# **OSCILLATIONS, TORSIONAL**

Torsional oscillations in the Earth's fluid core are the azimuthal oscillations of rigid cylindrical surfaces coaxial with the rotation axis (see Figure O18). The pattern of the time-dependent part of the fluid motion at the surface of the core revealed from geomagnetic data inversion is highly suggestive of the presence of these waves inside the core, with velocity amplitudes on the order of 10 km year<sup>-1</sup> and typical periods of decades (see Figure O19). The observation of torsional oscillations has important consequences for theoretical models of the geodynamo and provides a window through which we can observe some aspects of core dynamics.

Rigid azimuthal cylindrical flows of this sort, also called geostrophic flows, can be expected in the fluid core because rapid rotation prevents large variations in velocity along the rotation axis (see Proudman-Taylor theorem), and because purely azimuthal flows are not affected by the solid spherical boundaries of the mantle and the inner core. However, the Lorentz force prevents the cylindrical surfaces at different radii to rotate freely relative to one another. The magnetic field that permeates the core tends to be "frozen" in the fluid (see Alfvén's theorem) and a differential rotation of the cylinders shears the radial component of the field in the azimuthal direction. By Lenz' law, this produces a force that opposes further relative motion between the cylindrical surfaces. The radial component of the magnetic field behaves as if it were elastic strings attached to the cylindrical surfaces, and provides a restoring force for the establishment of waves that propagate in the direction perpendicular to the rotation axis. These are torsional oscillations, or torsional vibrations, as they were originally called in Braginsky's seminal work on the subject (Braginsky, 1970). Since the restoring force is purely magnetic, torsional oscillations are a type of Alfvén wave.

Strictly speaking, torsional oscillations are not a geostrophic flow because they result from an azimuthal force balance between the fluid acceleration and Lorentz forces. However, since the force balance in the direction pointing away from the rotation axis remains geostrophic and the form of the flow is identical to that of geostrophic flows, it is convenient to think of torsional oscillations as time-dependent geostrophic flows.

The importance of geostrophic flows in the core and their intimate connection to the dynamics governing the geodynamo was first established by Taylor (1963). He showed that if one integrates the azimuthal component of the momentum equation over the surface of cylinders coaxial with the rotation axis, the Lorentz force is the only term in the leading order force balance that does not identically vanish. This imposes a morphological constraint on the magnetic field in the core, namely that the axial Lorentz torque must vanish at all times, i.e.,

$$\int_{\Sigma} \left( \left( \nabla \times \mathbf{B} \right) \times \mathbf{B} \right)_{\phi} \mathrm{d}\Sigma = 0 \tag{Eq. 1}$$

where  $d\Sigma = sd\phi dz$  and  $(s, \phi, z)$  are cylindrical coordinates (see *Taylor's condition*). When this constraint is not satisfied, one possibility to balance the Lorentz torque is by an azimuthal acceleration of the cylindrical surface

$$\frac{\partial \mathcal{V}_{\phi}(s)}{\partial t} = \frac{1}{\rho \mu_{o}} \int_{\Sigma} ((\nabla \times \mathbf{B}) \times \mathbf{B})_{\phi} d\Sigma$$
 (Eq. 2)

where  $\mathcal{V}_{\phi}(s)$  is the geostrophic velocity,  $\rho$  is the density, and  $\mu_{o}$  is the permeability of free space. The class of motion described by the above equation is therefore not directly influenced by the Coriolis force, but only by the magnetic field. The above system allows oscillatory behavior of geostrophic motion (i.e., torsional oscillations) about an equilibrium position where the Lorentz torque vanishes. The damping of these oscillations by diffusion of the magnetic field naturally brings the system back toward this equilibrium. Torsional oscillations are therefore an essential ingredient of the geodynamo as they always allow the system to relax toward a state where Eq. (1) is satisfied everywhere in the core.

Braginsky (1970) was the first to exploit this theoretical concept in an effort to explain geophysical observations. He sought to explain the decade variations in the length of day (LOD) as exchanges of angular momentum between the mantle and the core, with the angular momen-

tum of the core carried by torsional oscillations. This type of fluid motion, he argued, would also be consistent with a part of the observed geomagnetic secular variation. Braginsky established the wave equation for the torsional oscillations predicted by J.B. Taylor. For  $\mathcal{V}_{\phi}(s)$  proportional to  $\exp(-i\omega t)$ , it is given by

$$-\omega^2 \rho s^2 h \mathcal{V}_{\phi}(s) = \frac{\mathrm{d}}{\mathrm{d}s} \left[ \frac{s^3 h}{\mu_{\mathrm{o}}} < (B_{\mathrm{s}})^2 > \frac{\mathrm{d}}{\mathrm{d}s} \left( \frac{\mathcal{V}_{\phi}(s)}{s} \right) \right] - \mathrm{i}\omega f(s)$$
(Eq. 3)

where *s* and *h* are, respectively, the radius and height of the cylinder, f(s) is the torque at the ends of the cylinders due to surface forces at the fluid-solid boundaries,  $B_s$  is the s-component of the field which is assumed to remain steady on the timescale of the oscillations, and <> denotes average over the cylinder surface. Note that the restoring force does not involve the steady azimuthal part of the magnetic field, as this component is not sheared by torsional oscillations.

Solutions of Eq. (3) depend on the knowledge of the radial magnetic field everywhere in the core and on the physical properties near the boundaries that enter f(s). Exact solutions are then not obtainable without solving the dynamo problem as a whole. Nevertheless, estimates of the form and periodicity of the natural modes of oscillation can be obtained for simple magnetic field morphologies and simple models for fluid–solid coupling. An order of magnitude estimate for the period of the fundamental mode is given by

$$\tau_{\rm to} \approx c \left(\frac{\rho \mu_{\rm o}}{\left< \left(B_{\rm s}\right)^2 >}\right)^{1/2} \tag{Eq. 4}$$

where *c* is the radius of the core. As an example, using a typical value of  $B_{\rm s} = 0.5$  mT, we find  $\tau_{\rm to} \sim 25$  years, which corresponds to the timescale of the changes in LOD and of a part of the geomagnetic secular variation.

Braginsky's original idea that torsional oscillations can both explain the LOD changes while being consistent with the secular variations of the magnetic field has since received further support. Jault *et al.* (1988) have reconstructed the changes in geostrophic velocities between 1969 and 1985 from maps of the flow at the top of the core which best

explain the secular variation of the magnetic field. The changes in core angular momentum calculated from these motions correspond roughly to the changes in mantle angular momentum required to explain the LOD variations during that period. Jackson et al. (1993) subsequently showed that this correlation extends back to 1900. In addition, the variations in time of the rigid cylinder flow suggest large exchanges of angular momentum inside the core and relatively little exchange with the mantle, indicating that the motion is likely to be that of waves of the type consistent with torsional oscillations, a fact that was later verified by Zatman and Bloxham (1997). An example of the timedependent geostrophic flows in the Earth's core, which possibly represent torsional oscillations, are shown in Figure O19 for the period between 1900 and 1990. Recently, Bloxham et al. (2002) showed that rigid cylindrical flows with shorter timescale and wavelength also have wave characteristics suggestive of torsional oscillations. This provides additional support for their presence in the Earth's core and indicates that higher modes are also excited. The same study also showed that a time-dependent flow model solely comprised of torsional oscillations can reproduce the part of the secular variation known as geomagnetic jerks. This suggests that the explanation for geomagnetic jerks is connected to torsional oscillations and further underlines their role in the observable part of the dynamics taking place inside the core.

Torsional oscillations are expected on theoretical grounds and we have good evidences that they occur in the Earth's core. Therefore, they represent one of the most robust links between geophysical observations on historical timescales and the dynamics responsible for maintaining the field against Ohmic decay on geologic timescales. Theoretical models of the dynamical processes involved in the geodynamo must then be consistent with torsional oscillations. Conversely, they can be used to extract a wealth of physical quantities and dynamics in the core that are otherwise not directly observable. For instance, Zatman and Bloxham (1997) have used the observed torsional oscillations to build a model of the steady rms value of  $B_s$  on cylinder surfaces inside the core. Similarly, Buffett (1998) used Eq. (3) in order to constrain physical parameters near the core-mantle boundary and the nature of the torque that transfers the angular momentum between the mantle and the core.

While a large part of the secular variation of the magnetic field can be explained by a combination of steady flows and torsional oscillations,

**Figure O19** The time-dependent axisymmetric, equatorially symmetric part of the azimuthal velocity at the surface of the core between 1900 and 1990 from inverted *ufm1* field model (Bloxham and Jackson, 1992). Colatitudes ( $\theta$ ) are given in degrees. If this part of the velocity extends rigidly inside the core, then it represents time-dependent velocities of rigid cylindrical surfaces (geostrophic flows) with radius *s* = *r*<sub>c</sub>sin $\theta$ , where *r*<sub>c</sub> is the (spherical) radius of the core. The undulations in radius and time are suggestive of a propagating wave consistent with torsional oscillations.

748

a part of the signal remains unaccounted for by this simple model of the dynamics. The unexplained signal may be due to nonaxisymmetric and/or meridional flows associated with the propagation of magnetohydrodynamic waves. The connection between these waves and torsional oscillations remains to be established. Another important issue still unresolved is that of the excitation of torsional oscillations. Estimates of the coupling with the mantle suggest that they should be damped after a few periods, which indicates that an efficient excitation mechanism must exist. The behavior described above, where torsional oscillations occur with respect to a steady equilibrium state, is correct only if the waves are excited by a mechanism that acts suddenly and then plays no further role in the dynamics. A perhaps more likely scenario is the one where a forcing term needs to be added to Eq. (3) and plays an active role in the dynamics at all times. If this latter view is correct, the resulting time-dependent geostrophic flows would consist of a combination of forced and free "torsional oscillations". The nature of this forcing is at present unknown but perhaps it simply consists of the continual changes in the magnetic field, and hence of the Lorentz torque on any cylinder, produced by the convective dynamics in the core. The changes in the Lorentz torque may occur on many different timescales but those that are close to the natural modes of torsional oscillations would provide efficient excitation. In any case, the elucidation of the excitation mechanism will likely lead to an improved understanding of the physical processes involved in the geodynamo.

A promising future avenue to further our understanding of torsional oscillations and of their excitation is through numerical models of the geodynamo (see Geodynamo, numerical simulations). This is because the time span of the simulations can far exceed the historical record, and also because the simulations allow direct access to field variables at every location in the core and thus offer a means to examine the details of the dynamics. Since torsional oscillations are one of our most robust observations of core dynamics, realistic numerical models of the geodynamo should include them. Oscillations of geostrophic flows have been observed in a numerical model (Dumberry and Bloxham, 2003) and their excitation is consistent with the above scenario of torques produced by the convective dynamics. However, these oscillations do not follow Eq. (3) because the current limits in computation prevent the use of realistic Earth parameters in the model, and the extrapolation of the results to the real Earth remains uncertain. Nevertheless, the ability of the numerical model to produce geostrophic flows is a step in the right direction. With numerical models becoming increasingly closer to Earth-like conditions, there is hope that they will soon encompass realistic torsional oscillations.

# PALEOINTENSITY: ABSOLUTE DETERMINATIONS USING SINGLE PLAGIOCLASE CRYSTALS

Single plagioclase crystals can contain minute magnetic inclusions, capable of recording and preserving a thermoremanent magnetization. Thellier paleointensity experiments using plagioclase feldspars from a historic lava on Hawaii provide a benchmark for the method. The comparison of rock magnetic and Thellier data from feldspars and whole rocks from older lavas indicate that the feldspars are less susceptible to experimental alteration. This resistance is likely related to the lack of clays and protection of the magnetic minerals by the encasing silicate crystals.

Thellier data sets based on single plagioclase crystals are available from continental flood basalt provinces formed during the Cretaceous Normal Polarity Superchron. These data suggest paleomagnetic dipole moments of approximately  $12 \times 10^{22}$  A m<sup>2</sup>, significantly higher than the average paleointensity thought to characterize times of frequent geomagnetic reversals. A correlation between intervals of low-reversal frequency and high-geomagnetic field strength is supported, as seen in some numerical simulations of the geodynamo.

On longer timescales, the magnetization held by plagioclase and other silicate crystals can be used to investigate the Proterozoic and Archean field. Data from plagioclase crystals separated from dikes demonstrate how outstanding questions related to growth of the solid inner core and the magnetic field of the young Earth can be addressed in future investigations.

#### Whole rock paleointensity analyses

The Thellier double heating method (Thellier and Thellier, 1959) is arguably the most rigorous means of learning about past field strength. But when applied to whole rocks, does this approach insure that the past field strength is accurately recovered? In tests using historic lavas, the Thellier method clearly works well because it retrieves the known field strength. Recent studies of lavas formed during the last 5 Ma have applied rigorous selection criteria to detect experimental alteration and nonideal behavior related to magnetic mineral domain state (e.g., Valet, 2003). But in older rocks, the effects of weathering are important. Clay minerals begin to form a progressively larger portion of a whole rock's matrix. Magnetic mineral phenocrysts undergo low-temperature oxidation.

During the successive heating steps required by the Thellier method, fine-grained magnetic minerals can form from clays (Cottrell and Tarduno, 2000). At relatively high, temperature treatments the alteration can be obvious; it is seen in experimental checks when a partial thermoremanent magnetization (TRM) is imparted at a lower temperature to check for the growth of magnetic minerals. The initial stages of alteration, however, are subtle and can be difficult to detect.

Low-temperature oxidation, or maghemitization, results in a fundamental change in the nature of the magnetization (e.g., Özdemir and Dunlop, 1985). Rather than a TRM, the basis of the Thellier approach, the magnetization can become a partial or complete chemical remanent magnetization (CRM). The accuracy of CRM in preserving the original geomagnetic field strength is unclear (Dunlop and Özdemir, 1997).

There are other reasons for concern about paleointensity estimates derived from older rocks. Many of the virtual dipole moments based on Thellier data from the whole rock and submarine glass samples are similar to values that characterize younger geomagnetic excursions and reversal transitions (Tarduno and Smirnov, 2004). Taken at face value, these data imply that the field has been extraordinarily energetic during the last 10 Ma. But factors that could change the magnetic field energy are generally associated with much longer timescales. Natural and experimental alteration of lavas and submarine basaltic glass tends to lower paleointensity values (Smirnov and Tarduno, 2003), suggesting that the apparent difference in field strength before and after 10 Ma is an artifact.

These issues motivate a search for natural paleomagnetic recorders that are less susceptible to alteration in nature and in the laboratory. Single plagioclase crystals are one such alternative recorder of geomagnetic field history.

#### Plagioclase feldspar paleointensity analyses

Transmission electron microscopy (TEM) analyses of magnetic extracts from plagioclase separated from basaltic lavas indicate that they can contain equal to slightly elongated magnetic particles 50–350 nm in size (Cottrell and Tarduno, 1999, 2000) (see Figure P1). Studies of the directional dependence of magnetic hysteresis indicate little anisotropy in the plagioclase crystals that could adversely affect Thellier analyses (Cottrell and Tarduno, 1999, 2000).

Unblocking temperatures indicate that the magnetic carriers in plagioclase have compositions that match those of the whole rock. Thermal demagnetization through warming of a saturation isothermal remanent magnetization acquired at low temperature has shown the presence of a blurred Verwey transition (the transition from cubic to monoclinic crystalline symmetry; Verwey, 1939) in plagioclase crystals separated from Cretaceous basalts of the Arctic (Tarduno *et al.*, 2002) (see Figure P1). These data, together with the thermal unblocking

**Figure P1** Optical, transmission electron microscope (TEM) and rock magnetic analyses of whole rocks, plagioclase crystals and magnetic separates. (a-f) Examples from the Strand Fiord basalts of the high Arctic after Tarduno *et al.* (2002). (g, h) Examples from the Rajmahal Traps of eastern India after Cottrell and Tarduno (2000). (a) Typical plagioclase crystal used for rock magnetic and paleointensity experiments. (b) TEM image of a magnetic separate from a plagioclase crystal. (c,d) Magnetic hysteresis data (slope corrected) for a whole rock basalt sample and plagioclase feldspar. In general, plagioclase crystals show single domain to pseudo-single domain behavior, while whole rocks display pseudo-single to multidomain characteristics. The former are better suited for Thellier paleointensity analyses. (e) Normalized hysteresis parameters versus rotation angle measured on a plagioclase crystal. The crystal was rotated by 45° increments on the stage of a Princeton Measurements Alternating Gradient Force Magnetometer parallel (solid line and triangles) and perpendicular (dashed line; only mean shown) P1 probes. Abbreviations:  $M_r/M_s$ , saturation remanence/saturation magnetization ratio;  $H_{cr}$  coercivity of remanence;  $H_{cr}$  coercivity. The lack of systematic variations of these parameters indicates that anisotropy is not a significant concern for Thellier paleointensity experiments. (f) Warming curve of a magnetization (solid line) acquired by a plagioclase crystal at 20 K in a 2.5 T field. Dotted line is the inverse of the derivative. (g,h) Slope corrected magnetic hysteresis curves for unheated and heated whole rock samples. The curve for the heated sample documents the growth of a fine-grained magnetic phase. The heating increments applied were those of a typical Thellier experiment. Magnetic hysteresis curves for plagioclase crystal start changes after heating (see discussion in Cottrell and Tarduno, 2000).

characteristics and TEM observations, further suggest the plagioclase crystals contain magnetic inclusions of composition similar to that of magnetic grains in the whole rock. In the case of the low-temperature data, the carrier is likely a low Ti titanomagnetite. These observations also suggest that the magnetic particles are inclusions rather than exsolved magnetic particles (Cottrell and Tarduno, 1999, 2000). The latter, which are characteristic of plagioclase in slowly cooled plutonic rocks, typically have end-member mineralogies and distinct shapes, most notably the magnetic "needles", tens of millimeters long, that are sometimes seen oriented along crystallographic axes (e.g., Davis, 1981).

In a test of the method, Thellier analyses of plagioclase crystals separated from a 1955 flow from Kilauea in Hawaii yielded paleointensity estimates that agreed with values reported in detailed comparisons of paleointensity methods based on whole rocks (Coe and Grommé, 1973) and from magnetic observatory data (Cottrell and Tarduno, 1999). The demagnetization of an oriented plagioclase from a Cretaceous lava flow of the Rajmahal Traps demonstrated that the plagioclase recorded the same paleomagnetic record as the whole rock (Cottrell and Tarduno, 2000).

Further comparisons of rock magnetic data from whole rock samples and plagioclase crystals taken from a Rajmahal lava flow demonstrated that the plagioclase crystals were less altered by Thellier heatings (Cottrell and Tarduno, 2000). Specifically, magnetic hysteresis data from heated whole rock samples indicated the formation of a finegrained magnetic phase; this behavior was not seen in the plagioclase crystals (see Figure P1). This difference in rock magnetic behavior with heating paralleled differences seen in the fidelity and absolute values of paleointensity data. Although whole rock samples meeting paleointensity reliability criteria (e.g., Coe, 1967) yielded paleointensity values that were within error of those derived from single plagioclase crystals, such samples were rare. In general, the whole rocks seldom met reliability criteria and yielded low nominal paleointensity values. The differences can be attributed to the formation of fine-grained magnetite from clays in the groundmass of whole rock samples, resulting in the anomalous acquisition of TRM during Thellier experiments (and a bias toward low values).

# Paleointensity during the Cretaceous Normal Polarity Superchron

The experimental alteration, nonideal behavior, and associated high rates of sample reject that typify the Thellier method as applied to whole rocks have generally resulted in a piecemeal approach to the definition of the past geomagnetic field. Directional and paleointensity data are seldom derived from the same rocks. The ability to derive paleointensity values from plagioclase crystals from long lava sequences provides the chance to look at all parts of the time-averaged field. Examining the potential relationships between geomagnetic reversal frequency, secular variation, field morphology and paleointensity is still a daunting task. But if relationships exist, they should be best expressed during superchrons, intervals tens of millions of years long with a few (or no) reversals.

Several continental flood basalt provinces were formed during the Cretaceous Normal Polarity Superchron; these provide an opportunity to gain a more complete view of the past geomagnetic field. For example, Thellier paleointensity analyses of single plagioclase have been derived from distinct lava units of the Rajmahal Traps. The term "lava unit" is used because sometimes it is necessary to combine results from adjacent lava flows that could have been erupted in a very short time. These units were selected from a larger paleomagnetic data set so that they span secular variation. This was gauged in two ways. First, the stratigraphic position of the lava units was considered. Second, the angular dispersion of paleomagnetic directions of the select units (derived from analyses of whole rock samples) simulated that of a complete sampling of the lava sequence. The data allow the calculation of a mid-Cretaceous paleomagnetic dipole moment. The resulting value of  $12.5 \pm 1.4 \times 10^{22}$  A m<sup>2</sup> (Tarduno *et al.*, 2001) is higher than

the present-day field, or estimates of the long term average field during the last 200 Ma.

A similar study has been conducted on lavas of the high Canadian Arctic, which were also erupted during the Cretaceous Normal Polarity Superchron. Plagioclase feldspars separated from these lavas have also yielded Thellier paleointensity estimate from distinct lava units. As in the case of the Rajmahal Traps, the units are thought to average secular variation because geological indicators show the passage of time, and the angular dispersion of paleomagnetic directions recorded by whole rock samples matches that of a larger data set that spans the entire sequence (Tarduno *et al.*, 2002). The paleomagnetic dipole moment of 12.7  $\pm$  0.7  $\times$  10<sup>22</sup> A m<sup>2</sup> suggested by these data agrees with the value from the Rajmahal Traps and indicates that high paleointensity of the latter rocks was not an isolated event within the Cretaceous Normal Polarity Superchron (see Figure P2). The data from the Rajmahal Traps and Arctic basalts support a correlation between high field strength and low reversal frequency, as suggested in early models (Cox, 1968; see also discussion by Banerjee, 2001) and in more recent numerical simulations of the geodynamo (Glatzmaier et al., 1999).

### Precambrian field strength

Mafic dikes of Proterozoic to Archean age are exposed on several continents. These contain feldspars that could carry magnetic inclusions and hence they are potential geomagnetic field recorders. This may provide a means of defining the field during a time interval that may have seen the onset of solid inner core growth. To explore this possibility, Smirnov et al. (2003) studied the 2.45 Ga Burakovka intrusion of the Karelian Craton (Russia). Thin mafic border dikes were sampled to minimize the influence of cooling rate. Clear feldspars were selected for study; in other Proterozoic-Archean dike provinces clouded feldspars reflecting exsolution are common (Halls and Zhang, 1998). Magnetic hysteresis parameters indicate multidomain-like behavior of whole rock samples and pseudosingle to single domain (SD) behavior for plagioclase crystals separated from the Karelian dikes. Whole rock samples also show a small anisotropy as recorded by systematic variations in magnetic hysteresis data, presumably recording a flow fabric within the dikes. No significant anisotropy was observed in the plagioclase crystals. The latter observation is important because it indicates that there is not a preferred alignment of elongated particles in the feldspars that could bias TRM acquisition in Thellier experiments.

Transmission electron microscopy analyses suggest that the magnetic inclusions in the plagioclase are equal to slightly elongated and range in size between 50 and 250 nm. Thermal demagnetization data of a saturation remanence imparted on single plagioclase crystals at 10 K are characterized by a well-defined Verwey transition at  $\sim$ 120 K, indicating the presence of stoichiometric magnetite, similar to that reported from whole rock samples.

These rock magnetic data demonstrate the feasibility of the single plagioclase paleointensity approach as applied to select Proterozoic-Archean rocks. Results from only four dikes are available to date from Karelia and it cannot be expected that these adequately record secular variation. Nevertheless, the Thellier paleointensity data are within the range of modern field values. Secular variation and field morphology during this Proterozoic-Archean interval also look amazingly similar to that of the last 5 Ma (Smirnov and Tarduno, 2004).

#### Discussion and summary

Prévot *et al.* (1990) concluded that geomagnetic reversal rate and paleointensity are decoupled. The contrast between this interpretation and that proposed here arises from differences in data selection. Only a few paleointensity results from rocks older than 10 Ma are based on multiple, independent cooling units that span significant secular variation. Standard paleointensity criteria exclude those lavas with larger multidomain magnetic carriers. A more widespread factor limiting the utility of lavas is weathering. The formation of clays can ultimately

**Figure P2** Geomagnetic reversal timescale, select Thellier results (1 $\sigma$  uncertainties shown), and reversal rate (based on a 10-Ma sliding window). Data sources are those selected by Tarduno *et al.* (2001, 2002), with the addition of a new data set from Goguitchaichvili *et al.* (2002). Only studies based on greater than 25 results shown. Data types: triangles, baked contacts; diamonds, basalt whole rocks; circles, plagioclase crystals (Tarduno *et al.*, 2001, 2002). Dashed horizontal line, a proposed mean Cretaceous-Cenozoic value based on Thellier analysis of submarine basaltic glass (Juarez *et al.*, 1998); Solid horizontal line, modern field intensity.

result in the formation of new magnetic minerals during Thellier experiments. In addition, magnetic mineral phenocrysts in the groundmass are transformed by low-temperature oxidation, and CRMs replace TRMs. Some of these effects lead to obvious failures of experimental reliability tests. Others are subtler that have probably led to a bias toward underestimates of field strength.

Because of these limitations, it is premature to apply statistical treatments to the entire basalt virtual dipole moment data set (e.g., Heller *et al.*, 2002) to draw conclusions on the geodynamo. Although there are high-resolution, time-averaged data sets from older lavas (e.g., Kosterov *et al.*, 1997) natural and laboratory alteration will fundamentally limit progress in understanding long-term paleointensity history. This is the prime motivation for a continued pursuit of plagioclase-based Thellier analyses.

Plagioclase feldspar separated from lavas contains minute magnetic inclusions, which appear to have been protected from weathering. Thellier analyses using such crystals have been benchmarked using historic lava. Subsequent tests show that plagioclase crystals are less susceptible to experimental alterations than whole rocks. Because the plagioclase feldspars can be collected from long basalt sequences, they afford a means to obtain joint paleointensity and secular variation data. This further provides the opportunity to investigate relationships between the frequency of geomagnetic reversals and the morphology, secular variation and intensity of Earth's magnetic field. These relationships should be best expressed during superchrons.

Available data from Thellier analyses of plagioclase crystals, coupled with paleomagnetic data from lavas covering various latitude bands, indicate that the time-averaged field during the Cretaceous Normal Polarity Superchron was remarkably strong and stable. A high-field intensity during the Cretaceous Normal Polarity Superchron has also been reported from continued analyses of submarine basaltic glass (Tauxe and Staudigel, 2004). The field was also overwhelmingly

dipolar, lacking significant octupole components (Tarduno *et al.*, 2002). These observations suggest that the basic features of the geomagnetic field are intrinsically related. Superchrons may reflect times when the nature of core-mantle boundary heat flux allows the geodynamo to operate at peak efficiency.

Thellier analyses of plagioclase separated from lavas can be used to further examine the reversing field, including times such as the Late Jurassic of peak reversal frequency (McElhinny and Larson, 2003). The approach can also be used to examine the Permian-Carboniferous Kiaman Reversed Polarity Superchron. The Precambrian history of the geomagnetic field bracketing inner core growth is relatively unexplored. Approaches utilizing rigorous Thellier analyses applied to single plagioclase crystals, and other single silicate grains, hold significant promise for revealing this history.

### PALEOINTENSITY, ABSOLUTE, TECHNIQUES

#### Introduction

The unique possibility to extract the ancient field intensity from magnetic remanence of rocks is to duplicate the acquisition of magnetization by laboratory experiments in presence of a field with a known intensity. This requires a precise knowledge of the mechanisms that govern the magnetization, which is actually the major difficulty inherent to the paleointensity experiments. Acquisition of remanence by strong magnetic fields does not concern natural rocks because the geomagnetic field has a weak intensity (unless they are affected by lightning but this has no interest for paleomagnetism). Another way of magnetizing rocks is by thermal activation, which leads to rotation of some magnetic moments in the direction of the field. The natural magnetization relevant from this process is called a thermoremanent magnetization (TRM). Thermoremanence is acquired by most igneous rocks during cooling from above the Curie temperature  $(T_c)$  in the presence of the Earth's magnetic field. Magnetic relaxation, in which remanent magnetization of an assemblage of magnetic grains decays with time, is the most straightforward effect of thermal activation. As temperature decreases through a critical temperature called "blocking temperature"  $(T_{\rm b})$ , an individual magnetic grain experiences a dramatic increase in relaxation time, which will continue down to room temperature. Thus the orientation of the magnetic moment can remain stable at the surface temperature and it will be resistant to effects of magnetic fields after original cooling. Depending on specific parameters inherent to the grain, this magnetic memory can be preserved for billions of years. Rock specimens contain many magnetic grains that can have different characteristics (size, shape etc.) and are thus frequently associated with a distribution of blocking temperatures  $T_{\rm b}$ ) from a few tens of degrees up to  $T_{\rm c}$  of the magnetic mineral carrying the magnetization.

# Thellier-Thellier technique and derivatives

A very specific characteristic of the total TRM is that it can be separated into the successive magnetizations that were acquired in distinct temperature intervals. For example, TRM of an igneous rock containing magnetite can be broken into portions acquired within successive windows of blocking temperatures from its Curie temperature ( $T_c$ ) of 580°C down to room temperature. The portion of TRM blocked in any particular  $T_b$  window is referred to as "partial TRM," abbreviated pTRM. The total TRM is the vector sum of the pTRMs contributed by all blocking temperature windows. The Individual pTRMs depend only on the magnetic field during cooling through their respective  $T_b$  intervals and are not affected by magnetic fields applied during

cooling through lower temperature intervals. This is the law of additivity of pTRM, which is essential for paleointensity experiments.

Indeed, as described above, paleointensity experiments rely on a direct comparison between thermal demagnetization of the natural remanent magnetization (NRM, original magnetization that was acquired during cooling of the material) and acquisition of laboratory partial thermoremanent magnetization (pTRM) in presence of a known field. In principle, NRM and TRM of single domain grains of magnetite retain the same proportionality in the applied field over the entire temperature spectrum (Dunlop and Özdemir, 1993). Thus the NRM/TRM ratio must remain constant. In the opposite situation it is impossible to perform suitable experiments of paleointensity because the response of magnetization to the field is not the same in the laboratory than it was during the initial cooling of the rock. In most cases, this is caused by changes in magnetic mineralogy that either altered the natural remanent magnetization (NRM) or which were produced during the laboratory experiments.

The initial and unique reliable technique for absolute paleointensity was proposed and experimented by Thellier and Thellier (1959). Basically the experiment involves a first heating and cooling of the sample in a known field at say 120C followed by measurement of the total magnetization  $M_1 = +\text{TRM} (0-120^{\circ}\text{C}) + \text{NRM} (120^{\circ}\text{C} - T_c)$ . The second heating and cooling are performed in presence of a field in the opposite direction and the total magnetization is thus  $M_2 = -\text{TRM} (0-120^{\circ}\text{C}) +$ NRM ( $120^{\circ}\text{C} - T_c$ ). The residual NRM is obtained by vectorial subtraction ( $M_1$ - $M_2$ ) while the TRM is given after substitution of the NRM. This operation is repeated at increasing temperatures up to  $T_c$ .

Coe (1967) modified the original Thellier protocol and proposed to demagnetize first the NRM in zero field and then to remagnetize the sample. However, measuring the NRM first does not allow one to detect remagnetization components that could be produced during the subsequent heating at the same temperature in presence of the field and carried by grains with high blocking temperatures. In order to solve this problem (see Figure P3), it is preferable to impart the TRM before heating the sample in zero field (Aitken *et al.*, 1988; Valet *et al.*, 1998; Valet, 2003). The two techniques have their own advantages.

The method of determining the final field value is to calculate the slope of an "Arai" plot (Nagata, 1963), which depicts the amount of NRM lost as a function of pTRM gained for each successive temperature interval (in principle both should keep the same proportion for every temperature interval). The paleointensity is simply obtained after multiplying the slope by the field intensity applied during the experiments. The basic assumption inherent to Thellier experiments is constant proportionality between the NRM lost and the TRM gained

after each heating step. Any departure from this behavior cannot be accepted. Unfortunately this ideal situation is not that frequent and linear diagrams over a very wide range of temperatures represent rarely more than 20%–30% of the samples. It is certainly arbitrary to rely on a specific segment of temperature because the quality of the determinations is linked to the amount of NRM involved. We can only be confident if a paleointensity estimate has been derived from a single straight line involving low (say <350°C) and high temperatures (beyond the domain of viscous components). Several indices have been defined (Coe *et al.*, 1978) to evaluate the quality of the determinations. They rely on the percent of initial magnetization involved in the segment selected for calculation, quality of the fit and dispersion of the data points.

#### Limits imposed by magnetomineralogical changes

Apart from their time-consuming aspect, paleointensity experiments are frequently affected by remagnetization caused by alteration of magnetic minerals during heating. It is thus not only essential to detect these changes during the experiments but also to improve the success rate by selecting appropriate samples. Concerning the first aspect, Thellier and Thellier (1959) introduced the pTRM checks that test for duplication of a TRM at one or several previous temperatures. If the new value is different from the previous one, then the magnetic grains were affected during the previous heating steps at higher temperatures. Unfortunately, the pTRM checks increase the number of heatings, making the full experiment more time-consuming, but they are unavoidable and essential to detect alteration. It is quite justified to consider that the absence of pTRM checks unvalidates the quality of a paleointensity experiment.

In some cases remagnetization can produce grains with blocking temperatures higher than the last heating step. In this case, the NRM itself can be affected and partly lost but the corresponding changes will not necessarily be detected by pTRM checks. There is linear relation between the NRM and the TRM; but the directions of the NRM fail to go through the origin of the demagnetization diagrams when plotted in sample coordinates. This is caused by remagnetization in the field direction of the oven. Kosterov and Prévot (1998) made the point that irreversible changes due to alteration can occur even at moderate temperatures. This was observed by measuring hysteresis loops after different heating steps following a previous suggestion by Haag *et al.* (1995). These changes were not always detected by standard pTRM checks, which again emphasizes the need for multiple and complementary verifications, at least for a limited number of samples per

**Figure P3** Schematic representation of the procedure for a Thellier-Thellier experiment according to the "modified" Coe protocol. In this case, a TRM is performed first instead of heating in zero field (see text). Black (gray) bars show temperature intervals with remaining NRM (TRM). White bars are for zero magnetization.

lava flow. McCLelland and Briden (1996) and Valet *et al.* (1996) proposed to detect this problem by adding a third heating in zero field, which is particularly appropriate and efficient in the case of the modified Coe version. Indeed if the NRM was affected during the previous heating in presence of field, the repeated experiment will evidently result into a different vector. This approach is possible but more delicate with the standard Thellier-Thellier procedure.

Preselection of the specimens using nontime-consuming techniques rapidly became a critical matter. The problem is that such experiments must necessarily be conducted on adjacent specimens (but from the same core) keeping in mind that there is always a little risk that inhomogeneous magnetic characteristics alter the quality of the selection. Thermomagnetic analyses (measurement of progressive loss of induced susceptibility (*K*) or saturation remanent magnetization ( $J_{rs}$ ) while heating up to Curie temperature and its recovery during subsequent cooling) provide useful information about the magnetic minerals and their evolution upon heating. Magnetomineralogical changes have a direct consequence on these two parameters and produce irreversible heating and cooling curves. This test has thus proved very efficient to rule out inappropriate samples, but it does not warranty that those samples which pass the test will necessarily be suitable for paleointensity experiments.

# Problems inherent to multidomain grains

Another aspect to consider is the behavior of multidomain (MD) and pseudo-single domain (PSD) grains. Significant progress has been made in this direction. The presence of MD and PSD grains is quite common in lava samples and they can have important consequences. A complete review concerning the theoretical and phenomenological developments on this matter is given by Dunlop and Özdemir (1997). MD and PSD grains do not obey the experimental law of additivity of partial TRMs acquired in nonoverlapping temperature intervals by single domain grains. A direct consequence is the existence of two different slopes in the NRM-TRM plots between low (<350°C) and high (350-580°C) temperatures. Such behavior is caused by the difference between the blocking  $(T_{\rm b})$  temperature required to randomize the orientation of a portion of magnetic grains and thus to create a pTRM during cooling in presence of field and the unblocking  $(T_{\rm ub})$  temperature needed to randomize the orientation of the magnetic grains with magnetization acquired at  $T_{\rm b}$ . Heating at temperature  $T_{\rm i}$ produce a wide range of  $T_{ub}$ 's, both lower and higher than  $T_{b}$ , due to repeated domain wall jumps during heating. The anomalous high  $T_{\rm ub}$ 's form a tail extending to the Curie point, which has been widely discussed in the literature (Bol'shakov and Shcherbakova, 1979; Worm et al., 1988; Halgedahl, 1993; McCLelland and Sugiura, 1987; McCLelland and Shcherbakov, 1995; McCLelland et al., 1996). In a recent paper Dunlop and Özdemir (2000) described how low  $T_{ub}$  tails can explain the typical concave shape of the Arai diagrams inherent to multidomain grains. Several theoretical and experimental studies (Bol'shakov and Shcherbakova, 1979; Dunlop and Xu, 1994; Xu and Dunlop, 1994) have shown that demagnetization of the NRM can begin at low temperatures, while a significant part of TRM is acquired at high temperatures. Dunlop and Özdemir (2000) suggested that a significant part of the NRM with low  $T_{ub}$  can be easily removed whereas pTRM acquisition is delayed by the presence of high  $T_{\rm b}$ . Thus NRM thermal demagnetization will greatly outweigh pTRM acquisition and this effect persists until the NRM is about half demagnetized.

The presence of MD grains can be detected in curves of continuous or thermal demagnetization by their characteristic tails (Bol'shakov and Shcherbakova, 1979). Following experiments by Vinogradov and Markov (1989), Shcherbakova and Shcherbakov (2000) noticed that TRM acquired between room temperature and 300°C after heating to the Curie temperature cannot be removed completely by heating in the zero field in presence of PSD and MD grains while this is not the case for single domain. The remains of the proportion of magnetization is a measurement of the tail and depends on the amount of MD grains. This approach can thus be recommended provided that standard hysteresis parameters confirm the diagnostic. It is frequent that a part of the NRM-TRM spectrum be touched by multidomain grains, which in this case are not clearly reflected by concave up Arai diagrams. McClelland and Briden (1996), Valet *et al.* (1996) and Dunlop and Özdemir (1997) suggested to compare the NRM measured at  $T_i$  before and after heating in presence of field. Riisager and Riisager (2001) recently demonstrated the efficiency of the test (that they renamed "pTRM-tail check") on Paleocene lavas from the Faeroe Islands as well as on baked sediments. All these results indicate that concave diagrams must not be used to extract paleointensity information but it is important to perform appropriate tests to detect MD grains.

#### Variations in the experimental protocol

In an attempt to reduce the number of heatings, Kono and Ueno (1977) proposed to apply a field perpendicular to the NRM direction in order to extract the NRM and the TRM by performing a single heating at each step. In addition to technical difficulties positioning the sample within the oven, the authors noticed that this approach requires exceptionally stable components and has greater experimental errors. Hoffman et al. (1989) suggested that one method of reducing alteration is to split the sample into a number of subsamples (usually about 10), each heated to a particular temperature, once in a zero field and again in a known field. The NRM and the pTRM values are then normalized using the initial intensity of the subsample. This approach relies on the assumption that subspecimens from the same sample are characterized by similar magnetic properties, which is not always true. The natural physical properties of a lava often vary over a few centimeters. Sherwood (1991) evaluated the multispecimen approach and found no improvement with respect to the classical Thellier technique and no evidence for reduced alteration.

Several suggestions have been made to increase the number of determinations. Valet et al. (1996) proposed a correction technique taking into account the deviations caused by creation or destruction of magnetization. Corrections rely on the hypothesis that the loss (or gain) of TRM induced by mineralogical transformations is indicated by difference between the pTRM check and the TRM that was initially measured at the same step. In a detailed paper aimed at detecting alteration with high-unblocking temperatures, McClelland and Briden (1996) reached basically the same conclusions. Corrections can be applied if (1) the NRM was not affected and (2) the alteration product has unblocking temperatures lower than the temperature of the last heating. These two conditions can be checked by (1) double demagnetization of the NRM (if NRM demagnetization was performed first) and/or (2) scrutinizing the evolution of the NRM in sample coordinates. The suitability of corrections was tested on contemporaneous lava flows. The technique was reasonably successful and gave field determinations within a typical error between 10% and 20% inherent to paleointensity studies. However, it is frequently questioned because there is no clear indication about the reliability of field determinations. For this reason corrections remain speculative particularly in the absence of determinations without corrections for the same flow.

A complete different track was followed by Tanaka *et al.* (1995) who performed continuous direct measurements of the total vector at high temperatures. They defended that this approach can give reliable determinations whereas the standard method does not. The sample was heated in a cryogenic magnetometer with a small furnace installed immediately outside one of the access holes and the measurements were done within the magnetometer. The authors noticed that the drop in temperature did not exceed  $1^{\circ}$ C at 400°C when moving the sample from the furnace into the magnetometer. The technique involves two successive heatings (with and without field) over successive temperature intervals and does not require cooling the sample to room temperature except at  $T_{i-1}$ . The operation is repeated at incremental steps

and allows determination of the NRM lost and the TRM gained within each successive temperature interval rather than in a cumulative manner.

A very similar approach has been developed recently by LeGoff and Gallet (2004) with a vibrating magnetometer. The system called "Triaxe" vibrates horizontally along a single direction and comprises three orthogonal sets of pickup coils. Heating is produced by a 2.5 kHz alternating current in a bifilaresistor, avoiding electromagnetic interference in the pickup coils. Heating and cooling rates can be adjusted up to a maximum of 60°C min<sup>-1</sup>. The sensor and heating-cooling systems are centered inside three perpendicular Helmholtz coils coaxial with the magnetometer axes. Thus a major advantage of this system is that the TRM can be produced in any direction and in particular along the same direction as the initial NRM, avoiding any problems related to anisotropy of the TRM. The same system is used also to produce a zero field. This equipment has been tested with success on archeological material and compared to results obtained with the classical Thellier experiments. Given the gain in precision in rapidity and the versatility provided by this apparatus, there is no doubt that it will be extensively used in future for archeo- and paleointensity studies.

#### Recent improvements using alternative materials

Pick and Tauxe (1993a) proposed that submarine basaltic glasses would be an ideal material for absolute paleointensity. The magnetic population of submarine volcanic glasses is consistent with very fine Ti-magnetite grains in the superparamagnetic or SD state. There was some concern about the primary origin of the magnetization because of the very fine grain sizes but consistent determinations were obtained from nicely linear Arai plots by Pick and Tauxe (1993a; 1993b), Meija *et al.* (1996), Carlut and Kent (2000), which rules out this possibility. These results must be considered along with recent studies by Zhou *et al.* (1999, 2000) using electron microscope analysis, which indicate that submarine glasses do not seem to be sensitive to alteration on a timescale of a few million years.

Volcanic glasses could thus be ideal candidates for studies of absolute paleointensity. However some aspects still prevent basaltic glasses from several paleomagnetic applications. In most if not all studies published so far, the glass samples were not oriented and the direction of the magnetic field could not be recovered. It is thus impossible to deal with the full vector (which somehow is a paradox after having measured directions without intensity for a very long period). This is even more critical in the case of submarine volcanics since there is a technical problem linked to the difficulty of collecting submarine samples (Cogné et al., 1995) oriented with respect to the geographic coordinates. In this case it is impossible to check the consistency of the magnetic polarity of the glass samples with the underlying crustal magnetic anomaly. This may change in future with the development of new collecting tools. Another limitation is the weak remanent magnetization of the small glassy fragments containing very few crystals. The total moment being on the order of some  $10^{-9}~A~m^2$  or less and the measurements are frequently noisy. The irregular size of small chips of glass requires special mounting to allow accurate orientation of the samples for the measurements. Carlut and Kent (2000) proposed a new mounting technique (based on potassium silicate instead of salt encapsulation) to measure magnetic moments as low as  $5 \times 10^{-10}$  A m<sup>2</sup>. Below this value, measurements are seldom possible and thus the material cannot be used for paleointensity. Lastly lavas enriched in magnetic oxides along ridge segments can induce high magnetic anomalies and thus add a significant contribution to the main magnetic field. There is no doubt that volcanic glasses are promising to study long-term changes in the average field intensity. It is interesting that the time-averaged field value derived so far from the experiments conducted with this material is lower than the one derived from lava flows.

Cottrell and Tarduno (1999) suggested that the use of plagioclase crystals may provide a viable source of paleointensity data. The major

argument is that these crystals are less affected by alteration during heating experiments. The plagioclase grains are picked after crushing the samples, but the direction can be obtained from other specimens taken from the same core. The paleointensity results for 10 plagioclase crystals taken from a sample drilled in the 1955 Kilauea lava flow (Hawaii) indicates a mean paleofield value of 33.8  $\mu$ T, 5% lower than the expected field of about 36 µT measured at the Honolulu magnetic observatory. Since no field measurement has been performed directly above the flow this could be explained by local anomalies (Coe and Gromme, 1973; Baag et al., 1995; Valet and Soler, 1999). It is important to report that the field determinations have been obtained from low temperature intervals. At higher temperatures, remanence decay was rapid and measurement errors became significant. Such difficulties for measuring extremely low intensities (sometimes  $<5 \times 10^{-12}$  A m<sup>2</sup>) may be a limiting factor on a wider use of this technique. In a subsequent study, Cottrell and Tarduno (2000) studied 113-Ma-old basalts from the Rajmahal traps using whole rocks and single plagioclase crystals. The paleointensity determinations derived from the whole rock measurements were of lower quality and gave lower values than the plagioclase crystals, which according to the authors was caused by a fine-grained magnetic phase formed during the Thellier-Thellier heating experiments.

Two recent studies indicate that these new materials, plagioclases and volcanic glasses may converge but actually being complementary. Tarduno *et al.* (2001) reported 56 experiments on plagioclase crystals from basalts that formed during the quiet period of the Cretaceous polarity chron and found a strong time-averaged dipole moment, three times greater than during periods with reversals. Similar strong paleointensity was obtained independently by Tauxe and Staudigel (2004) who measured submarine Cretaceous basaltic glasses from the Trodos Ophiolite.

#### Conclusion

Paleointensity studies remain extremely delicate and time-consuming. However the past two decades of research have seen many developments, which will improve the selection of the samples and the success rate of the determinations. Another important factor is that the conjugation of techniques but also the possibility of using different materials makes now possible a critical evaluation of the data and thus an estimate of their degree of confidence.

# PALEOINTENSITY, RELATIVE, IN SEDIMENTS

#### What is "relative" paleointensity?

The intensity of depositional remanent magnetization (DRM) in sediments is not absolute, that is, DRM intensity is not solely a function of the ambient field strength at the time of deposition (see Magnetization, depositional remanent, DRM). The intensity of DRM recorded in sediments, when treated with a normalization process, is termed "relative paleointensity." The term "relative" is used because, although the ratio of two intensity values is considered an accurate measure of the percent difference in field strength, a single intensity value is not a stand-alone measure of the Earth's geomagnetic dipole moment (see Figure P4). Sedimentary records must be calibrated against absolute intensity measurements derived from volcanic samples or archeological baked clays (see Magnetization, thermoremanent; Archeomagnetism).

This situation exists because the intensity of DRM is dependent on the amount of ferrimagnetic material present in the sediment sample, the magnetic domain-state of the ferrimagnetic particles, and the mineralogy of the recording assemblage. For example, a package of sediment deposited in the presence of a weak magnetic field may acquire a strong remanence if the sediment contains a large amount of magnetite. In contrast, a package of sediment deposited in a strong field may have a very weak signal if the sediment contains very little magnetite, such as in deepsea carbonates or biosiliceous ooze (see Figure P5). These nonfield effects must be removed in order to isolate the dependence of DRM on the ambient field intensity. Typically, the intensity of the natural remanent magnetization (see Magnetization, natural remanent, NRM) is divided by a correction factor that is sensitive to the amount of remanence-carrying grains present in the sample. The parameter NRM/(correction factor) yields the intensity of NRM per amount of remanence carrying grains.

The need to correct for nonfield effects has long been recognized. Johnson et al. (1948) suggested dividing DRM by isothermal remanent magnetization (IRM) to account for differences in the "magnetization potential" of the sediment (see Magetization, isothermal remanent, IRM). They further suggested that a DRM versus applied field curve derived from redeposition experiments could be used to calibrate NRM intensity in natural sediments. Kent (1973) explored this idea by carrying out a laboratory redeposition experiment in which natural deep-sea sediments were stirred in the presence of an applied field to simulate bioturbation. The resulting deposits were free of inclination error and the intensity of remanence was linearly proportional to the applied field over the range 20-120 µT. This elegant experiment demonstrated that a linear relationship between DRM intensity and ambient field strength existed when an invariant sediment assemblage was repeatedly redeposited. However, invariant sediment assemblages rarely exist in nature. Natural sediment assemblages vary with time as a consequence of environmental processes controlling sediment supply, transport, and deposition. This makes sediments interesting and valuable for their ability to monitor environmental processes and climate change (see Environmental magnetism). This is also responsible for the complexity of the magnetic recording processes in sediment.

# Normalization parameters and processes

King *et al.* (1983) proposed a set of guidelines to place limitations on the acceptable amount of sedimentological variability, and limit paleointensity studies to sediments most likely to yield reliable data. The "King Criteria," later modified by Tauxe (1993), attempt to ensure the homogeneity of the magnetic mineral assemblage. If the sedimentary sequence being studied is homogeneous, then one can be confident that any observed features in the geomagnetic field record represent true field behavior, rather than artifacts due to the sedimentology. The uniformity criteria were originally developed to test the suitability of sediments for normalization using anhysteretic

**Figure P4** The interval 36–46 ka from the North Atlantic Paleointensity Stack (NAPIS-75) (Laj *et al.*, 2000). The data set has been divided by its mean value, so that the mean is equal to 1. The Laschamp geomagnetic excursion, referred to as the Laschamp Event, is manifested as a 1–2 ka interval of very low intensity at 40–41.5 ka. The Laschamp Event is preceded by an intensity peak at ~45 ka, at which time the geomagnetic field was nine times stronger than during the Laschamp Event. Relative paleointensity records such as NAPIS-75 can reveal the percent change in the geomagnetic field intensity, but not the absolute field strength.

**Figure P5** Conceptual model of the intensity of depositional remanent magnetization (DRM) as a function of ambient field strength. Ideally, DRM would be linearly dependent on the amplitude of the ambient field (open circles). In sediments, DRM intensity is dependent on the concentration of remanence carrying grains and the magnetic domain state of the particles. Solid squares represent sediment deposited in the presence of a weak field, but carry a strong DRM due a high concentration of magnetite. Diamonds represent sediment deposited in a strong ambient field, but carry a weak DRM due to low concentration of magnetite, or inefficient recorders (coarse grains, hematite) (After Tauxe, 1993).

remanent magnetization (see Magnetization, anhysteretic remanent, ARM). Hence, the concentration dependence of ARM and the grain-size dependence of ARM observed in magnetite strongly influenced the development of these criteria. These criteria have since become a general set of guidelines, regardless of the normalization method chosen.

First, the sediments should record a strong, stable, single component of remanence whose orientation is appropriate for the site latitude. If the orientation of the remanence vector is inaccurate, then intensity is likely to be inaccurate. Second, the carrier of the NRM should be magnetite. Any mineral with a spontaneous magnetic moment will experience a torque in the presence of an ambient magnetic field.

The stronger the particle's moment, the stronger the torque, and presumably the greater the efficiency of aligning with the field. Magnetite, Fe<sub>3</sub>O<sub>4</sub>, has the strongest spontaneous moment of the commonly occurring iron-bearing minerals. Further, magnetite and titanomagnetite  $(Fe_{3-x}Ti_xO_4)$  are the most abundant magnetic minerals in sediments. Therefore magnetite and titanomagnetite are important carriers of DRM in most sediments. Accessory minerals such as hematite, maghemite, greigite and pyrrhotite have been shown to be carriers of a stable DRM in a few rare cases (Kodama, 1982; Tauxe and Kent, 1984; Hallam and Maher, 1994). Generally, hematite has a very low-saturation magnetization and therefore it experiences a weak magnetic torque. Thus its ability to align accurately with the ambient field is questionable. Further, hematite may form in situ long after deposition, such as in redbeds, thus acquiring a chemical remanence (see Magnetization, chemical remanent, CRM) rather than DRM. Maghemite and greigite are more commonly associated with low-temperature oxidation and iron-sulfur diagenesis, respectively (e.g., Roberts and Turner, 1993; Reynolds et al., 1994; Snowball and Torri, 1999), implying the alteration of the primary magnetization and acquisition of a CRM at some unknown time after deposition. Ideally, magnetite should be the only magnetic mineral present in the sediment, to avoid the possibility that the normalization method will activate grains that do not carry DRM.

Third, the magnetite particle size should be  $1-10 \ \mu\text{m}$ . Superparamagnetic particles (SP, <30 nm for magnetite) are thermally unstable at room temperature and do not carry DRM. Stable single domain (SSD) grains ( $\approx$ 30 nm-1  $\mu$ m for magnetite) have strong moments and experience a strong torque in an ambient field, in addition to weaker viscous drag due to their smaller size. However, fine SSD grains are susceptible to the influence of Brownian motion (Stacey, 1972). Lu *et al.* (1990) also suggested that fine SSD grains adhere to clay minerals and are rotated out of alignment with the ambient field when the clays are compacted into horizontal orientations. Multi-domain (MD) grains have low magnetization and therefore experience a weaker magnetic torque. Larger grains are more strongly influenced by the gravitational force than by the magnetic force (see Magnetic domain). PSD grains, corresponding to the 1–10  $\mu$ m size range in magnetite, are assumed to be the most efficient recorders of DRM.

Fourth, the concentration of magnetite should not vary by more than a factor of 10. This limitation on concentration variability is based on the effects of particle interaction during ARM acquisition. The concentration of magnetic material is typically monitored using magnetic susceptibility (k), saturation isothermal remanent magnetization (SIRM), or saturation magnetization ( $M_S$ ).

The normalization parameters currently in use are k, anhysteretic remanent magnetization (ARM), and (SIRM). Two other methods, the pseudo-Thellier method (Tauxe *et al.*, 1995) and the integral method (Brachfeld *et al.*, 2003), are normalization procedures that have been explored, but not widely used at present. There is not one single normalization parameter that is applicable to all sedimentary records. In selecting the most appropriate normalization parameter for a given sedimentary record, it is necessary to thoroughly characterize the composition, concentration, and grain size of the magnetic recording assemblage, which may be a small subset of the entire magnetic mineral assemblage.

Magnetic susceptibility is logistically and economically the most easily measured magnetic parameter. Susceptibility is a routine measurement conducted on sediment cores collected by ocean research vessels. The ease of measurement is one reason for the continued use of k as a normalization parameter. However, k is measured in the presence of an applied alternating field, whereas DRM is a remanent magnetization. MD and SP grains that do not contribute to DRM contribute strongly to k and lead to "over-correction." The ratio DRM/k is artificially low if these grains are present (Brachfeld and Banerjee, 2000). In addition, several studies have shown strong correspondence between k and  $\delta^{18}$ O. The presence of Milankovitch periodicities in k profiles from oceanic, lacustrine, and loess records (e.g., Bloemendal and deMenocal, 1989; deMenocal *et al.*, 1991; Peck *et al.*, 1994; Bloemendal *et al.*, 1995), suggests that climatic factors influence the supply of magnetic material to marine, lacustrine, and aeolian sediment. In such cases there is a risk that the climatically induced variability in *k*, or any potential normalization parameter, could be transferred to the normalized intensity record (e.g., Kok, 1990; Schwartz *et al.*, 1996; 1998; Lund and Schwartz, 1999; Guyodo *et al.*, 2000).

Levi and Banerjee (1976) laid out the arguments in favor of ARM as a normalization parameter. Levi and Banerjee (1976) analyzed a sedimentary record from Lake St. Croix, Minnesota. They compared the alternating field (AF) coercivity spectra of the NRM, ARM, and SIRM. The coercivity spectra of NRM and ARM were nearly identical, while that of a SIRM was much softer (Figure P6). They argued that ARM activated the same grains that carried the NRM, which is the critical factor for selecting a normalization parameter. In addition, since the coercivity spectra of NRM and ARM were identical, the ratio NRM/ARM did not vary with AF demagnetization level, whereas the ratio NRM/IRM (and hence the assumed paleointensity) varied strongly with the demagnetization level.

Complications with ARM normalization arise from strong grain-size and concentration dependencies. Below 1  $\mu$ m (approximately), small changes in grain-size result in large changes in ARM acquisition (Dunlop and Özdemir, 1997). Above 1  $\mu$ m, ARM acquisition is less dependent on grain size (Dunlop and Özdemir, 1997). This is the basis for uniformity criterion 3, which states that sediments suitable for paleointensity studies contain magnetite in the 1–10  $\mu$ m size range. Sediments in which 0.1–1  $\mu$ m magnetite is the carrier of remanence would be susceptible to miscorrection using ARM. Even relatively small changes in the grain-size of DRM carriers could translate into very large changes in ARM acquired.

ARM acquisition is strongly dependent on the concentration of magnetic material in a sample. Sugiura (1979) imparted ARM to synthetic sediments with varying volume fractions of magnetite. A sample with 2.5-ppm (parts per million) magnetite acquired an ARM that was four times stronger than a sample with 2.3% magnetite. At high magnetite

**Figure P6** Stepwise alternating field demagnetization of NRM, ARM, and IRM carried by a sediment sample from Lake Pepin, Minnesota (Brachfeld and Banerjee, 2000). Levi and Banerjee (1976) suggested that the most appropriate normalization parameter is the one that activates the same grains that carry the NRM. This is assessed using the alternating field (AF) demagnetization coercivity spectrum. For this sample, the coercivity spectrum of the ARM is nearly identical to the NRM, while the IRM spectrum is softer. ARM is the most appropriate normalization parameter for this sediment sample. The shaded region denotes the area under the NRM demagnetization curve, which is the basis for the integral normalization method (see text).

concentrations, ARM acquisition is less efficient due to particle interactions, which tend to demagnetize the assemblage. The criterion that magnetite concentration vary by no more than a factor of 10 was designed to ensure that the mechanism of ARM acquisition, be it efficient or inefficient, is at least consistent throughout the entire sediment sequence.

Isothermal remanent magnetization (IRM) is imparted by exposing a sample to a steady field for several seconds, then reducing the field nearly instantaneously to zero. By applying stepwise increasing fields and measuring the remanence after each step, one can obtain an IRM acquisition curve. At some field strength the sample acquires its maximum possible signal, at which point the sample has acquired a saturation isothermal remanent magnetization. SIRM and the magnitude of the saturating field vary for different minerals. Magnetite saturates in fields of 100-300 mT. Hematite and goethite requires fields in excess of several tesla to achieve saturation (Dunlop and Özdemir, 1997). SIRM acquisition is less sensitive to grain interactions than ARM acquisition because the applied field which is very strong can overcome the demagnetizing effect of grain interactions. The danger in using SIRM is that-at high fields, nearly all of the magnetic minerals will acquire an IRM or SIRM, even those grains that do not contribute to the DRM. In particular, MD grains that do not contribute to DRM will contribute disproportionately to SIRM.

Tauxe *et al.* (1995) proposed the pseudo-Thellier method of relative paleointensity normalization. The pseudo-Thellier method is an analog of the Thellier. Thellier double heating experiment that is applied to absolute intensity samples. In the pseudo-Thellier method, one plots NRM lost at each AF demagnetization level versus ARM gained at that AF demagnetization level. Relative paleointensity is calculated as the slope of the best-fit line fit to the data (see Figure P7). This method is particularly useful for identifying viscous components of magnetization, which are typically removed after the 5–20 mT demagnetization step. Viscous components are manifested as a line segment with a slightly steeper slope. One can identify these components from the pseudo-Thellier plot, and avoid these intervals when calculating the best-fit line.

Brachfeld et al. (2003) proposed an integration method of normalization. This method expands on Levi and Banerjee (1976) who argued

**Figure P7** The pseudo-Thellier plot for a sediment sample from Lake Pepin, Minnesota. Tauxe *et al.* (1995) devised this alternate normalization method to simulate the Arai diagram obtained through the Thellier. Thellier absolute intensity analysis. NRM remaining at each demagnetization level is plotted against ARM gained at the same AF level. Viscous components of remanence are identified by the change in slope of the trend line. This sample has a viscous component of remanence that is removed after AF demagnetization at the 10 mT level. Relative paleointensity for this sample is calculated as the slope of the trend line from 20–60 mT.

that the coercivity spectrum of the normalization parameter should match the coercivity spectrum of the NRM. The integral method involves integrating the area under the NRM/NRM<sub>MAX</sub> demagnetization curve over an optimal AF range, for example 20–50 mT. The normalization parameter, ARM/ARM<sub>MAX</sub> is integrated over the same interval. Relative paleointensity is calculated as

$$\int_{20 \text{ mT}}^{50 \text{ mT}} \text{NRM}(H_{\text{AF}}) dH_{\text{AF}}$$
$$\int_{20 \text{ mT}}^{50 \text{ mT}} \text{ARM}(H_{\text{AF}}) dH_{\text{AF}}$$

(see Figure P6). The goal of this method is to ensure that the same coercivity spectrum is reflected in both the NRM and the normalization parameter.

There are several ways to assess the quality and accuracy of a normalized intensity record. The simplest and most common method is to apply several normalization parameters. It has traditionally been assumed that if several normalization parameters yield similar profiles, then the sediment is homogeneous and any of the parameters is an adequate normalizer. Normalized intensity records can be judged by comparison with records from other sites, for example other sedimentary records, absolute intensity records, or records of cosmogenic isotopes (<sup>10</sup>Be, <sup>36</sup>Cl), whose production rates are modulated by geomagnetic field intensity (Frank *et al.*, 1997; Frank, 2000; Baumgartner *et al.*, 1998; Wagner *et al.*, 2000a,b).

Normalized intensity records from the same geographic region should yield similar patterns and amplitudes if properly normalized. Unfortunately, the amplitude of normalized intensity features can be quite different depending on the normalization method used (Schwartz *et al.*, 1996, 1998; Lund and Schwartz, 1999; Brachfeld and Banerjee, 2000). Several workers have suggested that the variable amplitudes of crests and troughs as a function of normalization method are the result of subtle grain-size variations that are not removed during normalization (Amerigian, 1977; Sprowl, 1985; Lehman *et al.*, 1994, 1998; Schwartz *et al.*, 1996; Williams *et al.*, 1998; Brachfeld and Banerjee, 2000).

An internal check on the quality of a normalized intensity record is to examine correlations between rock magnetic parameters and normalized intensity. Harrison and Somayajulu (1966) pointed out that the paleointensity estimate should not be correlated with rock magnetic parameters, which they assessed using a linear regression correlation coefficient. Tauxe and Wu (1990) brought this test into the frequency domain by calculating coherence spectra for the normalized paleointensity and the normalization parameters. This permits the identification of frequency bands where paleointensity and rock-magnetic parameters are responding to the same external influence, climatic or otherwise. Tauxe and Wu (1990) proposed that true normalized intensity should not be coherent with its specific normalization parameter. Coherence is typically tested between NRM/k and k, NRM/ARM and ARM, and NRM/SIRM and SIRM. The best relative paleointensity record is the one that shows no coherence with its normalization parameter. Brachfeld and Banerjee (2000) recommended that normalized intensity also be tested for coherence with grain-size parameters such as the median destructive field of the NRM (NRM<sub>MDF</sub>) or the coercivity of remanence  $(H_{CR})$ .

#### Paleointensity as a correlation and dating tool

Until the late 1980s, the study of geomagnetic field behavior recorded in sediments was largely undertaken for magnetostratigraphy and to study the geodynamo (see Magnetostratigraphy; Paleomagnetism). Beginning in the late 1980s-early 1990s, several researchers noticed the globally coherent pattern of geomagnetic field paleointensity variations over the last 50 ka–100 ka years (Constable and Tauxe, 1987; Tauxe and Valet, 1989; Tauxe and Wu, 1990; Tric *et al.*, 1992; Meynadier *et al.*, 1992). Soon thereafter, advances in instrumentation enabling the rapid measurement of continuous u-channel subsamples (Tauxe *et al.*, 1983; Weeks *et al.*, 1993; Nagy and Valet 1993) led to a large increase in the number of long, continuous, sedimentary records analyzed for geomagnetic paleointensity variations. The resulting database of globally distributed records enabled the construction of stacks (weighted averages of many records), which are now used as millennial-scale correlation and dating tools.

The dipole component of the geomagnetic field exhibits temporal variations in its intensity on timescales of hundreds to millions of years. Variations in the geomagnetic dipole are synchronously experienced everywhere on the globe. Therefore, a specific geomagnetic field paleointensity feature represents the same "instant" in time everywhere on Earth. Sedimentary records of geomagnetic field paleointensity from nearly all of Earth's shallow seas, deep ocean basins, and large lakes demonstrate the global coherence of features with wavelengths of 10<sup>4</sup>-10<sup>5</sup> years (Figure P8, Tric *et al.*, 1992; Meynadier *et al.*, 1992; Schneider, 1993; Yamazaki et al., 1995; 1999; Guyodo and Valet, 1996, 1999; Laj et al., 1996, 2000, 2004; Lehman et al., 1996; Peck et al., 1996; Verosub et al., 1996; Channell et al., 1997; 2000; Roberts et al., 1997; Schwartz et al., 1998; Stoner et al., 1998, 2000, 2002; Kok and Tauxe, 1999; Channell and Kleiven 2000; Guyodo et al., 2001; Nowaczyk et al., 2001; Sagnotti et al., 2001; Mazaud et al., 2002; Thouveny et al., 2004; Valet et al., 2005). A common characteristic of these records is the presence of several intervals of very low intensity during the past 800 ka. These are interpreted as geomagnetic excursions, which often involve large but short-lived directional changes (>45° deviation of the virtual geomagnetic pole from its time-averaged position) followed by a return of the vector to its previous state (see Geomagnetic excursion). Several of the sedimentary records listed above suggest that excursions are associated with a reduction in field strength to less than 50% of its present day value, but are not always associated with a directional change.

These intervals of weak geomagnetic field intensity are partly responsible for peaks in radionuclide production rates. Peaks in <sup>10</sup>Be and <sup>36</sup>Cl concentration interpreted as the Mono Lake Event and the Laschamp Event have been observed in the Vostok, Dome C, Byrd, Camp Century, and GRIP ice cores (Beer *et al.*, 1984, 1988, 1992; Yiou *et al.*, 1985, 1997; Raisbeck *et al.*, 1987; Baumgartner *et al.*, 1997, 1998; Wagner *et al.*, 2000b). Excursions, whether detected through paleomagnetism or cosmogenic isotopes, are marker horizons that can be used to correlate records from widely separated regions. However, an excursion is one single tie point. A more powerful correlation and dating tool uses time series of geomagnetic paleointensity variations and cosmogenic nuclide production rates for stratigraphic correlation.

Correlation and dating using geomagnetic paleointensity is a "tuning" method. The paleointensity record from the site of interest is compared to a well-dated reference curve. By matching peaks and troughs between the two records, one can import the reference curve ages to the study area. This method has been used to construct chronologies for sites that lacked materials for radiocarbon dating and lacked calcite for oxygen-isotope stratigraphy (Stoner *et al.*, 1998; Sagnotti *et al.*, 2001; Brachfeld *et al.*, 2003).

Any single record of geomagnetic field variability is not suitable for a reference curve. Any single record may contain errors in its chronology or contamination of its remanent magnetization. Guyodo and Valet (1996) proposed using a "stack" to combine many records, thereby enhancing the signal to noise ratio, averaging out any flaws present in the individual records, and extracting the broadscale global features of the geomagnetic field. Guyodo and Valet (1996) showed that a distinctive pattern of geomagnetic field paleointensity was observable in deep-sea sedimentary records from around the globe (see Figure P8). They produced a 200 ka global stack of 19 paleointensity records, named Sint-200, which they suggested could be used as a millennialscale correlation and dating tool. Each of the 19 constituent records in Sint-200 had its own oxygen-isotope stratigraphy. By correlating paleointensity variations in an undated sediment core with the Sint-200 target curve, one could import the SPECMAP oxygen isotope stratigraphy to the core site.

**Figure P8** A comparison of globally distributed paleointensity records for the interval 10–80 ka. (A) Sint-800 (Guyodo and Valet, 1999) is a stack comprised of 33 records. Short wavelength features are not preserved in this low-resolution stack. (B) Labrador Sea (Stoner *et al.*, 1998), (C) Mediterranean Sea (Tric *et al.*, 1992), (D) Somali Basin (Meynadier *et al.*, 1992), (E) NAPIS-75 (Laj *et al.*, 2000). Features with wavelengths of 5–10 ka can be recognized and correlated from the Labrador Sea south to the Somali Basin.

The constituent records of Sint-200, and its subsequent extension to the 800 ka Sint-800 (Guyodo and Valet, 1999) were all deep-sea sediment cores with relatively low-sedimentation rates. Therefore, short wavelength features are not preserved in Sint-800. Two newer stacks with higher temporal resolution, the 75 ka North Atlantic paleointensity stack (NAPIS-75) and the South Atlantic paleointensity stack (SAPIS), were constructed from high-sedimentation rate records from sediment drifts in the North Atlantic and the South Atlantic, respectively (Laj *et al.*, 2000; Stoner *et al.*, 2002). NAPIS-75 is a stack of six individual high-resolution records (sedimentation rates = 20 to 30 cm/ka) from cores recovered from the Nordic seas and the North Atlantic. The stacks cover the time interval 10-75 ka, providing overlap with the radiocarbon timescale. The NAPIS-75 chronology is linked to the GISP2 ice core chronology. First, Heinrich layers and a volcanic ash were used as tie points to correlate the six cores. Second, a fine scale correlation was achieved by matching magnetic susceptibility oscillations and ARM oscillations, which put all six cores on a common depth scale (Kissel *et al.*, 1999). The resulting stack was placed on the GISP2 age model of Grootes and Stuiver (1997) by correlating the planktonic foraminifera  $\delta^{18}$ O record in one of the sediment cores with the  $\delta^{18}$ O record in the GISP2 ice core (Voelker *et al.*, 1998; Kissel *et al.*, 1999).

There are striking similarities between NAPIS-75 and a synthetic geomagnetic field record calculated from <sup>36</sup>Cl and <sup>10</sup>Be data obtained from the GRIP/GISP2 ice cores (Baumgartner *et al.*, 1997, 1998; Finkel and Nishiizumi, 1997; Yiou *et al.*, 1997; Wagner *et al.*, 2000a,b), which suggests a common geomagnetic origin. Features with a 1000 to 2000-year wavelength can be recognized in both records. The millennial scale features of NAPIS-75, coupled to the precise GISP2 timescale, constitutes a highly efficient tool for correlating and dating cores in different oceans basins around the world (Stoner *et al.*, 2000, 2002), particularly in the Arctic Ocean and southern Ocean, where  $\delta^{18}$ O stratigraphy is not available. The extension of NAPIS-75 to NAPIS-300, a 300 ka stack, is now in progress (C. Laj and C. Kissel, personal communication).

SAPIS was constructed from five cores from the South Atlantic (Stoner *et al.*, 2002). The five cores were placed on a common depth scale by correlating magnetic susceptibility, oxygen isotope stratigraphy, geomagnetic inclination, and relative paleointensity. The age model for SAPIS comes largely from one core, Ocean Drilling Program (ODP) Site 1089, whose oxygen isotope stratigraphy was correlated to a nearby core with 14 radiocarbon dates, and by correlating the oxygen isotope stratigraphy to SPECMAP (Stoner *et al.*, 2003).

NAPIS and SAPIS display remarkable similarities over the interval 30–65 ka. The two records display similar peak-to-trough amplitudes, and features with 5-ka wavelengths can be recognized and correlated between the two records. Some differences were present, which the authors ascribed to subtle flaws in chronology—uncorrected environmental influences on the magnetic mineral assemblage, or genuine differences in the nondipole geomagnetic field behavior at these two sites. Nevertheless, the excellent correspondence between the two stacks over key intervals, for example 30–45 ka, illustrates the potential to use geomagnetic field paleointensity as a global, millennial-scale correlation and dating tool.

A high resolution global paleointensity stack (GLOPIS-75, Laj *et al.*, 2004) is a stacked record consisting of 24 paleointensity records distributed world wide, and all with sedimentation rates exceeding 7 cm/ka. The 24 paleointensity records were each individually correlated to NAPIS-75, which was used as the master curve. Each record was resampled every 200 years, normalized to a mean value of 1, and stacked arithmetically (Laj *et al.*, 2004). An iterative process was applied to successively remove discrete intervals in the individual records that may be unreliable, followed by recalculation of the stack using the remaining points. The resulting GLOPIS-75 record covers the interval 10-75 ka.

GLOPIS-75 was calibrated to absolute virtual apparent dipole moment values (VADM) using the archeomagnetic dataset of Yang *et al.* (2000) and globally distributed volcanic data spanning 0-20 ka (Laj *et al.*, 2002). The main trends in this calibrated global stack are very similar to NAPIS-75. There are several noteworthy features. The Mono Lake Event and the Laschamp Event are dated at 34.6 ka and 41 ka, respectively, precise ages that are tied to the GISP2 ice core age model. The duration of these excursions are 1100 years for the Mono Lake Event and 1000–1900 years for the Laschamp Event (Laj *et al.*, 2004). Refinements to GLOPIS-75 can be expected as the number and distribution of paleointensity records increases, particularly with the addition of new records currently under construction from the North Atlantic, Arctic and Antarctic, and with the addition of records spanning 0–20 ka.

#### Summary

The intensity of DRM recorded by sediments is influenced by the concentration, domain state, and composition of the magnetic mineral assemblage. These nonfield effects on the DRM are removed by normalizing the DRM with a laboratory-derived correction factor such as k, ARM, or SIRM. No single normalization parameter is appropriate for all sediments. The magnetic mineral assemblage of each sedimentary record must characterized in order to select the most appropriate normalization parameter. High-quality sedimentary geomagnetic paleointensity records are now being used as global correlation and dating tools. Features with wavelengths of 5 ka, and possibly shorter, can be recognized and correlated between the Northern and Southern hemispheres. By synchronizing geomagnetic intensity records, we may now have the ability to determine millennial-scale leads and lags in Earth's climate systems. Ongoing studies are extending paleointensity stacks further back through time (Valet et al., 2005), and investigating the extent to which finescale features can be recognized and correlated. This includes marine, estuarine, and lacustrine records, with the goal of expanding the temporal and spatial distribution of records, particularly in the Southern Hemisphere (Gogorza et al., 2000, 2002; Stoner et al., 2002, 2003; Brachfeld et al., 2003) and the Arctic (Nowaczyk et al., 2001; St. Onge et al., 2003, 2005; King et al., 2005; Stoner et al., 2005).

# PALEOMAGNETIC FIELD COLLECTION METHODS

The primary aim of paleomagnetic research is to reconstruct the orientation of the Earth's magnetic field at a given location from the study of a rock unit of known age. For this purpose, it is required to collect samples from the unit to be studied with the purpose of determining their magnetization and magnetic mineralogy in the laboratory. In order to conduct consistency tests of the direction of magnetization of the unit of interest, it is advisable to sample the unit at several localities as widely as possible. This procedure helps to avoid biasing effects introduced by undetected tectonic complications or other, probably more local alteration effects. In return, more effort is required in collecting samples in the field and the adoption of a well-defined hierarchy that needs to be followed during sampling is also needed.

In paleomagnetic parlance, a site refers to the location of each place where a particular sedimentary bed, or cooling igneous unit (i.e., one lava flow or one dyke) is exposed and samples are collected. A sample refers to each oriented piece of rock separately that is retrieved from the outcrop, whereas a specimen refers to smaller pieces of rock, which are well-determined in shape and dimensions obtained from one sample. Commonly, six to eight samples are required within 5-10 m of outcrop at a single site to average out the nonsystematic errors possibly made during sample orientation. At the laboratory, each sample will be split in specimens that can be inserted in the holder of the available instrument that is used for the measurement of magnetization and other laboratory tests. In practice, it is a good idea to have samples large enough to provide multiple specimens, even when only one specimen per sample is all that is required for the measurement of magnetization. This is the case because if more than one specimen per sample is measured at each site, the averaging of the orientation errors will not be unbiased unless the specimens measured for each sample is equal in number. In any case, little is gained in accuracy if more than three specimens from each sample are measured in one site.

Although this hierarchy is easy to follow in general, there are some aspects that require closer examination. For example, if the only access to the rock is through a long drill core (for example those obtained in exploration wells), then following the above definitions we would be limited to only one sample per site (unless more than one core is retrieved at the same location), as little would be gained in terms of accuracy of orientation by measuring more than one specimen per rock-unit traversed by the core. In thick enough units, however, it might prove to be convenient to measure six to eight specimens from the same unit to get a more representative estimation of the magnetization of the unit at that site (core). Certainly, in these conditions the error in the reconstructed magnetization (even when it might only refer to the inclination as the horizontal orientation of the core might not be available) introduced by the error in the orientation of the core will not be averaged out, but at least some internal checks for consistency and homogeneity of the magnetic properties of each rock unit can be made in this form.

As for the actual samples, these can be grouped in three main types depending on the procedure followed for their collection. The most common type of paleomagnetic sample is collected by using a portable drill with a water-cooled diamond bit. The drill is commonly powered by a gasoline engine, but in some occasions it might be necessary to use an electric drill that uses a rechargeable battery. The diameter of the cores drilled in this form is commonly  $\sim 2.5$  cm and the length depends on the hardness of the rock, the type of drill-bit used and the expertise of the operator. After coring the outcrop to the desired depth and the drill apparatus has been retrieved, an orientation devise is introduced in the space left by the bit. The orientation devise consists of a long tube that has a slot extending from one of its extremes, and a swiveling surface with some type of level attached to the other. The devise is rotated until the surface on the outer extreme becomes horizontal, allowing the correct orientation of the core before retrieving it from the outcrop. The slot in the lower end of the orienting devise (now inserted in the rock) is used to mark the sample, commonly with a brass rod. The orientation is made using a magnetic or a solar compass (or both) attached to the orientation devise, and by reading the angle of the core relative to either the horizontal or the vertical plane. The accuracy of orientation with this method is about  $\pm 2^{\circ}$ . After the completion of orientation, the orienting devise is retrieved and the core is broken from the outcrop, labeled, and packed.

Another type of paleomagnetic sample is collected by the simpler method of orienting a block of the outcrop that is later broken and labeled. These types of samples are commonly collected when the lithology is not suitable for coring. There are logistic complications for transporting the coring equipment (including water and gasoline) to the outcrop, there are laws forbidding the use of coring equipment (as for example in some national parks or reserve areas), or in desperation when the coring equipment breaks down in the middle of a field season. Although simpler in logistics, this method of sample collection is not as good as the coring method because of the limitations in the accuracy of orientation and on the need of collecting joint blocks that are more likely to have been affected by weathering than the massive portions of the outcrop. It also requires carrying of an excess material that has to be thrown away after specimens have been sliced out of the sample in the laboratory.

The third main type of paleomagnetic sample is collected in the form of core sample obtained from lake- or sea-bottom cores or from exploration wells. These samples are typically  $\sim 10$  cm diameter and can be from a few meters to some hundreds of meters and even kilometers long. There are two main types of coring techniques in this category: piston coring (in which the bit is introduced forcefully into the sediment) and rotary drills (similar in all respects to the first type of samples discussed above, but with drills that are much larger and not likely to be handled by just one bare-handed operator). Both types of cores are commonly azimuthally unoriented and the direction of the core is assumed to be vertical. Evidently, these types of samples provide less reliability in terms of accuracy of orientation, which often involve the operation of expensive machinery and may not yield recovery of the entire core, but as already mentioned they can be the only access to one particular rock unit.

In some particular situations, paleomagnetic samples can be collected by using very specific (and sometimes very ingenious) methods that often combine some aspects of the three main types just mentioned. For example, loose sediments that are accessible in outcrop cannot be suitable for drilling or for block sampling. In this case, samples can be collected by inserting small plastic boxes in the sediment and orienting them before removing the material around to retrieve the box. Some degrees of impregnation with an epoxic resin might also be used for this purpose, or any other method that allows the operator to retrieve a reasonably well oriented sample.

In summary, the most important aspect to have in mind when collecting samples for any paleomagnetic work is the ability to orient the samples. Although in some circumstances the orientation must be necessarily limited to a distinction between the up and down directions, therefore limiting the utility of such samples.

Paleomagnetism

# PALEOMAGNETIC SECULAR VARIATION

The source of the Earth's magnetic field has been the subject of scientific study for more than 400 years (e.g., Gilbert, 1600). At present we believe that most of the field measured at the Earth's surface is of internal origin, generated by hydromagnetic dynamo action in the liquid-iron outer core. Historic measurements of the geomagnetic field have documented its primarily dipolar spatial structure at the Earth's surface and its temporal variability, which is termed as secular variation. One notable characteristic of the Earth's magnetic field and secular variation is its full vector nature, with significant space-time variability in both directions and intensity. Recent historic secular variation (HSV) studies (e.g., Thompson and Barraclough, 1982; Bloxham and Gubbins, 1985. Olson *et al.*, 2002) have characterized the global pattern of short-term secular variation and have related its variability to the core dynamo process.

Paleomagnetic studies make it clear, however, that the Earth's magnetic field has undergone a wider range of temporal and spatial variability than has been seen in historic times. Geomagnetic field polarity reversals have occurred intermittently in time (e.g., Cande and Kent, 1995) and the intervening time intervals of stable dipole polarity contain paleomagnetic secular variation (PSV) larger in amplitude and broader in frequency content than HSV. PSV studies have also documented occasional excursions (Watkins, 1976; Verosub and Banerjee, 1977), which are anomalous PSV fluctuations that may be aborted polarity reversals or represent a fundamentally different multipolar state of the geomagnetic field (Lund *et al.*, 1998, 2001).

PSV is estimated from the paleomagnetic study of archeological materials, unconsolidated sediments, and rocks. The paleomagnetic methods used to recover PSV data are well documented (e.g., Butler, 1992. Tauxe, 1993. Merrill *et al.*, 1998; Dunlop and Özdemir, 2001), and everyone noticed that rather different methods are normally used to recover estimates of paleomagnetic field direction and intensity. Therefore, historically, PSV directional data usually do not have associated paleointensity estimates and vice versa. However, over the last decade that tendency has finally been balanced by the development of numerous high-resolution full-vector PSV records.

This article surveys our current knowledge of PSV; it will provide an overview of PSV data sources, methods of PSV analysis, long-term characteristics of PSV, and models for PSV behavior. The survey will discuss both intensity and directional variability. Special attention will be paid to the relationship between PSV and HSV, the evidence for or against long-term stationarity of PSV, the relationship of PSV to excursions, and the characteristics of PSV that may be useful in dynamo studies.

#### **PSV data**

PSV data come from a wide variety of paleomagnetic studies that can be separated into three groups based on the type of sediment or rock measured, the degree of detail in stratigraphic sampling, and the degree of age control for each study. The three resulting PSV data groups are (1) studies of Quaternary-aged sequences of unconsolidated sediments, lava flows, or archeological materials, which can be dated in detail by radiocarbon methods or oxygen isotope stratigraphy, and which are sampled in detail sufficient to resolve the temporal pattern of PSV variability (termed waveform information); (2) studies of older sediment or lava flow sequences that have waveform information but no detailed age control; and (3) studies of any aged rock or sediment sequences that have poor within sequence age control and no waveform information (sequential data are not serially correlated). The first type of PSV study can be used for a full spectrum of time series analyses (waveform, spectral, or statistical analyses); the second type of study can be used for waveform and statistical analyses; the third type of study is only suitable for statistical analysis.

The materials normally used for detailed paleomagnetic studies of PSV are archeological materials (kilns, fire pits, etc.), lava flows, and lake or marine sediment sequences. Each of these materials has inherent advantages and disadvantages for the accurate recording of PSV and the accumulation of paleomagnetic records from all three materials in parallel is the ideal way to establish regional patterns of PSV. Figure P9 illustrates the use of multiple PSV records derived from multiple

767

**Figure P9** Comparison of paleomagnetic and historic secular variation directional data from Eurasia. Composite PSV records, summarized in Constable *et al.* (2000), extend from Iceland (ICE) to Japan (JPN). Solid dots are original paleomagnetic data, heavy solid lines are interpolated time-series (PSVMOD1.0 available at http://earth.usc.edu/~slund), and open circles in the last 400 years are estimated historical field variations based on spherical harmonic analysis.

data sources (data summarized in Constable *et al.*, 2000) to reconstruct the paleomagnetic directional variability across Eurasia for the last 3 ka. PSV records ICE, Loch Lomand, Scotland (LLO), Lake Vukonjarvi, Finland (VUK), and Lake Baikal, Russia (BAI) are derived from lake sediment sequences, while the other six PSV records are based on archeological and lava-flow measurements. The solid dots in Figure P9 are the actual paleomagnetic measurements, the heavy solid lines are interpolated equi-spaced time series (PSVMOD1.0, available at http://earth.usc.edu/~slund), and open circles in the most recent 400 years are estimated historical secular variation based on spherical harmonic analysis.

Lava flows and archeological materials have the advantage that their natural remanent magnetization (NRM) is normally a thermoremanent magnetization (TRM). A TRM is acquired over time intervals of less than a few minutes to days by heating a material to high temperatures and cooling it in the presence of the geomagnetic field. Therefore, the TRM retains a truly "instantaneous" record of PSV. The primary disadvantage of archeological materials is their scarcity prior to about 2000 years B.P. The primary disadvantage of lava flows is the difficulty in finding sufficient radiocarbon dated flows within a region to develop a long duration, composite PSV record; only a few such studies are currently available in the whole world (e.g., Champion, 1980. Holcomb *et al.*, 1986; Kissel and Laj, 2004).

Sediments acquire their NRM, termed as depositional or postdepositional remanent magnetization (DRM/PDRM), due to mechanical alignment of magnetic grains with the geomagnetic field while they are in the water column or in interstitial spaces just below the sediment-water interface. The grains are subsequently locked into that orientation by grain-grain contacts during dewatering, normally within 10-20 cm of the sediment-water interface. The primary advantage of sediment sequences is their potential to provide continuous, high-resolution PSV records far back in time from many sites around the world. The primary drawback to sediments, however, is the lower resolution of the DRM/PDRM recording process due to some degree of inherent smoothing of the PSV signal during remanence acquisition near the sediment-water interface. In most high-resolution sediment records, the smoothing interval can be estimated to be less than 100 years in duration, but further study is necessary to establish the role of smoothing in a better manner in the acquisition process of DRM/PDRM.

An added complexity associated with all PSV data is the limited extent to which they can be compared to HSV data. This difficulty in correlation occurs because (1) PSV data does not have the broad spatial (global) sampling distribution of HSV data, (2) the inherent vector resolution of PSV data ( $2^{\circ}$  to  $4^{\circ} \alpha 95$  at best) is significantly lower than the resolution of HSV data (typically 1° α95 or better), and (3) the radiometric ages associated with PSV have relatively large errors (ca.  $\pm 100$  years or greater). PSV records derived from sediments have the added disadvantage, noted previously, of not recovering instantaneous estimates of secular variation due to inherent DRM/ PDRM smoothing. Because of these differences, it is difficult to compare the space-time structures of HSV and PSV data in detail, even though site measurements of PSV and HSV may agree within the limit of data resolution (e.g., Figure P9). What we can hope is that analysis of PSV data will yield spatial and/or temporal characteristics that relate, in some way, to observed HSV characteristics.

Three examples of total-vector PSV records are shown in Figures P10-P12. Figure P10 is a Holocene PSV record from wet lake sediments of Lake St. Croix (Lund and Banerjee, 1985; Lund and Schwartz, 1999), Figure P11 is a late-Pleistocene PSV record from uplifted (dry) lake sediments surrounding Mono Lake (Liddicoat and Coe, 1979; Lund *et al.*, 1985), and Figure P12 is a late-Pleistocene PSV record recovered from deep-sea sediments of the western North Atlantic Ocean (Lund *et al.*, 2001, 2005).

Figure P10 Holocene full-vector paleomagnetic secular variation record recovered from Lake St. Croix, Minnesota (USA) (Lund and Banerjee, 1985; Lund and Schwartz, 1999).

## Time-series analysis of PSV

The conceptual framework for analysis of PSV data is based on the fact that HSV records are too short in duration to adequately characterize the totality of temporal field variability, while PSV records are too scattered spatially to routinely describe the prehistoric spatial field variability. We can hope, however, to identify spatial and short duration temporal components of the HSV that may relate to long-term temporal components of the PSV. We can also attempt to improve the spatial estimates of PSV by, perhaps, appealing to analogs in HSV. Such a coordinated analysis of PSV and HSV can perhaps address a key to an unresolved question in secular variation studies: What is the mapping function between the observed spatial and temporal variations of the geomagnetic field? Only with a coherent view of the total spatiotemporal variability of the historic and prehistoric geomagnetic field can we properly evaluate models of the core dynamo process, which is the source of the field variability.

Analysis of PSV data uses a variety of time-series and modeling techniques in order to delineate the spatial and temporal characteristics of PSV. Time-series techniques that can be applied to PSV data will be considered in this section; modeling techniques will be considered in the next section. Time-series techniques are classified into three broad categories: waveform analysis, spectral analysis, and statistical analysis. Each of these techniques has unique advantages for characterizing a particular type of PSV data and thereby providing a point of comparison with HSV data.

# Waveform analysis

PSV records that display good serial correlation between adjacent data points (e.g., Figures P9-P12) can be used to assess the actual time evolution of geomagnetic field variability. This time evolution can be characterized either by evaluating simple PSV features, such as maxima or minima of inclination, declination, or paleointensity, or more distinctive sets of features termed vector waveforms (Lund, 1996). One type of vector waveform that may have fundamental importance for dynamo studies is the vector-looping pattern termed circularity (Runcorn, 1959. Skiles, 1970) often exhibited by HSV and PSV records (e.g., Bauer, 1895. Creer, 1983. Lund, 1996). Comparisons of simple features or vector waveforms may take place (1) within individual paleomagnetic records, (2) between records of different sites, and (3) between PSV and HSV records (where they overlap in time), and can be used to assess the temporal evolution of secular variation. Comparisons of the amplitudes and phase relationships of PSV features or waveforms with their spatial counterparts(?) in global maps of the present-day field may be used to assess the spatial-temporal mapping of secular variation. Below we discuss three different types of waveform comparison that document distinctive PSV characteristics.

The first type of waveform comparison that should be considered is between PSV records and HSV records from the same sites. For example, Figure P9 shows a transect of PSV records for the last 3 ka across Eurasia. Open circles in the interval A.D. 1600 to A.D. 2000 estimate the historic secular variation for each site based on spherical

**Figure P11** Late Pleistocene full-vector paleomagnetic secular variation record recovered from uplifted lake sediments exposed at Mono Lake, California (USA) (Liddicoat and Coe, 1979; Lund *et al.*, 1988). Note the presence of the Mono Lake excursion near 28000 radiocarbon years B.P. and indication of at least four cycles of a complex repeating vector waveform ( $\alpha$ -e?) associated with the excursion.

harmonic analyses. Such comparisons indicate that only the largest amplitude, longest period (~200–400 years) HSV features can be correlated with the PSV variability (indicated by solid circles in Figure P9). This limited correlation is due to the fact that PSV records only resolve features greater than about 4° in amplitude and a few hundred years in duration. Even then, this correlation shows that high-resolution PSV records can accurately record and extend the long-term temporal variation only hinted at in HSV records.

The second type of comparison, between different high-resolution PSV records from the same region (e.g., Europe or East Asia), can be used to assess the spatial extent of PSV features. For example, Figure P9 shows late Holocene PSV records from seven different sites in Europe (Iceland, ICE to CAU) spread over  $70^{\circ}$  of longitude ( $\sim$ 7000 km) and four different sites in East Asia (MON to Japan, JPN) spread over  $30^{\circ}$  of longitude ( $\sim$ 3000 km). Within each of these regions, it is readily apparent that a large number of directional features can be correlated among the records. (i.e., not to say that the records are identical, but variations in sampling rate and signal to noise ratios or errors in data acquisition and analysis probably can explain most of the differences in single records). One interpretation of these observations is that PSV features with periods longer than a few hundred years must correspond to spatial features that are observable in historic maps of the geomagnetic field and have spatial domains of several 1000 km.

A similar comparison between PSV records from different geographic regions is more problematic. For example, the comparison between European and East Asian PSV records in Figure P9 indicates that there is no simple correlation between directional records from the two regions that preserves phase relationships or long-term trends in the directional data. Similarly, there is no simple vector pattern that

**Figure P12** Late Pleistocene full-vector paleomagnetic secular variation record from deep-sea piston core JPC-14, western north Atlantic Ocean (Lund *et al.*, 2001, 2005). Note the presence of the Laschamp excursion near ~40000 years B.P.

can be traced all the way across Eurasia for the last 3000 years. It thus appears that straightforward PSV vector correlations break down beyond perhaps 5000 km. Thompson (1984) noted a similar scale of spatial coherence in the correlation of HSV waveforms. He determined that HSV could be broken down into about nine different regions over the Earth's surface. Within each region, HSV waveforms are broadly correlative, but between regions the patterns are significantly different (and uncorrelated except for an overall vector average approximating the axial dipole expectation). This lack of global-scale correlation appears to be present in directional PSV records as well and indicates that there is no persistent westward (or eastward) drift of distinctive geomagnetic features over thousands of years, as has been suggested most recently by Merrill *et al.* (1998).

Paleointensity, on the other hand, does show clear evidence of global-scale coherence in its variability. Comparisons of paleointensity records from around the world (e.g., Guyodo and Valet, 1999; Laj *et al.*, 2000; Stoner *et al.*, 2003) show clear evidence that most long-term (>1000 years) paleointensity variability is correlatable on a global scale. For example, Figure P13 shows two high-resolution relative paleointensity features that are synchronous in age (~500 years resolution) based on oxygen isotope age determinations, including a distinctive paleointensity low associated with directional records of the Laschamp Excursion at each site. One future task of PSV studies is to rationalize how significantly different patterns of directional variability can exist around the world in the presence of such globally coherent paleointensity variability.

A third type of waveform comparison can be made between PSV features or vector waveforms within individual paleomagnetic records. Such comparisons have occasionally identified distinctive vector

**Figure P13** Late-Pleistocene paleointensity comparison between sediment PSV records from the North Atlantic Ocean and western Equatorial Pacific Ocean (Stott *et al.*, 2002). A number of distinctive and correlatable paleointensity features are noted in the two records; independent oxygen isotope stratigraphies suggest that these features are synchronous (~500 year uncertainty).

waveforms that seem to recur every 2500 to 4000 years. The PSV record from Mono Lake, shown in Figure P11, illustrates this recurrence pattern. At least four recurrences ( $\alpha$ - $\delta$ ) of basically the same complex waveform can be noted (Lund *et al.*, 1988). With each recurrence, the waveform is slightly altered; however, the general pattern persists for more than 16 ka. It is likely that this distinctive waveform has evolved out of the Mono Lake excursion (waveform  $\epsilon$ ? in Figure P11). Similar recurring patterns have been noted in the Holocene PSV record from Lake St. Croix (Figure P10; Lund and Banerjee, 1985) in a late Pleistocene PSV record from Russia (Ekman *et al.*, 1987), and after the Summer Lake Excursion recorded in lake sediments from Oregon (Negrini *et al.*, 1994).

Recurring vector waveforms can also be identified by their distinctive sequences of vector looping (circularity). Such looping patterns (Runcorn, 1959) are characteristic of both PSV (e.g., Creer, 1983) and HSV (e.g., Bauer, 1895) and have been suggested (Skiles, 1970) to be an indicator of westward or eastward drift of the geomagnetic field (although there is no significant evidence of long-term persistent drift of the field as noted above). However, the correlation between observed looping and drift is not unique (Dodson, 1979). Large amplitude loops, often associated with recurring vector waveforms, last about 1000 to 1400 years; small amplitude loops have also been noted that last about 500–800 years. Looping intervals might be used as an indicator of the simplest temporal scale for PSV coherence at individual sites.

#### Excursions

One type of vector waveform deserves special note-magnetic field excursions, which are anomalous PSV fluctuations defined by virtual geomagnetic poles (VGPs) located more than 45° away from the geographic pole. It is clear that excursions do occur; it is often not clear, however, what is their waveform morphology or whether some excursions are really artifacts of field-laboratory measurement errors. There is growing evidence (e.g., Lund et al., 2001, 2005) that at least seventeen excursions have occurred in the Brunhes Epoch (0-780000 years B.P.). One distinctive element of all these excursions is that they occur within intervals of anomalously low global-scale paleointensity (see Figures P11-P13). Most excursion records are difficult to correlate around the world because of uncertainties in their age estimates. But, three of the most recent excursions are becoming better understood: the Mono Lake excursion (CA. 28000 years B.P.; Denham and Cox, 1971; Liddicoat and Coe, 1979; Figure P11), The Laschamp excursion (CA. 41000 years B.P.; Bonhommet and Zahringer, 1969; Figures P12 and P13) and the Blake Event (CA. 125000 years B.P.; Smith and Foster, 1969). For each of these excursions, there are now multiple independent records from around the world, which are sufficiently well dated to correlate the records and estimate that individual excursion records are synchronous to  $\sim$ 500-year resolution. There are also a number of high-resolution excursion records (e.g., Liddicoat and Coe, 1979; Lund et al., 2005.rpar; that assess the local waveform patterns of excursions and the surrounding normal PSV. However, there are still not enough high-resolution excursion records to be certain about their global pattern of field variability or relationship to normal PSV or magnetic field reversals.

# Spectral analysis

Spectral analysis describes the frequency content of PSV over timescales of  $10^2-10^5$  years. Traditional ideas suggest that PSV should be a band limited process. That is, that the spectral power of PSV should markedly diminish beyond some cutoff period on the order of  $10^4$  years. PSV records longer than the cutoff period should then be stationary in a statistical sense and have an average field vector direction that is constant through time for a given site. The axial dipole hypothesis, a cornerstone of plate tectonic reconstructions, assumes that the PSV process is stationary and that each site's average field vector (during intervals of normal polarity) satisfies the formula,

771

 $\tan I = 2 \tan \lambda$ ,  $D = 0^{\circ}$ , where  $\lambda$  is the site paleolatitude. One important goal of PSV studies is to test the long-term validity of the axial dipole hypothesis and the notion of a stationary PSV spectrum with limited power at  $> 10^4$  years.

Spectral analysis also describes the characteristic distribution of continuous spectral power within the overall PSV process (Barton, 1982, 1983) and identifies whether there are distinct frequency bands within the continuous spectrum that have higher than average spectral power. Knowledge of the PSV power spectrum and its potential changes in time and space is critical for better understanding the relationship between PSV and the core dynamo process that generates it.

The primary limitation in recovering detailed estimates of the PSV spectrum is the quality of age estimates associated with the PSV records. Records dated using radiocarbon methods over the last 40 ka or so may have systematic errors with respect to "true" time due to radiocarbon reservoir effects. They may also have random errors on the order of  $10^2$  years or worse due to random dating errors. Older PSV records can also be dated using oxygen isotope stratigraphies, but such age estimates have random uncertainties on the order of  $10^3$  years.

Despite these limitations, important and convincing spectral estimates of late-Quaternary PSV have been recovered from several regions around the world: Europe, North America, the Far East, Australia, and South America. Figure P14 shows the stacked PSV spectrum of unit-vector (RMS of scalar inclination and declination spectra) and paleointensity results from three deep-sea sediment PSV records in the western North Atlantic Ocean that are >50 ka in duration. These results provide a good overview of the long-term PSV spectrum. The unit-vector and paleointensity spectra are continuous in their power distribution, with the largest amplitude secular variation occurring at periods much greater than  $10^3$  years (far beyond the range of HSV). Both spectra are red (power-law relationship between frequency and power) for periods <5 ka-12 ka, and white (~constant power as a function of frequency) for longer periods with no indication of a marked decrease in spectral power at the longest observed periods ( $\sim$ 50 ka). These characteristics suggest that the geomagnetic field is not stationary (band-limited) over timescales of less than about 10<sup>5</sup> years. The corner frequencies (boundaries between dominantly red and white spectra, indicated by arrows in Figure P14), are about 5 ka for the unitvector spectrum and about 12000 years for the paleointensity spectrum. One interpretation of the corner frequency is that the red spectrum describes the intrinsic dynamics of field variability associated with the dynamo process, while the white spectrum describes random perturbations of that process or longer-term external forces acting on that process (e.g., Channell et al., 1998). In this scenario, the corner frequency in paleointensity of  $\sim 12$  ka defines the longest time constant of normal dynamo activity. The fact that the unit-vector corner frequency is only  $\sim$ 5 ka is due to the observation that vector variations only reflect nonaxial dipole field variability, not total field variability. It is probably not coincidental that the longest repeating vector waveforms noted in individual PSV records approach the unit-vector corner frequency of ~5 ka. There is also evidence of selected spectral bands in the red portion of the spectra with larger than average spectral power. That is the pattern noted in most other PSV spectra determined from shorter duration records (e.g., Barton, 1982, 1983). These spectral bands probably define the detailed pattern of dynamo activity in a region at any one time, but none of these components are probably periodic on a long-term spatial or temporal scale and they should tend to smear out when spectra from different time intervals or spatial regions are stacked.

Most of these spectral characteristics have no temporal analog in HSV because of the short time span of historic measurement. One might, however, attempt to relate the long-term PSV spectral characteristics to the present day geomagnetic field spatial spectrum. The spatial field due to core sources has a cutoff near spherical harmonic degree 12 and the spectral power decreases quickly from a maximum at harmonic degree 1 (dipole terms). Only spatial terms of about degree 6 or less have vector amplitudes large enough to be recorded in PSV., One might therefore hypothesize that the long-term PSV spectrum must be

**Figure P14** Paleointensity and unit-vector spectra for a stack of three long-term deep-sea sediment PSV records from the western North Atlantic Ocean. One of the records, JPC-14, is shown in Figure P12. Arrows indicate corner frequencies, which separate "white" and "red" portions of the spectra.

772

PALEOMAGNETIC SECULAR VARIATION

due to temporal variations of spatial components of the present-day field with spherical harmonic degree 5–6, under normal conditions.

## Statistical analysis

The aspect of PSV that is easiest to analyze is its statistical behavior averaged over some interval of time. For this reason, statistical properties of PSV, within time windows in the order of 10<sup>5</sup> or 10<sup>6</sup> years, were the first PSV characteristics to be compared spatially, and even today they are the only PSV characteristics that can be easily compared on a global scale. Such comparisons provide the strongest evidence relating to possible long-term stationarity of geomagnetic field behavior, the axial dipole hypothesis, and the potential global pattern of selected PSV characteristics. Statistical study of PSV follows two very different paths on the basis of sampling frequency and age control of the paleomagnetic measurements. In the first approach, paleomagnetic field directions in undated rock sequences are measured under the assumption that the age difference of successive rock units is large compared to the longest period of PSV (often assumed to be about 10000 years). Each data point is therefore assumed to be an independent random value picked from an assumed frequency-band-limited PSV process. Data sets from small regions, averaged over  $10^5$  or  $10^6$  years, are then statistically analyzed and compared with some global model of the expected statistical behavior. (Even if the underlying assumptions of spectral content are wrong, as they likely are, results from this type of statistical analysis should not be seriously biased if the data are truly randomly spaced in time.) The second approach is to measure well-dated (either by radiocarbon or oxygen isotope methods) paleomagnetic sequences where the sampling interval is less than the shortest period of PSV (about 30 years). It is not often feasible to find sequences with such short time spacing, but useful information can be obtained with sample intervals up to perhaps 250 years (and even longer under special circumstances). Statistics are estimated from equispaced time-series derived from the dated paleomagnetic records. This method permits spatial comparison of statistical parameters averaged over much shorter time intervals, on the order of  $10^3 - 10^5$  years. In such studies, it is likely that the statistics does not represent a "stationary" estimate of space-time field variability but rather a "statistical snapshot" of an evolving space-time field structure.

Statistical analyses of the probability distributions of both field vectors and their equivalent VGPs from single sites indicate that neither distribution is typically Fisherian (Fisher, 1953; spherical analog of the Gaussian or normal distribution). For example, Brock's (1971) results from equatorial Africa (Figure P15) show that both field vectors and VGPs tend to have somewhat elliptical distributions. Engebretson and Beck (1978) have summarized the statistical parameters normally used to characterize the shape of the probability distribution. It is probable that shape statistics vary systematically as a function of

Figure P15 Statistical distribution of PSV directions and virtual geomagnetic poles (VGPs) from Equatorial Africa (Brock, 1971).

latitude (and longitude?) and future studies of shape statistics may provide important added characteristics of the Earth's long-term PSV. As a starting point, it is worth noting that the range of vector variability (as a function of latitude) noted in historic maps of the geomagnetic field is comparable to the range of vector variability noted in individual PSV records from the late Quaternary. This suggests that, even though secular variation changes on timescales far beyond the range of historic measurements, the normal range of its spatial variability is completely present in the observed historic field. A similar observation has been made for the long-term pattern of PSV angular dispersion by McFadden *et al.* (1988).

Currently, the two statistical parameters most often measured in PSV studies are the  $\Delta I$  anomaly, which is the site mean inclination minus the expected axial dipole field inclination and the angular dispersion associated with a site's vector (or equivalent VGP) variability. The global pattern of the  $\Delta I$  anomaly estimates how well the axial dipole hypothesis, the cornerstone of plate tectonic reconstructions, fits the actual geomagnetic field behavior. The global pattern of angular dispersion should provide some measure of the spatial pattern of intrinsic "energy" or "dynamics" in the core dynamo process. This variability may be due to differing proportions of dipole versus nondipole field variability (see summary in Merrill *et al.*, 1998) or it could be interpreted as the relative importance of primary versus secondary family spherical harmonic components (McFadden *et al.*, 1988), two orthogonal components of the geomagnetic field that may have fundamental relationships to dynamo theory (Roberts and Stix, 1972).

The  $\Delta I$  anomaly was perhaps first quantified by Wilson in 1970 who noticed that the average paleomagnetic pole positions associated with individual geographic regions (e.g., Australia, Europe, North America) were always farther from the sampled region than the known geographic pole. This offset, termed the farsided effect, is due to paleomagnetic inclinations that are systematically more negative than their axial dipole expectation (negative  $\Delta I$  anomaly), on average. McElhinny *et al.* (1996) have determined the global  $\Delta I$  anomaly for the last 5 Ma (see Figure P16), on average, and noted that the  $\Delta I$ anomaly is mostly negative with a maximum anomaly near the Equator and a latitudinal variation that is symmetric about the Equator and

**Figure P16**  $\Delta I$  anomaly as a function of latitude for selected time intervals: solid symbols—last 5 Ma average, open circles last few thousand years average, open squares, last ~10–20 ka average.

zonal (any site along a line of latitude will have the same magnitude of  $\Delta I$  anomaly). Their analysis also indicated that  $\Delta I$  anomaly has persisted with the same general pattern and magnitude for the last 5 Ma during both normal and reversed polarity. Other workers (e.g., Coupland and Van der Voo, 1980; Livermore et al., 1984; Schneider and Kent, 1990) have noted that a similar pattern of  $\Delta I$  anomaly has persisted for at least the last 100 million years, but with slow variations in the maximum anomaly magnitude. Statistical studies of shorter-term equispaced PSV time-series (e.g., Lund, 1985; Lund et al., in review) indicate that the  $\Delta I$  anomaly averaged over 10<sup>3</sup> years (see open circles in Figure P16) and 10<sup>4</sup> years (see open squares in Figure P16) also show the same general  $\Delta I$  anomaly pattern noted in the longer-term data. However, Constable and Johnson (2000) have argued that nonzonal components of the  $\Delta I$  anomaly are significant and have persisted for the last several million years, with some Equatorial regions having more significant  $\Delta I$  anomalies than other regions and some highlatitude regions actually having positive  $\Delta I$  anomalies. These observations all suggest that the spatial pattern of the  $\Delta I$  anomaly is persistent but nonstationary in its detailed pattern over timescales greater than  $\sim 10^4$  years. The implication of the  $\Delta I$  anomaly for plate tectonic studies is that paleolatitude estimates derived from paleomagnetic studies may be in error by as much as 8° depending on time and paleolatitude. Similar analyses of declination have shown no significant deviations in declination values from  $0^{\circ}$  over the last several million years.

Analysis of PSV angular dispersions (either directions or their equivalent virtual geomagnetic poles, VGPs) has established that this parameter also displays a distinctive zonal pattern of amplitude variation with latitude. The average latitudinal pattern of VGP angular dispersion for the last 5 Ma (McFadden et al., 1988) is shown in Figure P17. Lund (1985) and Lund et al. (in review) have noted, however, that VGP angular dispersion averaged over 10<sup>3</sup> and 10<sup>4</sup> year intervals (open circles and open squares in Figure P17) using equispaced PSV time-series is significantly lower than the 5 Ma average, and Merrill and McFadden (1988) have shown that it can vary on much longer  $(10^7 \text{ year})$  timescales as well. A variety of parametric models, summarized in Merrill et al. (1998), have been developed to attempt to explain the observed spatial pattern of angular dispersion in an ad hoc manner. More recently, McFadden et al. (1988) were able to relate the long-term average pattern of VGP angular dispersion to historical field observations and developed model G, based on the relative importance of primary versus secondary family magnetic field components (Roberts and Stix, 1972), to explain the latitude dependence.

**Figure P17** VGP angular dispersion as a function of latitude for selected time intervals: solid symbols—last 5 Ma average, open circles last few thousand years average, open squares, last  $\sim$ 10–20 ka average.

These statistical observations indicate clearly that PSV varies in a nonstationary manner over a variety of timescales, a pattern consistent with the PSV spectrum described above, and may be related to the continuing time evolution of regional PSV waveforms. One discordant note in this discussion of PSV nonstationarity is the qualitative sense that, even though PSV statistics may vary quantitatively in a nonpredictable manner over time, the PSV vector mean for any site is heavily "attracted" to its axial dipole expected direction. This may be due to the symmetry associated with the Earth's rotation, one of the driving forces of the dynamo. But, whatever be the cause, it seems prudent, perhaps, to think of PSV as "quasi-stationary" in its behavior based on the overall sense of "attraction" to such a "fixed point" (the axial dipole expectation) in time and space.

## Models of PSV

An alternative method for the analysis of PSV is to develop models for the observed field variability. Such models may be conceptual in nature with their primary purpose being to qualitatively estimate the style of variability that a potential dynamo source might generate, or the models may be more quantitative (essentially mathematical simulation models), with their primary purpose being to replicate observed PSV. The mathematical simulation models may be developed from more conceptual models, with sources that may have some basis in reality, or purely from empirical (unrealistic) inputs. A third group of models that characterize the actual hydromagnetic process that generates the Earth's core field is beyond the scope of this survey.

## Conceptual models

Previously, various conceptual models have been proposed to qualitatively explain characteristic features of HSV. Three models that have been discussed most often are (1) dipole wobble, (2) westward (or eastward) drift of the total nondipole field, and (3) standing and drifting nondipole fields. These conceptual models have also been called upon to qualitatively explain specific components of PSV or to justify and physically explain specific mathematical simulation models of PSV.

Dipole wobble has been suggested as one component of HSV and PSV based on the presence of an  $11.5^{\circ}$  offset in the present day dipole field, its persistence during historic time, and the indication from paleomagnetic data that the field has an average declination of 0° over timescales of  $10^4$  years or longer. Therefore, the average dipole field direction must have moved prehistorically and perhaps it has "wobbled" irregularly.

The paleomagnetic evidence for dipole wobble is problematic because of non uniqueness. PSV at a single site is really the nonaxial dipole variation (dipole wobble plus true nondipole variation) at that site. The proportion of dipole wobbles versus true nondipole contributions to PSV can only be assessed by analyzing globally distributed paleomagnetic data. Merrill and McElhinny (1983) carried out such an analysis of Northern Hemisphere archeomagnetic data for the last 2000 years and suggested that a significant dipole wobble component does exist. Dipole wobble contributions have also been estimated from the statistical analysis of angular dispersion (e.g., McFadden *et al.*, 1988); however, the proportion of dipole wobble depends upon the proposed model of dipole wobble variability.

Westward drift has been suggested as an important element of HSV based on the observation that temporal changes in nondipole field components at the Earth's surface are due primarily to the westward drift in time of the spatial nondipole field components. The cause of westward drift has been related to differential rotation of the fluid outer core, where the field is generated, versus the overlying lithosphere. The importance of westward drift is complicated by the fact that some areas of the Earth have exhibited eastward drift and other areas have exhibited no drift at all during historic times (e.g., Thompson, 1984). Paleomagnetic evidence for westward drift comes from a variety of

774

PSV observations, of which a few are unique. The circularity of PSV data has long been associated with westward or eastward drift of the paleomagnetic field, although other nonaxial dipole variations could produce the same effect. The recurring waveforms, noted earlier, may indicate westward (or eastward) drift of a complex nondipole waveform that changes very slowly in time compared to the time it takes for the waveform to drift entirely around the Earth (2500-4000 years). In such a model, similar waveform and spectral characteristics should be noted at all sites along a line of latitude. The Holocene waveform comparisons noted earlier, however, do not appear to be compatible with this model. Regional PSV comparisons within Europe, East Asia, or North America separately display waveform correlations that are consistent with a westward drift model; however, no simple correlation can apparently be made between the three regional data sets. Such a correlation between regional PSV records is necessary if persistent westward (or eastward) drift is a predominant aspect of PSV.

Standing nondipole field components have been proposed to improve the fit of drifting nondipole field components to the total HSV. If truly present, their origin might be related to standing components of fluid flow near the core mantle boundary caused by irregularities in the boundary conditions. The presence of standing nondipole components in the paleomagnetic record, however, is very difficult to evaluate because of problems of nonuniqueness and the uncertainties of spatial PSV behavior. To the extent that standing nondipole components might produce nonzonal components of I and D, their importance must be below the level of noise associated with parametric statistical analyses of long-term PSV (average I, D; AI; angular dispersion), for all of these parameters are apparently zonal in their spatial distribution. However, in the study of late Ouaternary PSV waveforms, standing nondipole sources have been suggested as reasonable (but nonunique) alternatives to westward drift to explain the observed waveform variability within individual paleomagnetic records.

## Mathematical simulation models

Models that are more quantitative have also been applied to HSV and PSV. Spherical harmonic models separate the field into dipole and nondipole components and may include secular change coefficients for predicting short-term temporal variations. The primary drawback to spherical harmonic models is their general lack of relevance to the underlying physical causes of the Earth's internal magnetic field. (The exception to this may be the separation of spherical harmonic coefficients into primary and secondary family field components.) Models based on the variability of multiple localized sources in the outer core have occasionally been used as alternatives to spherical harmonic models. These models, which may use a distribution of dipoles, current loops, or wave patterns in their formulation, are more appealing in that those sources may mimic that part of the core process associated with observed nondipole foci observed at the Earth's surface (e.g., Thompson, 1984).

Spherical harmonic models are hard to apply to PSV because of the inherent timing uncertainties associated with PSV data and because of the poor spatial distribution of most PSV data. Even so, several recent summaries of PSV for the last few thousand years (e.g., Hongre et al., 1998; Constable et al., 2000; Korte and Constable, in press), based on worldwide (but poorly distributed) sites, have begun to give us a lowdegree spherical harmonic view of PSV. Figure P18, for example, shows the geomagnetic field radial flux (Br) and non-axial dipole radial flux (Br-anomaly) at the core-mantle boundary for two prehistoric epochs based on SHA of PSV time-series (Constable et al., 2000). The advantage of PSV derived SHA data sets is that they can be tied to HSV derived SHA data sets and used to extend our view of the true global-space-time pattern of secular variation back thousands of years beyond the range of HSV. In this way, we can finally begin to address the global space-time pattern of secular variation on scales appropriate to the dynamics of PSV and the geodynamo.

Historically, time-averaged PSV statistical parameters, such as the  $\Delta I$  anomaly and vector dispersion, have been more amenable to time-averaged spherical harmonic analysis. For example, the  $\Delta I$  anomaly can be modeled by an axial dipole with added quadrupolar and octupolar components; the long-term changes in  $\Delta I$  can then be modeled as changes in the quadrupole-octupole (or primary-secondary family) amplitude ratio. (See Merrill and McElhinny (1983) for more detailed discussion.)

Localized dipole-current-loop models, with either standing or drifting sources, have been applied to individual high-resolution PSV records, as well as to statistical PSV records. An example of a drifting radial dipole model for the Lake St. Croix PSV record (Figure P10; Lund and Banerjee, 1985) is shown in Figure P19. Two drifting radial dipoles plus an axial dipole are able to model almost all of the

**Figure P18** Models of geomagnetic field radial flux (Br) and nonaxial dipole radial flux (Br-nad) at the core-mantle boundary for two prehistoric epochs, 500 B.C. and 400 B.C. The models are the result of downward continuation of spherical harmonic models of PSV data from Constable *et al.* (2000).

Figure P19 Radial-dipole and dynamo-wave models of the Lake St. Croix PSV record.

observed variability at Lake St. Croix for the last 9 ka. Unfortunately, more complicated standing radial dipole models could also fit the data. But, these models would require more sources in order to fit the characteristic phase relationships of the Lake St. Croix PSV data. The drifting radial dipole model for Lake St. Croix predicts similar PSV behavior for other sites on Lake St. Croix's latitude; the standing radial dipoles model will only produce regional coherence. The difficulty in correlating the Lake St. Croix PSV record with other global records outside of North America argues that a drifting radial dipole model is probably not appropriate to explain recurring waveforms. However, the complex recurrent waveforms noted in several PSV records are very difficult to model with standing sources due to the number of sources required and the detailed timing of recurrent intensity variations that each source must maintain relative to the other sources.

An alternative model of PSV, based on poleward migrating dynamo waves in the Earth's outer core, has been developed by Olson and Hagee (1987). Figure P19 shows the results of their model applied to the observed Lake St. Croix PSV. It is apparent that the polewardmigrating dynamo-wave model does just as good a job of fitting the observed variability as the drifting radial-dipole model. The dynamo wave model, however, only requires regional coherence in waveform correlations, but not a global-scale correlation. Hagee and Olson (1989) have also applied this dynamo wave model to a global set of Holocene PSV records and shown that the same general pattern of dynamo-wave variability noted to Lake St. Croix, can also explain all other Holocene PSV around the world.

# PALEOMAGNETISM

## Introduction

Most people, certainly mariners and explorers since at least the 15th century, are aware of the value of a compass as a navigational aid. This works because the Earth generates a magnetic field, which, at the Earth's surface, is approximately that of a geocentric axial dipole (GAD). By geocentric we mean that this dipolar field is centered at the center of the Earth and by axial we mean that the axis of the dipolar field aligns with the spin axis of the Earth. This means that a magnetic compass will align approximately in the north-south direction. It also means that a magnetic dip circle will give the inclination of the magnetic field (the angle the direction the magnetic field makes with the horizontal) which, together with a knowledge of the structure of a dipole field, gives the approximate latitude. If the field were precisely that of a GAD then the north-south direction and the latitude could be obtained accurately. The deviation of magnetic north from geographical or true north is called the magnetic declination and was known to the Chinese from about A.D. 720. In 1600, William Gilbert published the results of his experimental studies in the treatise De Magnete and confirmed that the geomagnetic field is primarily dipolar.

The properties of lodestone—now known to be magnetite—were known in ancient times to the Chinese, who invented the earliest

known form of magnetic compass as early as the 2nd century B.C. This compass consisted of a lodestone spoon rotating on a smooth board. Magnetic inclination (or dip) was discovered by Georg Hartmann in 1544. Hence it has been known for some time that natural rock can behave as a compass needle and align itself along what is now recognized as being the direction of the magnetic field.

At the end of the 18th century, it was recognized that deviation of magnetic compasses could occur because of nearby strongly magnetized rocks. Delesse and Melloni were the first to observe that the magnetization in certain rocks was actually parallel to the Earth's magnetic field. Folgerhaiter extended their work and studied the magnetization of bricks and pottery. He argued that when a brick or pot was fired in the kiln then the remanent magnetization it acquired on cooling provided a record of the direction of the Earth's magnetic field. With the wisdom of hindsight, specifically a better understanding of the physics of magnetization and the mineralogy of rocks, it is fairly obvious that this would be the case. Volcanic rocks are heated well above the Curie point so the magnetization is free to align with the external magnetic field and becomes locked in as the rock cools. This is known as a thermoremanent magnetization (TRM) (q.v.). In sedimentary rocks the magnetic particles will act just like a compass needle and align themselves with the external magnetic field as they settle and then become mechanically locked in as the rock is formed. This is known as a depositional remanent magnetization (DRM) (q.v.).

This is the essence of paleomagnetism that the rock will lock in a fossil record of the ancient (or paleo) magnetic field. The fossil magnetism naturally present in a rock is termed the natural remanent magnetization (NRM) (q.v.). The primary magnetization is the component of the NRM that was acquired when the rock was formed, and may represent all, part, or none of the total NRM. After formation the primary magnetization may decay either partly or completely and additional components, referred to as secondary magnetizations, may be added by several processes. A major task in all paleomagnetic investigations is to identify and separate the magnetic components in the NRM, using a range of demagnetization and analysis procedures. Typically there is also significant effort put in to date the magnetizations so that not only the direction of the magnetic field at that particular sampling site is known but also the time when the field was in that direction. Many of the successful applications of paleomagnetism have derived from an effective partnership with geochronology.

David in 1904 and Brunhes in 1906 reported the first discovery of NRM that was roughly opposite in direction to that of the present field and this led to the speculation that the Earth's magnetic field had reversed its polarity in the past. In 1926 Mercanton pointed out that if the Earth's field had in fact reversed itself in the past, then reversely magnetized rocks should be found in all parts of the world. He demonstrated that this was indeed the case for Quaternary-aged rocks around the world. The speculation gained further support when Matuyama in 1929 observed reversely magnetized lava flows from the past one or two million years in Japan and Manchuria. However, doubts about the validity of the field reversal hypothesis surfaced during the 1950s after Néel presented theory that showed it was possible for samples to acquire a magnetization antiparallel to the external field during cooling, a process referred to as self-reversal. Shortly thereafter Nagata and Uyeda found the first laboratory-reproducible self-reversing rock, the Haruna dacite. Subsequently it was recognized that self-reversal is relatively rare and by the early 1960s it was accepted that the Earth's magnetic field has indeed reversed and that the phenomenon of field reversal has occurred many times. An excellent history of this subject has been given by Glen (1982).

By 1960 the study of the magnetic properties of minerals and rocks and the use of magnetization in rocks to infer the properties of the Earth's past magnetic field had evolved into two separate but related disciplines, respectively referred to as rock magnetism and paleomagnetism. By providing information about the location and orientation of continents relative to the Earth's magnetic pole, paleomagnetism has played a significant role in our understanding of Earth processes, particularly with regard to continental drift and polar wander and the development of plate tectonics.

As currently practiced, paleomagnetism includes topics such as age determination, stratigraphy, magnetic anomaly interpretation and paleoclimatology, as well as the traditional paleomagnetic topics of tectonics, polar wander, and studies of the evolution and history of the Earth's magnetic field.

# Determining a paleomagnetic pole

A central assumption for much of paleomagnetism is that if the field directions at any given locality are averaged over an appropriate time interval then the resulting direction is the same as that for a geocentric axial dipole. If that is the case then the inclination *I* is related to the paleolatitude  $\lambda$  by

$$\tan I = 2\tan\lambda \tag{Eq. 1}$$

Hence it is possible to determine the angular distance (paleocolatitude  $p = 90 - \lambda$ ) of the sampling site from the pole at the time that the magnetization was acquired. Using the declination *D* and the paleocolatitude of this time-average field direction it is then possible to determine the latitude and longitude ( $\lambda_p$ ,  $\phi_p$ ) of the time-average magnetic pole, known as the *paleomagnetic pole*, relative to the latitude and longitude ( $\lambda_s$ ,  $\phi_s$ ) of the sampling site. The spherical geometry needed for this can be visualized with the help of Figure P20. If the continent has moved and/or rotated since the magnetization was acquired, then the paleomagnetic pole will not coincide with the current north pole, leading to the concept of apparent polar wander (see polar wander). Paleomagnetic poles for magnetizations with different ages, but from the same continent, will plot in different positions, providing an apparent polar wander path (APWP) for the continent.

Alternatively, it is a simple matter to place the continent on the globe such that the paleomagnetic pole coincides with the north pole. This then places the continent correctly on the globe with regard to its latitude and orientation at the time the magnetization was acquired. It does not, unfortunately, give any longitudinal information.

**Figure P20** Position of the paleomagnetic pole *P* relative to the sampling site *S*. Modified after Merrill *et al.* (1996).

778

In addition to geochronology, various geological field tests are used to provide additional evidence on the nature and timing of the acquisition of the magnetization. The three traditional, and most common, tests are known as the fold test (see Magnetization, remanent, fold test), the conglomerate test, and the baked contact test (q.v.). The field relationships for these classical tests are shown in Figure P21. If the in situ directions of magnetization in a folded rock-unit differ from place to place, but agree after "unfolding" the rock-unit to its original prefolding structure, then the magnetization must predate the folding and must have been stable since that time. Conversely, if the in situ directions agree then the magnetization must postdate the folding. If cobbles from the rock formation under investigation can be found in a conglomerate then, because the orientations of the cobbles will have been randomized, the magnetization of these cobbles should have no preferred direction if their original magnetization has been stable. If the direction of magnetization in the baked contact zone surrounding an intrusion is parallel to that observed in the intrusion, but differs from that of the unbaked country rock, then the magnetization of the intrusion has been stable since cooling. It is also important to determine the paleohorizontal of the rock-unit accurately so that the inclination I used in Eq. (1) is meaningful.

It has already been noted that it is necessary to use the time-average field to determine a paleomagnetic pole. This is because the Earth's present magnetic field, and most probably Earth's past field at any particular time, is not that of a simple geocentric axial dipole. Only about 75% of the present field intensity is attributed to a dipole field, a percentage that was about 82% or 83% at the beginning of the 20th century. This dipolar field is not static and is currently tilted about 10.7° from the rotation axis. The remainder of the field is referred to as the nondipole field, which characteristically exhibits more rapid spatial and temporal variations than the dipole field. Consequently it is necessary to average out these variations. Some rocks, for example thin lava flows, can acquire their primary magnetization in less than a year and so that primary magnetization often reflects the instantaneous field and not the time-average field. Thus it becomes necessary to use a sampling scheme that will average out these variations in order to give a reliable paleomagnetic pole.

A hierarchical scheme is typically used to obtain an estimate of a paleomagnetic pole position from a given location. Oriented samples are taken throughout the rock formation of interest. Specimens obtained from these samples are used to investigate rock magnetic properties. Statistical analysis of sample directions provides an estimate of the ancient field direction and its variance for the rock-unit. The mean magnetic direction for this unit is then used in Eq. (1)to determine a virtual geomagnetic pole (VGP). It is referred to as a "virtual" pole because at this level in the hierarchy it is unlikely that the field would have been averaged to that of a GAD. This makes it possible to average a "sufficient" number of VGP from widely dispersed sampling sites as a final step in the hierarchy to obtain an estimate of the paleomagnetic pole position. Alternatively, if it is apparent from the geology that sampling localities spatially close to each other will provide coverage of a sufficient time interval, then it is possible to average the magnetic field directions and use this mean direction in

**Figure P21** Field relationships for the fold, conglomerate, and baked contact tests. From Merrill and McElhinny (1983).

Eq. (1) to estimate the paleomagnetic pole position. It is presumed that at this level in the hierarchy the geocentric axial dipole assumption is satisfied and that the paleomagnetic pole position provides a reliable estimate of the paleogeographic pole position. There are no hard and fast rules and the procedures used in collecting samples and analyzing them vary depending on such factors as the properties of the site, the nature of the rocks sampled, the goals of the investigation and, to some extent, on the nature of the investigators. Detailed procedures on how this is done are described elsewhere in this volume.

Buried within this process is the question of how much time is required to obtain a good approximation of the time-average field so that the GAD assumption is in fact reasonable. If a very short interval is used, then the averaging will be incomplete and this can produce significant errors. Conversely, if too long an interval is used then, for example, global tectonic processes can become significant and the sampling locality may have moved a substantial amount relative to the geographic pole. There is no widespread agreement on the optimum time interval for averaging but a minimum of 10 ka is generally viewed as necessary. The GAD assumption appears to be excellent for the time-average magnetic field over the past 5 Ma, although a small nondipole component may also be present. It is difficult to determine whether the GAD assumption has been valid throughout most of geological time but there is reasonable evidence to indicate that the assumption is very good to first order for the last few hundred million years. The evidence is less compelling for times prior to about 300 Ma ago.

## Paleomagnetic field

Probably the best-documented fact stemming from paleomagnetism is that Earth's magnetic field has reversed polarity many times. By this it is meant that the north and south geomagnetic poles (the two locations where a line through the geocentric dipole intersects the Earth's surface) have traded places. The duration of a polarity transition is imperfectly known but it is probably in the order of  $10^3$  to  $10^4$  years, a time during which the intensity drops to a minimum of around a quarter of its normal value. The field is said to have normal polarity when the north geomagnetic pole is above 45° north latitude, reverse polarity when this pole lies below 45° south latitude, and transitional for all other latitudes. Hundreds of reversals have now been documented and for the past 160 Ma there is now a fairly reliable geomagnetic polarity timescale (GPTS). From this timescale it is evident that reversals do not occur with a simple periodicity but instead appear to occur randomly in time. The underlying rate at which reversals occur seems to vary on a timescale of about 10<sup>8</sup> year, probably reflecting changes in the lower mantle.

The very nature of the generative process of the geomagnetic field-a dynamo operating in the iron-rich liquid outer coredemands that the field is ever changing. The resulting gradual change in the magnetic field with time is referred to as *secular variation* (q.v.)which, as already discussed, must be averaged out in order to obtain a paleomagnetic pole. This secular variation occurs over a wide range of timescales, the shortest period that can be observed being around a year. This is because of the shorter period variations screened out by the semiconducting mantle. It is generally felt that the characteristic times of dynamo processes are less than 10<sup>6</sup> years, so variations due to internal processes in the dynamo typically occur in less than 10<sup>6</sup> years. Longer timescale variations, such as in the reversal rate, probably reflect changes in boundary conditions on the core. Apart from reversals, the largest changes in the Earth's magnetic field are known as excursions short intervals of time (of the order  $10^4$  years) when VGP deviate unusually far from the geographic pole.

The intensity of the field also changes with time. However, because of rock magnetic problems, these changes are more difficult to determine than the changes in direction. Direct measurements of the Earth's magnetic field from magnetic observatories indicate that that the dipole intensity decreased by about 5% during the 20th century.

Indirect measurements from archeomagnetism and paleomagnetism (there are several different absolute and relative paleointensity methods) indicate that the intensity of the Earth's field has varied significantly on a timescale that is geologically short. For example, 2 ka ago the intensity appears to have been 30%-40% greater than the present value but 6 ka ago it was found to be 30% less. Good relative paleointensity data from marine sediments provide a reasonable estimate of the intensity variation for the most recent several hundred thousand years. Intensities from times prior to this come from so-called absolute paleointensity methods, which seemingly should provide more accurate estimates than relative estimates. However, absolute intensity estimates are obtained from lava flows, which provide estimates that represent essentially an instantaneous estimate of the magnetic field rather than a time-average value. Typically there are large spatial and temporal gaps between such estimates. Although there is an incomplete agreement on what constitutes a reliable absolute paleointensity estimate, most paleomagnetists would agree that there are only about 1000 reliable estimates for all of geological time prior to about 5 Ma ago. A consequence is that several models have been advanced to describe the intensity variation over the past few hundred million years and there is little agreement on which model should be preferred.

# Tectonics

In the 1950s it was not immediately clear whether apparent polar wander was indeed due to polar wander itself or to movement of the continents. However, because the apparent polar wander paths were different for different continents, paleomagnetists argued that continental drift had occurred. For example, the APWPs from 350 Ma to present for North America and Europe (including Russia west of the Ural Mountains) can effectively be made to coincide by removing the Atlantic Ocean and closing up the continents. This is consistent with Wegener's pioneering suggestion of continental drift to explain various geographic and geologic features-but not magnetic. Nevertheless the claims by paleomagnetists were often dismissed prior to the mid-1960s by other scientists, primarily because of concerns about the reliability of the geocentric axial dipole field assumption, questions concerning the fidelity of rocks as recorders of the primary remanent magnetization and because of the apparent absence of a driving mechanism for continental drift.

Today, paleomagnetic poles are widely used to locate the past positions of continents, particularly when marine magnetic anomaly data are not available. Indeed, as the oldest marine rocks are slightly less than 200 Ma old, paleomagnetic poles and APWPs are the primary quantitative tools for locating land masses prior to 200 Ma. In addition, paleomagnetic poles provide valuable information on tectonics on a smaller scale. For example, a substantial part of north-western North America appears to have been added to the craton in pieces, referred to as displaced terranes, during the Cenozoic.

Marine magnetic anomalies (variations in the intensity of the magnetic field that are usually measured at the sea surface) played a prominent role in the establishment of seafloor spreading and plate tectonics. It was noticed that these magnetic anomalies formed stripes parallel to and symmetric about the mid-ocean ridges. Vine and Matthews and Morley and Larochelle independently recognized that these magnetic stripes were caused by alternating blocks of normally and reversely magnetized volcanic rocks in the upper part of the oceanic crust. According to their model, crust is formed at the mid-ocean ridge, spreads away on both sides of the ridge and cools. As the rock cools at the Curie temperature it acquires a thermoremanent magnetization parallel to the ambient direction of the Earth's magnetic field. Reversals of the Earth's magnetic field will then produce blocks of alternate polarity. Hence the spreading crust acts like a magnetic tape recorder by recording the reversals of Earth's magnetic field, producing the observed stripes. It is now recognized that this magnetization is recorded in Layer 2 of the oceanic crust, an igneous layer of pillow

basalts and dikes that lies beneath Layer 1, a sedimentary layer that was deposited later. Because this field varies over Earth's surface, the geocentric axial dipole field assumption is invoked and marine magnetic anomalies are transformed to the poles in order to make comparisons between anomalies from different localities. Because polarity contrast is used, undetected nondipole components will not have a significant effect on the final result. These marine magnetic anomalies have played a major role in the development of a geomagnetic polarity timescale for the last 170 Ma and in our understanding of the motions of tectonic plates during this recent time interval.

In a strict interpretation of plate tectonics, all deformation is confined to three types of plate boundaries: divergent plate boundaries (spreading centers)—where new material is produced; convergent plate boundaries (subduction zones)—where material descends back into the Earth, and transform faults where no new material is produced or removed. Support for this approximation comes from many sources including that the vast majority of energy released by earthquakes occurs at plate boundaries. However, there are places where this strict interpretation must be modified. For example, much of the Tibetan Plateau has experienced uplift of more than 5 km since the collision of India with the rest of Eurasia, which occurred about 50–65 Ma ago. Even such cases as this where interplate tectonics is important, paleomagnetism has proven to be a valuable tool in determining the character of the deformation.

The final tectonic example we give involves an ongoing controversy concerning features known as hot spots. These features are associated with interplate basaltic volcanism characterized by linear volcanic chains that grow older in the direction of plate motion. For more than a quarter of a century, it was believed that hot spots were maintained by material rising from the lower mantle through lower mantle plumes that formed part of the upward flow of a long-lived stable pattern of whole-mantle convention. Furthermore, it was supposed that these plumes do not change their relative positions. As already noted, given a single APWP, it is not immediately apparent whether this is due to polar wander or continental motion, and this is because it is difficult to find a fixed reference frame. Consequently a fixed hot spot reference frame was an enormously attractive concept. The fixed hot spot model implies that all islands and seamounts along a particular hot spot chain are formed at the same latitude and longitude. However, recent inclination data obtained by drilling seamounts from the northern end of the Hawaiian Emperor Seamount chain suggests that this is not the case. The magnetic inclinations of drilled samples from the Emperor Seamounts at the northern end of this chain seem to indicate the seamounts formed at significantly higher latitudes than that of the present hot spot, which lies beneath the island of Hawaii. If the paleomagnetic data from the Emperor Seamounts are sufficient to average out secular variation, if the paleohorizontal has been accurately obtained, and if the primary magnetization has been properly obtained, then the fixed hot spot model is not obeyed, at least for the Hawaiian-Emperor hot spot chain. In 1998 Steinberger and O'Connell showed how it was possible for hot spot plumes under a single plate to show less relative motion while at the same time it was moving relative to plumes under a different plate. This suggests it is unlikely that plumes can be effectively anchored in a convecting mantle and it seems that the weight of evidence is currently against the idea of a fixed hot spot reference frame.

## Magnetostratigraphy and paleoclimate studies

Because there is an excellent first-order reversal chronology for most of the Mesozoic and all of the Cenozoic and because reversals occur randomly in time, sequences of reversals can be used for age dating and stratigraphic control. For example, a distinctive reversal pattern found in sediments in one area can sometimes be correlated with the same pattern in a different area. Sedimentation rates will typically be different in the two areas and so some stretching of the record from one area is required to make a correlation. This makes the match nonunique and so the correlation is more convincing the more distinctive the local pattern of reversals is. Absolute ages can be assigned to the sediment sections involved when the pattern of reversals can be identified in the reversal chronology. In addition, rock magnetic properties, such as magnetic susceptibility are sometimes used for correlation of marine cores taken in the same general location. Details on how magnetostratigraphy is done in practice are provided in books such as Opdyke and Channell (1996).

Often the detailed characteristics of a sediment will vary with depth because the source of the sediments has changed with time or because of physical, biological, or chemical alteration of the sediments after deposition. This provides a record that can be used for paleoclimate and environmental studies. Typically, although the magnetic properties will often vary with depth in sediments, this does not usually provide primary information on paleoclimatic changes. However, magnetic properties such as magnetic susceptibility can frequently be correlated with primary proxies for paleoclimate such as the variation in oxygen isotopes. Thus susceptibility, which can be measured relatively quickly, provides valuable data when there are gaps in the isotope record.

Paleomagnetism also plays a key role in testing global paleoclimatic hypotheses. For example, in 1969 Mikhail Budyko proposed a model for ice sheets that could lead to a runaway situation in which the whole Earth becomes covered in ice. The possibility of one or more glaciations that led to an entirely, or mostly, ice-covered Earth around 600 Ma ago is referred to as the snowball earth hypothesis. Paleomagnetism has provided significant support to this hypothesis by showing that, for example, Precambrian igneous rocks associated with glacial deposits in Namibia exhibit shallow magnetic inclinations, providing a clear implication that glacial deposits were formed at tropical latitudes in the Late Precambrian.

## **Concluding remarks**

In essence, paleomagnetism provides three types of information: first, it provides a record of the Earth's magnetic field, which is a proxy for processes deep within the Earth; second, with some assumptions about the structure of the magnetic field, it provides information on the past location of rock-units; and, third, having calibrated the magnetic information, it provides the possibility to use APWPs and the geomagnetic polarity timescale as dating tools. Each of these types of information will contribute to our ongoing quest to understand our planet and its processes.

A major question to be addressed is whether global tectonics early in the Earth's history had a substantially different character from today. Hence paleomagnetism must develop the capacity to provide reliable location information for rocks formed early in the Earth's history.

The geomagnetic polarity timescale for the past 160 Ma is reasonably well developed and provides significant information on processes deep within the Earth with characteristic times in the order of 10<sup>8</sup> years. However, this timescale continues to evolve and it is necessary to invest the effort to obtain a complete and accurate record. The plate tectonic process has ensured that seafloor older than about 160 Ma has been recycled and so there is no well-ordered "tape recording" of reversals older than this. Instead, it is necessary to develop the reversal chronology for times before this through a painstaking process of dating, correlation, and assembly of information from continental rocks. Although the reversal chronology has been extended back into the Paleozoic, large gaps in coverage remain and there are a few data for the Precambrian. This timescale will provide valuable information on internal Earth processes and will also itself become a valuable dating tool.

Reliable paleointensity data for almost all times are needed. The resulting information is required to understand the long-term evolution of the Earth's magnetic field. In turn, this is likely to provide better understanding of the evolution of the Earth's inner core.

At this stage there is insufficient evidence regarding the structure of the time-average field for times earlier than about 300 Ma. This is an impediment to accurate reconstruction of earlier land masses. To some extent this creates a circular problem: a GAD field is assumed and paleoreconstructions are performed; inconsistencies in the paleoreconstructions are then attributed to non-GAD structure in the ancient geomagnetic field. If the structure of the field is actually known then it is possible to obtain an accurate paleoreconstruction. Conversely, if the paleolocations of the continental masses are known then it is possible to get information about the structure of the paleofield. It is going to require substantial innovation to achieve both of these without independent evidence.

## PALEOMAGNETISM, DEEP-SEA SEDIMENTS

#### Introduction

Deep-sea (pelagic) sediments, deposited remotely from sources of continental detritus, have been a very important source for learning about the direction and intensity of the ancient geomagnetic field (paleomagnetism) because they often carry a primary natural remanent magnetization (NRM) acquired at the time of deposition, or shortly thereafter. The age of a primary magnetization can be determined from the accompanying biostratigraphy or isotope stratigraphy. The magnetization directions of known age have been used to assess plate motion (continental drift) or to record the characteristics of the ancient geomagnetic field, such as the sequence of polarity reversal in the geologic past. The record of geomagnetic polarity reversal (magnetostratigraphy) in deep-sea sediments, first practiced by Opdyke et al. (1966), has become important in paleoceanography and biostratigraphy, and in geologic timescale construction. The geomagnetic polarity time scale (GPTS), based on the sequence of polarity reversal through time, is the central thread to which the other facets of geologic time (radiometric, isotopic, biostratigraphic) are correlated in the construction of geologic timescales for the last 150 Ma (see Opdyke and Channell, 1996). Prior to  $\sim$ 150 Ma, the GPTS is less well defined, due to the lack of in situ oceanic crust and hence marine magnetic anomaly records, and is not adequately correlated to the biozonations that define geologic stages. The global synchronicity of polarity reversals (of the main axial dipole field) means that magnetic polarity stratigraphies can be used to correlate environmental (isotopic) and biostratigraphic events among contrasting environments and remote locations. The stochastic (unpredictable) occurrence of polarity reversal, and our inability to distinguish one normal (reverse) polarity chron from another, means that precise correlation through magnetic polarity stratigraphy is only possible at polarity reversals, with interpolation between these tie points. Within individual polarity chrons (time intervals between polarity reversals) magnetic records can be used for correlation if geomagnetic directional "secular" variation and/or paleointensity are adequately recorded. The conditions for adequate recording of secular variation and geomagnetic paleointensity are more stringent than for the recording of polarity reversals as contamination (overprint) of primary magnetization is less crippling for polarity records (~180° directional changes) than for the more subtle changes that define secular variation and paleointensity.

# Origin of primary magnetizations

What makes deep-sea sediments efficient recorders of the geomagnetic field at time of deposition? Sediments can acquire a detrital remanent magnetization (DRM) at the time of deposition by mechanical orientation of fine grained magnetite (Fe<sub>3</sub>O<sub>4</sub>) or titanomagnetic (*x*FeTiO<sub>4</sub> [1 - x] Fe<sub>3</sub>O<sub>4</sub>) into line with the ambient geomagnetic field at the sediment-water interface. The natural remanent (permanent) magnetization (NRM) of ferrimagnetic (titano) magnetite results in a torque that statistically orients the magnetic moment of the grain population into line with the ambient geomagnetic field. The mechanical orientation of grains may be achieved either at the sediment-water interface (DRM) or in the uppermost few centimeters or decimeters of the sediment in which case the resulting remanence is referred to as pDRM (post-depositional detrital remanent magnetization).

Following introduction of the concept by Irving and Major (1964), progressive acquisition of postdepositional detrital remanent magnetization (pDRM) has been modeled as an exponential or cubic function of progressive lock-in with depth (Hyodo, 1984; Mazaud, 1996; Meynadier and Valet, 1996; Roberts and Winklhofer, 2004). Teanby and Gubbins (2000) used an 8 cm uniform mixed layer (magnetization = 0) to simulate the bioturbated surface layer, underlain by an exponential lock-in function. Channell and Guyodo (2004) have used a sigmoidal pDRM function based on tanh(x). The function can be defined by a

surface mixing layer depth (M) at which 5% of the magnetization is acquired, and a lock-in depth (L) that is the depth below M at which 50% of the magnetization is acquired (see Figure P22). The assumption of a well-mixed layer (M), in which the sediment is thoroughly consumed by sipunculid or echiuran worms and other benthos, is valid in deep-sea sediments where the mixing coefficient exceeds the product of mixed layer depth and sedimentation rate (Guinasso and Schink, 1975). In deep-sea sediments, isotopic tracers indicate mean mixed layer thicknesses of about 10 cm (values vary by an order of magnitude from 3-30 cm) that is largely independent of sedimentation rate (Boudreau, 1994). Using <sup>14</sup>C of the bulk carbonate fraction as the isotopic tracer, Thomson et al. (2000) estimated mixed layer thicknesses of 10-20 cm in box cores collected close to the Rockhall Plateau. These values are greater than the 2-13 cm mixed layer thicknesses obtained from further south in the North Atlantic using <sup>14</sup>C in foraminifera (Trauth et al., 1997; Smith and Rabouille, 2002). Estimates of mixed layer thickness are grain size sensitive (see Bard, 2001) and would be expected to be lower for the coarse fraction (foraminifera) than for the bulk carbonate (nannofossils). For this reason, mixed layer thickness estimates based on <sup>14</sup>C and other isotopic tracers should be considered as minimum estimates for the fine (PSD) grains that carry stable magnetization. The main control on the mixed layer thickness appears to be organic carbon flux derived from surface water productivity (Trauth et al., 1997; Smith and Rabouille, 2002). A recent redeposition study has suggested that, at least for some lithologies, intergranular interactions overcome the magnetic aligning torque so that bioturbation would not enhance, but rather disrupt, the remanent magnetization (Katari et al., 2000). This proposition is in agreement with Tauxe et al. (1996) who, based on an analysis of the position of the Matuvama-Brunhes boundary relative to oxygen isotope records, concluded that magnetization lock-in depth is insignificant in marine sediments. Other studies (DeMenocal et al., 1990; Lund and Keigwin, 1994; Kent and Schneider, 1995; Channell and Guyodo, 2004) invoked pDRM, and hence a finite (decimeter-scale) lock-in depth, to explain reversalisotope correlations and observed attenuation of secular variation records.

Magnetite and titanomagnetite grains carrying DRM or pDRM in marine sediments may be of detrital or biogenic origin. Titanomagnetite is likely to have a detrital origin from the weathering of igneous rocks (such as mid-ocean ridge or oceanic island basalts) or from volcanic ash falls. A magnetic remanence known as thermal remanent magnetization (TRM) is acquired as the (titano)magnetite grain cools through a blocking temperature spectrum within its igneous host. The detrital grains retain this TRM during erosion, transport, and subsequent incorporation into the deep-sea sediment. The interaction of the TRM of individual grains with the ambient geomagnetic field

**Figure P22** The sigmoidal function based on tanh(x) used to model the mixing zone (thickness *M*) and the underlying lock-in zone (thickness *L*) (after Channell and Guyodo, 2004).

782

at the time of sediment deposition generates the orienting torque that produces DRM or pDRM.

Magnetite (Fe<sub>3</sub>O<sub>4</sub>), with low or insignificant Ti (titanium) substitution, is commonly associated with biogenic sources. Magnetotactic bacteria are ubiquitous in freshwater and marine environments (e.g., Kirschvink and Chang, 1984; Petersen et al., 1986; Vali et al., 1987). They inhabit aerobic and anaerobic sediments and form intracellular chains of fine-grained (single domain) "magnetosomes" of magnetite (Blakemore and Blakemore, 1990) or, less commonly, goethite (Mann et al., 1990; Heywood et al., 1990). Magnetite and goethite magnetosomes have been observed to coexist within the same bacterium (Bazylinski et al., 1995). The intracellular magnetite and goethite crystals are formed by a process referred to as biologically controlled mineralization (BCM) (Lowenstam and Weiner, 1989; Bazylinski and Frankel, 2003). Intracellular magnetite and goethite are usually structurally well ordered and have a narrow (single domain) size distribution that is optimal for the retention of magnetic remanence in ferrimagnetic minerals such as magnetite and goethite (Figure P23).

Other Fe(III)-reducing bacteria secrete magnetite, and a range of other iron minerals, outside the cell by a process referred to as biologically induced mineralization (BIM) (Lowenstam and Weiner, 1989; Frankel and Bazylinski, 2003). Magnetite and other iron minerals produced by BIM are often poorly crystalline, fine-grained, and not structurally ordered. In the case of *Geobacter metallireducens* (also referred to as bacterium strain GS-15), magnetite is produced outside the cell as fine (superparamagnetic) grains produced by the oxidation of organic matter and Fe(III) reduction (Lovley, 1990). Unlike magnetotactic bacteria, these iron reducers are nonmagnetotactic (nonmotile), unconcerned about the size, shape, or composition of the iron mineral product, and can produce a range of iron minerals depending on the nature of the surrounding medium.

Magnetotactic bacteria apparently utilize the internal magnetitegoethite chains to navigate along geomagnetic field lines (magnetotaxis) to find optimal redox conditions in the near-surface sediment. In the absence of sensitivity to gravity due to neutral buoyancy in seawater, the ambient magnetic field provides up-down orientation, either in the Northern or Southern hemisphere (Kirschvink, 1980). The single-domain grain size typical for magnetite and goethite produced by BCM indicates that magnetic remanence is central to magnetosome function. Living magnetotactic bacteria tend to be concentrated at depths of few tens of centimeters below the sediment-water interface at the transition from iron-oxidizing to iron-reducing conditions (Karlin *et al.*, 1987). The conditions under which BIM and BCM of magnetite takes place, and the depth in the sediment column to which these microbes are active (see Liu *et al.*, 1997), are clearly of great importance in understanding the origin of the magnetic signature in sediments. Magnetic methods for the recognition of magnetosome chains, and individual magnetosomes, have been proposed by Moskowitz *et al.* (1988, 1994).

Apart from bacteria, other biogenic marine sources of magnetite are chiton (mollusk) teeth, fish, whales, and turtles. The role of magnetite in fish and marine mammals is thought to be navigational (Kirschvink and Lowenstam, 1979; Kirschvink *et al.*, 2001; Walker *et al.*, 2003). As for bacterial magnetite, these biogenic magnetite grains are often in the SD grain size range, the optimal grain size range for a stable magnetic remanence and are usually pure magnetite. The grains acquire a so-called chemical remanent magnetization (CRM) as they grow through their "critical" volume within the host organism.

Biogenic magnetite has been commonly observed in marine sediments on the basis of particle shape and size (e.g., Kirschvink and Chang, 1984; Petersen et al., 1986; Vali et al., 1987). The small elongate (SD) grain size of biogenic magnetite, typically  ${\sim}0.2$   $\pm$ 0.05 µm across (Figure P23), and the resulting high surface area to volume ratio makes these grains susceptible to diagenetic dissolution. A large proportion of the biogenic magnetite in surface sediment may not survive sediment burial. Detrital magnetite (often titanomagnetite) appears to have greater survivability perhaps due to larger initial grain size and/or less intimate contact with pore waters. Stable primary NRMs in deep-sea sediments are commonly associated with PSD, rather than SD or MD, magnetite. Larger multidomain (MD) magnetite, with dimensions in excess of a few microns, carry a lower coercivity magnetization (than PSD or SD grains) that is more prone to remagnetization during the history of the sediment or sedimentary rock.

**Figure P23** (a) Size and axial ratio (breadth/length) of fossil magnetite magnetosomes observed in Mesozoic and Tertiary sediments (open circles) and Quaternary sediments (closed circles). (b) Size and axial ratio (breadth/length) of magnetite magnetosomes from living bacteria (modified after Vali *et al.*, 1987). Boxed regions in (b) from observations of Kirschvink (1983). Size distribution of multidomain (MD), single-domain (SD) and superparamagnetic (SP) magnetite grains after Butler and Banerjee (1975).

## Origin of secondary magnetizations

## **Reduction diagenesis**

CRM acquired during sediment diagenesis is the principal process that generates secondary magnetizations in marine sediments. The other important secondary magnetization is viscous remanent magnetization (VRM), the time-dependent acquisition of magnetization by the ambient (usually Brunhes Chron) geomagnetic field. A CRM postdates sediment deposition (usually by an unknown amount of time) and must be differentiated from the primary magnetization if sedimentary magnetic data are to be correctly interpreted. The primary and secondary magnetizations are differentiated in the laboratory by stepwise, progressive, demagnetization using either temperature or alternating fields. The differentiation can be successful if the two magnetization components respond differently to the demagnetization process (see Dunlop and Ozdemir, 1997).

A wide range of reactions, many of which are mediated by microbes, occur during deep-sea sediment diagenesis. Studies of pelagic pore waters indicate a sequence of electron acceptors used in the oxidation of sedimentary organic matter: O2, nitrate NO3, manganese  $(Mn^{3+})$ , iron (Fe<sup>3+</sup>) then sulfate SO<sub>4</sub><sup>2-</sup> (see Burdige, 1993). The utilization of sulfate has been found to be particularly important in the dissolution of magnetite grains in pelagic sediments. Microbial reduction of pore water sulfate (usually derived from seawater) yields sulfide ions that combine with the most reactive iron phase often magnetite to produce iron sulfide (Canfield and Berner, 1987). In most marine sedimentary environments, authigenic iron sulfides are dispersed throughout the sediment or associated with organic-rich burrows. In visual core descriptions of deep-sea sediments recovered during the 20-year duration of the Ocean Drilling Program, "pyrite" and amorphous iron sulfides are widespread and these iron sulfides probably originated through microbial sulfate reduction. The initial products are iron monosulfides (FeS), such as mackinawite, and further diagenesis may produce greigite (Fe<sub>3</sub>S<sub>4</sub>), pyrite (FeS<sub>2</sub>) and pyrrhotite (FeS<sub>1+x</sub> where x = 0-0.14). Pyrite is paramagnetic and therefore does not carry magnetic remanence. Pyrrhotite (e.g., Fe7S8) and greigite, on the other hand, are ferrimagnetic and capable of carrying a stable magnetization.

A secondary magnetization (CRM) carried by authigenic pyrrhotite often develops at the expense of a primary magnetization carried by magnetite. The dissolution of magnetite will be accentuated where sufficient pore water sulfate and labile organic matter support microbial sulfate-reducing communities. In organic rich, reducing, diagenetic conditions, such as the Japan Sea, pyrite and pyrrhotite are readily formed (Kobayashi and Nomura, 1972), at the expense of magnetite and other forms of reactive iron. Iron sulfide formation in marine sediments is limited either by the availability of pore-water sulfate (usually derived from sea-water) or the availability of organic carbon to sustain sulfate-reducing bacteria (Canfield and Berner, 1987). On the Ontong-Java Plateau, increased Corg in glacial isotopic stages has led to enhanced magnetite dissolution (Tarduno, 1994). In Taiwan, Pleistocene sediments contain detrital magnetite, authigenic greigite and pyrrhotite (Horng et al., 1998). Authigenic gregite has been detected in lake sediments (Giovanoli, 1979; Snowball and Thompson, 1988; Roberts et al., 1996) and in marine environments (Tric et al., 1991; Reynolds et al., 1994; Lee and Jin, 1995; Roberts and Weaver, 2005).

The dissolution of magnetite within the upper few decimeters of hemipelagic sediments has been documented by a reduction in coercivity and magnetization intensity as finer grains undergo preferential dissolution (Karlin and Levi, 1983; Leslie *et al.*, 1990). In pelagic, high sedimentation rate, "drift" sediments from the Sub-Antarctic South Atlantic (see Figure P24a) and Iceland Basin (see Figure P24b), the pore water profiles indicate steady sulfate depletion with depth. At both sites, a primary magnetization records the polarity stratigraphy (Channell and Lehman, 1999; Channell, 1999; Channell and Stoner, 2002; Stoner *et al.*, 2003) although there is abundant visual evidence that authigenic iron sulfide formation accompanies pore-water sulfate depletion.

In the case of the Sub-Antarctic South Atlantic site (Figure P24a), NRM intensity decreases with depth, together with reduction in the ratio of anhysteretic susceptibility ( $k_{arm}$ ) to susceptibility (k). This ratio ( $k_{arm}/k$ ) is a magnetite grain-size proxy where higher values indicate finer grains. In the Iceland Basin record, the depletion of sulfate is not accompanied by marked changes in these magnetic parameters (Figure P24b). This may be due to the presence of a more reactive iron phase than magnetite at the Iceland Basin site and /or to the presence of a particularly reactive *magnetite* phase (e.g., fine-grained biogenic magnetite) at the Sub-Antarctic South Atlantic site.

Two additional profiles from the sub-Antarctic South Atlantic indicate a marked decrease in NRM intensity and  $k_{arm}/k$  at 150–200 cm depth (see Figures P25 and P26). This denotes a marked *increase* in grain size of magnetite at this depth relative to surface sediment (Figure P25) due to preferential dissolution of fine-grained magnetite due to the higher surface area to volume ratio. This dissolved fine-grained magnetite fraction carries NRM but is not an important contributor to volume susceptibility (Figure P25). Its fine grain size  $(k_{arm}/k \text{ values } >6 \text{ are consistent with magnetite grain sizes of less than} 0.1 \ \mu\text{m})$  imply that the magnetite may be partly biogenic in origin. We conclude that the fine-grained (biogenic) magnetite is often lost during early diagenesis due to its small grain size and hence high reactivity. Note that  $k_{arm}/k$  values  $>\sim3$  are absent in the Iceland Basin record (Figure P24b) implying that biogenic magnetite is a less important component of the total magnetite budget at this site.

At some deep-sea sites, the concentration of sulfate in pore waters remains high to the base of the recovered section indicating (in the absence of a sulfate source at depth) that sulfate reduction is not a continuing process, even in the presence of a few percent organic carbon. This has been observed in siliceous sediments from the South Atlantic (ODP Leg 177), NW Pacific (ODP Leg 145), equatorial Pacific (ODP Leg 138) where magnetostratigraphic records indicate preservation of a primary magnetization (Channell and Stoner, 2002; Weeks *et al.*, 1995; Schneider, 1995). We speculate that the organic carbon associated with diatomaceous (siliceous) oozes may be too refractory, or otherwise unavailable due to adsorption or encapsulation in/on siliceous surfaces, to be utilized by sulfate reducing microbes. Under these conditions of arrested sulfate reduction, a primary magnetization carried by magnetite will often be preserved.

Dissolution of magnetite by combination with sulfide ions, released by microbial reduction of pore water sulfate, is the most important process that accounts for the degradation of the magnetic signal in deepsea sediments. In the presence of an iron phase that is more reactive than magnetite (e.g., goethite), the formation of iron sulfides may occur without appreciable magnetite dissolution.

# Oxidation diagenesis

In contrast to the role of reduction diagenesis on magnetite dissolution, the primary magnetic signal in deep-sea sediments can be destroyed by oxidation of magnetite to maghemite. Kent and Lowrie (1974) and Johnson et al. (1975) documented this process in the so-called red clay facies that occurs over a large part of the mid-latitude Pacific (Davies and Gorsline, 1976). Henshaw and Merrill (1980) showed that the magnetic signal in these sediments is also affected by the authigenic growth of ferromanganese oxides and oxyhydroxides. The red clays are devoid of calcareous and siliceous microfossils and accumulated below the CCD (calcium compensation depth) at rates of ~25 cm/Ma, more than an order of magnitude slower than "average" pelagic sedimentation rates. The primary magnetization in the red clay facies is lost at depths of a few meters below the sediment-water interface, and the loss of magnetization often coincides with the later part of the Gauss Chron, close to the time of onset of Northern Hemisphere glaciation. The reduced grain size of eolian detrital magnetite, due to lower prevailing wind velocities prior to the onset of Northern Hemisphere glaciation, may influence the degradation of the magnetic signal in these sediments (Yamazaki and Katsura, 1990).

**Figure P24** Volume susceptibility, NRM intensity after demagnetization at peak fields of 25 mT, anhysteretic susceptibility divided by susceptibility ( $k_{arm}/k$ ), and pore water sulfate concentrations: (a) ODP Site 1089 (sub-Antarctic South Atlantic at 40.9°S, 9.9°E, 4620 m water depth) and (b) ODP Site 984 (Iceland Basin at 61.4°N, 24.1°W, 1648 m water depth). Data from Stoner *et al.* (2003), Channell (1999), and Shipboard Scientific Party (1996, 1999). At both sites, the 90 m composite depths (mcd) shown here represent ~600 ka, at mean sedimentation rates of 15 cm/ka.

Other origins of secondary magnetizations

Florindo *et al.* (2003) attribute low susceptibilities at some deep-sea drilling sites to dissolution of magnetite to form smectite in the presence of high concentrations of dissolved silica. Although authigenic smectite is widespread in deep-sea sediments, there are a number of different pathways for its formation and magnetite is one of a number of different possible precursors.

Degradation of the primary magnetic signal in deep-sea sediment cores can be attributed to factors associated with drilling and recovery. For example, magnetite in calcareous oozes from ODP Leg 154 (Ceara Rise, equatorial Atlantic) carry a secondary magnetization imposed by drilling that is apparently oriented radially in the core cross-section (Curry *et al.*, 1997). No primary magnetization was resolved in these sediments. Magnetite grains are, however, not apparently greatly affected by sulfate reduction as pore water sulfate remains high (>20 mM) to ~200 m depth and magnetic susceptibility does not decrease with depth (Curry *et al.*, 1997; Richter *et al.*, 1997). Low activity of sulfate reducing microbes may be due to low levels of (labile) organic matter in these sediments. The magnetic susceptibility record is not affected by diagenetic dissolution or authigenesis of

**Figure P25** Volume susceptibility, NRM intensity after demagnetization at peak fields of 25 mT, anhysteretic susceptibility divided by susceptibility ( $k_{arm}/k$ ) for two piston cores (4-PC03 and 5-PC01) collected during cruise TTN-057 in the sub-Antarctic South Atlantic at 40.9°S, 9.9°E and 41.0°S, 9.6°E, respectively, and 4620 m water depth. The 500 cm record shown here represents ~25 ka at a mean sedimentation rate of 20 cm/ka. Data from Channell *et al.* (2000).

**Figure P26** Anhysteretic susceptibility ( $k_{arm}$ ) plotted against susceptibility (k) for Cores 4-PC03 and 5-PC01, from the sub-Antarctic South Atlantic. The measurements represent the last ~25 ka. Open symbols indicate Holocene samples. Data from Channell *et al.* (2000). The lines corresponding to magnetite grain size estimates of 0.1 µm and 5 µm after King *et al.* (1983).

magnetic minerals, and the cycles in susceptibility, produced by variations in surface water productivity, have provided a robust astrochronology (Shackleton *et al.*, 1999). The fidelity of the cyclostratigraphy supports other rock magnetic data (Richter *et al.*, 1997), indicating that magnetite has remained unaltered in ODP Leg 154 sediments. The magnetite grains are at least partially in the pseudo-single domain (PSD) size range (Richter *et al.*, 1997) and therefore capable of carrying stable primary magnetization. The observed radial (re)magnetization is attributed to an isothermal remanence (IRM) imposed by the coring procedure (Curry *et al.*, 1997).

In pelagic and volcaniclastic sediments of ODP Leg 157, from close to the Canary Islands, PSD magnetite appears to carry an inward-directed radial magnetization (Herr *et al.*, 1998; Fuller *et al.*, 1998). The coercivity of this radial remagnetization is greater than the more commonly observed downward-directed remagnetization associated with drilling, that can often be eliminated in peak alternating fields of  $\sim 20$  mT. The coercivity of the radial remagnetization is greater than that of a simple IRM acquired in the few tens of mT fields associated with the steel core barrels and the remagnetization is more pronounced in poorly lithified sediments (Fuller *et al.*, 1998). We speculate that the nonmagnetic matrix in these sediments, when disturbed or shocked by drilling, allows physical re-orientation of magnetite grains in ambient magnetic fields emanating from the core barrels, bottom hole assembly or cutting shoe.

At any time during the history of the sediment or sedimentary rock, secondary magnetizations may be acquired (as CRMs) by chemical alteration of existing magnetic minerals, or by growth of new magnetic minerals. Apart from the diagenetic changes noted above, events such as uplift, weathering, and deformation can all trigger the development of secondary CRMs. For example, much of the Paleozoic sequence of North America and Europe was remagnetizated coeval with the Hercynian (Late Carboniferous) orogenic pulse. This "orogenic" remagnetization is very widespread in North America, extending thousands of kilometers into the continental interior from the Appalachian margin. In carbonate rocks in North America and Europe, the Hercynian remagnetization is a CRM carried by magnetite. Authigenesis of magnetite may be triggered by orogenic activity in the Appalachians and the migration of hydrocarbon rich fluids into the hinterland (McCabe *et al.*, 1983, 1989; McCabe and Channell, 1994). Weathering and

uplift can result in the growth of magnetic iron oxides and oxyhydroxides (such as hematite and goethite) from preexisting Fe-bearing minerals such as clays or iron sulfides. The high coercivity of CRMs carried by hematite and goethite makes them difficult to remove by alternating field demagnetization techniques.

#### Conclusions

On the basis of a survey of the global distribution of high-quality magnetic stratigraphies in deep-sea sediments, Clement et al. (1996) concluded that terrigeneous sediment input is a factor that contributes to data quality. Sediments from the North Atlantic and the North Pacific, and the Indian Ocean, often contain terrigeneous material that appears to have aided preservation of a primary magnetization in these sediments and hence enhanced the magnetostratigraphic records from these regions. Although biogenic magnetite is ubiquitous in modern deep-sea sediments, fine SD particles are particularly susceptible to dissolution due to their high surface area to volume ratio. Much of this biogenic magnetite fraction does not appear to survive early diagenesis. The detrital magnetite component is more likely to survive, and record the direction and intensity of the geomagnetic field at the time of deposition. Diagenetic dissolution of magnetite in deep-sea sediments often occurs by reaction with sulfide ions to form iron sulfides. The formation of sulfide ions is generally a result of microbially mediated reduction of seawater sulfate in pore waters. The resulting sulfide ions in pore water react with magnetite or, if present, a more reactive iron phase, to produce iron sulfides that may carry a secondary CRM. The process is limited by the availability of sulfate and labile organic matter required by sulfate-reducing bacteria. Even in the presence of abundant pore water sulfate, high-quality magnetic records (preservation of primary magnetization) in siliceous sediments may be due to the low activity of sulfate-reducing microbes due to the role of tests of siliceous organisms in shielding labtile organic matter from sulfate-reducing microbes.

# PALEOMAGNETISM, EXTRATERRESTRIAL

With the advent of the space age, a rich paleomagnetic record has been discovered in the inner solar system. The various bodies of the solar system differ in their interactions with the solar wind, depending upon their size, the presence or absence of active dynamos, remanent magnetic fields, and atmospheres. Observations of these interactions have shown that like Earth, Mercury appears to have an active dynamo, whereas Venus, the Moon, Mars, and those asteroids studied do not.

In a planet with an active dynamo, magnetic fields arise from magnetic material because of the induced magnetism in the ambient field and their earlier acquired remanent magnetism. Magnetic fields observed on the Moon and Mars in the absence of an active dynamo must be due to remanent magnetism only. These fields due to remanent magnetization, or paleomagnetic fields, have been investigated on the Moon and Mars with satellite-based surveys. In addition, samples brought to Earth by the Apollo missions from the Moon and those that have come to Earth from the Moon, Mars, and asteroids in the form of meteorites provide additional paleomagnetic data. Other meteorites include primitive material from the early solar system and even presolar grains.

This extraterrestrial paleomagnetic record may offer a fascinating glimpse of the magnetic fields in the early solar system, providing we are clever enough to interpret it correctly.

## Lunar paleomagnetism

Observations from spacecraft prior to Apollo established limits on any lunar dipole moment should be at least five orders smaller than the geomagnetic dipole, but to the surprise of many, the Apollo-returned basalts and breccias carried stable natural remanent magnetization (NRM). With the advent of surface magnetometers on Apollo 12, 14, 15 and 16, subsatellites in low orbits on Apollo 15 and 16, and the more recent Lunar Prospector, it also became clear that the substantial volumes of the lunar crust are magnetized.

## Apollo samples

The Apollo samples were collected from the lunar regolith and consisted of igneous rocks, breccias, and soil. Their rock magnetism is very different from that of terrestrial samples. The dominant magnetic phases in the lunar samples are metallic iron and iron-nickel as shown in Figure P27 (Strangway *et al.*, 1970; Nagata *et al.*, 1972). The Fe-Ni is in the form of the Ni poor alpha phase kamacite. Kamacite has an irreversible thermomagnetic curve with a Curie point between 740°C– 770°C, whereas taenite has a range of Curie points dependent upon Ni content. On heating, kamacite converts to taenite with a sluggish return transition on cooling, whose temperature is dependent upon Ni content. This inversion is responsible for the irreversible thermomagnetic curve illustrated in Figure P27b. The mare basalts recovered from the regolith had iron as the dominant remanence carrying phase, whereas the breccias contained the Fe-Ni. In some breccias

**Figure P27** Magnetic phases in lunar rocks: (a) Apollo 14 mare basalt showing reversible thermomagnetic curve demonstrating presence of metallic iron and (b) Apollo 15 breccia, illustrating the effect of kamacite-taenite transition (Nagata *et al.*, 1972).

with extreme coercivity the mineral "tetrataenite" may be present (Wasilewski, 1988).

The rock magnetism of the soils presented an immediate problem because they contained more ferromagnetic iron than the basalts from which they were principally derived. This iron is predominantly superparamagnetic as demonstrated by Nagata (1972). Three possible explanations of the origin of the excess iron were suggested: (1) by reduction of paramagnetic iron-rich silicates in the presence of solar wind hydrogen in the uppermost surface layer of the soil (Houseley *et al.*, 1973), (2) by reduction in the thermal blankets of ejecta material (Pearce *et al.*, 1972), and (3) by shock decomposition of iron rich silicates (Cisowski *et al.*, 1973). To some extent these processes overlap and all may contribute to the excess metallic iron, but the first mechanism appears to be dominant and may have relevance elsewhere in the

**Figure P28** AF demagnetization of natural remanent magnetization (NRM) and saturation isothermal remanent magnetization (IRMs) of an Apollo 11 mare basalt. Note the directional similarity of the two samples after demagnetization to 100 Oe (10 mT).

solar system, for example on asteroids. The paramagnetic and ferromagnetic iron content of soils forms a useful classification scheme for soils and serves an indicative of provenance (Wasilewski and Fuller, 1975). The magnetic properties of the breccias vary according to their subgroups. The regolith breccias are similar to the soil from which they are derived by varying degrees of shock metamorphism. The fragmental breccias contain clasts in a porous matrix. The melt breccias, which consist of clasts in an igneous textured matrix, have properties similar to the igneous rocks.

The lunar paleomagnetic record comes primarily from the mare basalts and the melt breccias (see Figure P28). The plutonic rocks that are largely unsuitable for paleomagnetism are in the form of clasts in breccias. The paleomagnetism of the breccias is frequently hard to interpret, but in the melt breccias thermoremanent magnetization (TRM) appears to dominate, so that their mode of magnetization is similar to that of the mare basalts. The samples had experienced some degree of shock, exposure to radiation, and thermal cycling on the lunar surface.

The role of shock as a possible source of magnetization in the presence of a magnetic field, or demagnetization in the absence of such a field, was investigated in a number of experimental studies (Cisowski *et al.*, 1973, 1976). Flying plate experiments in which soil samples were encapsulated in the plate demonstrated that shock levels of a few GPa (tens of kilobars) in fields of tens of microteslas were sufficient to induce magnetization in lunar soil comparable in intensity with that found in the regolith breccias samples. In the absence of the magnetic field, shock was shown to harden thermoremanent magnetization by preferentially demagnetizing the softer magnetic phases. A flying plate impact at a velocity of 17 km/s into a block of terrestrial basalt in an ambient field of 1 mT field demonstrated shock

**Figure P29** Model of field compression by impact in flying plate experiment. The plate was traveling at 17 km/s and impacted a block of basalt. The ambient field was 10 Oe (1 mT). The block was magnetized by the event and pick up coils demonstrated the formation of a plasma and field compression consistent with the model shown.

magnetization and the generation of a plasma that displaced and compressed the ambient field (Figure P29, Srnka *et al.*, 1986). Effects of radiation and thermal cycling were also investigated and are unlikely to be important factors in the origin of lunar magnetism.

Later it became clear that at least some stable primary magnetization was preserved from the initial cooling of samples on the moon as igneous rocks. In the absence of any knowledge of the orientation,-in which the samples acquired their magnetization-the interest focused in on the intensity of magnetization they carry and the possibility of finding the history of the intensity of ancient lunar magnetic fields. Despite some success, classical methods of determining intensity involving heating the sample to give a TRM in a known field in the laboratory, were confounded by irreversible changes brought about by heating the samples. Various other methods including using ARM as a proxy for TRM (Shaw Stephenson and Collinson, 1974), heating by microwave radiation (Hale et al., 1978) and IRM normalization (Cisowski and Fuller, 1986) were utilized. The IRM normalization method is admittedly a poor substitute for classical intensity determination methods, but because of the availability of data from a large number of samples it had a value as a rough indicator. Such a distinctive result followed that even the poor accuracy likely for IRM normalization was useful. From all of the intensity work it emerged that there was a high field with a surface intensity comparable to the Earth's surface field between 3.85 and 3.65 Ga (Figure P30). Two discussions of the subsequent history were that the field intensities gradually decreased over a period of about 1 Ga (Collinson, 1984; Runcorn, 1994). In contrast, Cisowski and Fuller (1986) suggested that there was a relatively brief period of high intensity from about 3.85 to 3.65 Ga and that outside of this period intensities could not be distinguished from background noise. Additional work is needed to clarify this point.

**Figure P30** Paleointensity estimates from Apollo mare basalts by the IRMs normalization method. Calibration of the method by thermoremanent magnetism (TRM) experiments suggest that values of NRM(200)/IRMs(200) are equivalent to field intensities of 0.5 Oe. Note that only some of the Apollo 11 and 17 basalts with ages between approximately 3.85 and 3.65 Ga show values of NRM(200)/IRMs(200) greater than 0.5 suggesting that only in this age range were fields comparable to or greater than the geomagnetic surface field at present.

# Magnetization of the lunar crust observed with surface and subsatellite magnetometers and electron reflectance experiment

The Apollo surface magnetometers (e.g., Dyall, 1972) revealed fields from a few tens of gammas (nT) at the Mare sites to 100 nT at the Fra Mauro Apollo 14 site and hundreds of nanoteslas at the Apollo 16 highland site. The stronger magnetizations could be explained by the strong magnetization of basin ejecta of the Fra Mauro and Cayley formations (Strangway et al., 1973). The scale length of coherence appeared to be relatively short -from 100 m to km. The results from the subsatellite magnetometers (Coleman et al., 1972; Russell et al., 1975) and the electron reflectance experiments (Lin et al., 1988) confirmed the results from the surface magnetometers in finding stronger fields over the highlands than over the Mare. They also showed stronger fields over the older eastern Mare than the younger western Mare. The high resolution of the electron reflectance experiment demonstrated that cratered regions were not systematically more strongly, or weakly, magnetized than surrounding regions (Lin, 1979). It is also confirmed from the observation of the subsatellite magnetometer surveys that the strongest magnetic anomalies were antipodal to the younger large impact basins. This suggested that a lunar field was required at the time of the younger giant impacts to account for the field compression and magnetization at the antipodes proposed by (Hood and Huang, 1991) as well as to account for the strong magnetization of mare basalts of this age. The sites of the strongest anomalies include regions of swirls similar to the Reiner gamma feature. These features are probably caused by the strong fields of the magnetic anomalies that stand off the radiation that otherwise darkens the albedo of the lunar surface.

The magnetometer/electron reflectometer experiment on Lunar Prospector has greatly improved the resolution and coverage of the magnetic mapping of the Moon, so that the entire surface is now mapped. The results were not only confirmed but also extended the earlier results that showed that the fields over the highlands were strong compared with those over the Mare despite the fact that the dominant occurrence of iron is of course in the Mare (Lucey et al., 1995). The electron reflectance results (Mitchell et al., 2004) also confirmed the ubiquitous presence of small-scale anomalies with dimensions of order tens of kilometers. This is consistent with the small scale of surface anomalies observed with the Apollo surface magnetometers. The absence of fringing anomalies around craters of up to 50 km in diameter (Halekas et al., 2003) indicates that there cannot be coherent magnetization in the upper tens of kilometers of the crust. Moreover, since the Curie point of iron is soon reached in deeper regions, it appears that the crust does not contain large volumes of uniform magnetization. Thus the elegant theorem of Runcorn (1975), which proved that the field recorded in a spherical shell from cooling in the field of an internal dipole source is not be detectable from the outside, may not be relevant to the interpretation of lunar crustal magnetism. Following the assumption of shallow sources, Mitchell et al. (2003) developed a simple model for the magnetism of the lunar crust. They reconstructed the field by sequentially applying the magnetizing and demagnetizing effects of the known basin forming events to give the field illustrated in Figure P31. They found that the model was much improved by adding 1 nT background field. It therefore appears that the magnetization of the lunar crust is basically due to the effects of large basin forming events and that a relatively stronger field is required at the age of the proposed strong field era to explain the anomalies over the antipodes of the young basins.

## Origin of lunar magnetism

After attempts to explain the magnetization of the Moon and of returned samples by exotic models had been investigated and found wanting, Runcorn's initial suggestion of a lunar dynamo (e.g., Runcorn, 1975) was generally accepted. The history of this dynamo was less clear and two rival ideas emerged corresponding to the two views of the field intensity records. One invoked a lunar dynamo that operated from about 3.9 Ga, giving a surface field comparable to the Earth's surface field and gradually lost intensity over about a billion years (Collinson, 1984; Runcorn 1994). In contrast, Cisowski and Fuller (1986) argued for a relatively brief period of high intensity between about 3.9 and 3.6 Ga with intensity outside of this interval indistinguishable from background noise. But still, it is not clear which of these suggestions were correct. With either model, the strongly magnetized mare and highland samples would have acquired their NRM as they get cooled in the dynamo field and the strongest anomalies antipodal to the younger giant basins could have acquired their magnetization in an enhanced antipodal field by shock magnetization as suggested by Hood et al. (1991). Recently, a short period of dynamo action has been proposed to be associated with a major overturn of the lunar mantle that made the core cool rapidly. This could have generated a magnetic field between 3.85 and 3.65 Ga, during a brief period of convection (Stegman et al., 2003).

In conclusion, it should be remembered that the lunar dipole moment required to give a particular surface field on the Moon is smaller than the geomagnetic dipole moment required to give a comparable surface field on Earth because the radius of the Moon is smaller than the Earth's. Moreover, since we do not know how dynamo fields scale with the size of the region in which they are generated, we should not assume that the ratio of lunar to terrestrial dipole moments varies as the volume (Stevenson, 2002), or as the cube of the radii of the cores. Only in this case, does the cube of the core dimension cancel with the inverse cube of the dipole field fall off, so that the decrease in moment of the core is canceled by the decrease in the distance to source. In contrast, if the lunar dynamo had given the same moment as the geodynamo, which is admittedly unlikely given the small size of the lunar core, the lunar surface field would be two orders stronger than the surface field on the Earth. Admittedly, this is a rough and ready argument, but dynamo action in the lunar core with a dipole moment weaker than that of the geodynamo could still have generated surface fields similar to those interpreted from the paleomagnetic studies.

## Martian paleomagnetism

Studies of Martian magnetism consist of direct observations of the magnetism of the soil by Viking, the magnetic surveys of the crustal field carried out by Mars Surveyor, and the paleomagnetic record of the Shergotite, Nahklite, and Chassignite (SNC) meteorites.

# Viking and Pathfinder: soil and dust magnetic experiments

The Viking Magnetic Properties Experiment (Hargraves *et al.*, 1977, 1979) provided an estimate of the amount of magnetic material in the martian soil at a few percent. Moreover, the magnet experiments demonstrated that some 80% of the magnetic material was strongly magnetic suggesting that it was magnetite, titanomagnetite, or their more oxidized equivalents maghemite and titanomaghemite. Their preferred interpretation was that the mineral was maghemite and that its occurrence was in the form of a pigment dispersed throughout the soil.

Pollack *et al.* (1977) analyzed the airborne dust from the Martian images and found that the best match they achieved to their derived imaginary refractive indices was for fine-grained magnetite. Additional analysis of the airborne dust particles including Pathfinder data indicated that fine magnetite rather than titanomagnetite was required to explain the high-saturation magnetization.

The Mars Pathfinder lander carried similar magnetic experiments to those on Viking with the important addition of a multispectral imager (Hargaves *et al.*, 2000). Despite difficulties, the results of these analyses confirmed the earlier suggestion that there is a strongly magnetic phase present either as coatings, or nanoparticles. The phase is either magnetite or maghemite. Again, maghemite was the preferred choice.

Figure P31 Model for lunar crustal magnetization; the top panel for mid-latitudes shows the magnetic anomaly data and the bottom panel shows the model reconstruction (With permission, Halekas, 2003).

On the missions presently at Mars, there are Mössbauer experiments that should identify the phases present. Such identification of the magnetic phases in the soil will be important in distinguishing an origin by direct weathering from surface basalts, or something more exotic. In the former case, titanium would be expected to be present, whereas pure magnetite, or maghemite, would suggest the latter.

Viking had also measured the composition of the martian atmosphere, which turned out to be a key piece of information demonstrating that the meteorites Shergottites, Nahklites, and Chassignites (SNC) did indeed come from Mars. The main discussion of them will therefore be given in this martian section.

# Shergottites, Nahklites, and Chassignites (SNC) meteorites: the Martian meteorites

As noted above, the primary evidence for the martian origin of the SNC meteorites is that they contain noble gases that match the present martian atmosphere. In particular, it was found that the trapped noble gases in impact glass melt in EETA79001 were a perfect match for those measured by the Viking lander. Moreover, the ages of all except ALH84001 are young enough (200–1300 Ma) that given their volcanic nature they must have come from an evolved body with recent

volcanic activity. Histories have been established for the various meteorites with estimates of the age of their initial formation on Mars, the age of the event that blasted them from the martian surface, their time in transit, and finally the age of arrival on Earth.

The rock magnetism of the SNC meteorites is much more like that of terrestrial samples than is that of the lunar samples, or indeed of other meteorites. The dominant carriers of the paleomagnetic record in these martian samples are magnetite and low Ti titanomagnetites and pyrrhotite. The paleomagnetism of the SNC meteorites has yielded a possible record of the surface magnetic field of Mars. Estimates of the order of 1  $\mu$ T have come from microwave intensity determinations with Nakhla (Shaw *et al.*, 2001).

ALH84001 has played such a special role because of the claims of the presence of life forms in it (McKay *et al.*, 1997) that a separate discussion is given here. ALH84001 is a cataclastic orthopyroxenite. It initially crystallized at 4.5 Ga, was involved in a major impact event at 4.0 Ga, was excavated from the Martian surface by another event at approximately 16 Ma, and eventually landed in Antarctica 13 ka ago. It contains secondary carbonate of controversial origin within which magnetite also of controversial origin is found. The carbonate has been dated at approximately 4.0 Ga. This magnetite played a critical role in the controversy over the evidence for life because it was interpreted to be biogenic having been formed in martian bacteria analogously to the magnetite formed in terrestrial bacteria (Thomas-Keprta, 2000, 2001). However, the demonstration of a topotactic relationship of both the magnetite in iron-rich carbonate and periclase in magnesium-rich carbonate strongly suggests that most of the magnetite was formed by breakdown of the iron-rich carbonate during the impact event at 4.0 Ga (Barber and Scott, 2002). Whether there is other magnetite of biogenic origin remains to be seen, although Barber and Scott (2002) see no requirement for it.

The natural remanent magnetization (NRM) of ALH84001 is predominantly carried by the fine magnetite (Collinson, 1997; Cisowski, 1986). Collinson's initial study of mutually oriented samples of ALH84001 (Collinson 1997) indicated that individual subsamples had soft magnetizations whose directions were dissimilar, but that a harder magnetization, which demagnetized between 20 and 40 mT, was similar in different samples. His interpretation of the magnetization gave an estimate of the Martian field of one order smaller than the geomagnetic field.

Isolated NRM in two neighboring pyroxene grains of ALH84001 was reported by Kirschvink *et al.* (1997) to differ by some 70°. The magnetization was interpreted to have been acquired during cooling

after the 4.0 Ga impact event and now differed due to subsequent differential rotation of the grains during brittle deformation. Given this interpretation, Kirschvink *et al.* (1997) argued that the differing magnetizations in the neighboring grains leads to an upper temperature limit, since magnetization on Mars of 110C (the maximum temperature the sample was exposed to during sample preparation). Using exquisite technique with high-resolution SQUID magnetometers, Weiss *et al.* (2000) discovered that the magnetization was inhomogeneous on the scale of the individual carbonate blebs. They suggested that the magnetization was probably carried by pyrrhotite and magnetite in association with the carbonate. In this work, observations of partial thermal demagnetization of small regions of millimeter size with the high-resolution SQUIDs further reduced the constraints on heating, since the time that the magnetization was acquired on the Martian surface, to 40C (Figure P32).

Antretter *et al.* (2003) confirmed the observation by Collinson (1997) that despite soft magnetization, which differed from one subsample to another, at higher intermediate harder magnetization from different subsamples agreed in direction. Assuming that the magnetite was formed from the carbonate in the major impact event at 4.0 Ga, as petrological evidence suggests, the NRM will record this field.

**Figure P32** Results of partial thermal demagnetization of a region within ALH 84001 measured with high-resolution SQUID measurements. Note that the magnetization is changed upon heating to 40°C. Hence assuming that the NRM was acquired entirely on Mars, the material cannot have been heated subsequently above 40°C (With permission; Weiss *et al.*, 2000).

794

Normalizing the intensity of the NRM by the saturation isothermal remanence (IRMs) then gives an estimate for the 4.0 Ga martian field one order smaller than the present geomagnetic field. If the magnetization is heterogeneous due to magnetization at different times, or due to subsequent misalignment as suggested by Kirschvink *et al.* (1997), this may be a minimum field value.

## Crustal magnetic field of Mars

Just as the paleomagnetic record discovered by the Apollo missions was one of the bigger surprises of the lunar exploration, so the magnitude and distribution of the martian magnetic anomalies has proved a major surprise in martian exploration. The magnetic crustal field on Mars differs from the terrestrial crustal field in its intensity and distribution (Acuna *et al.*, 1999; Connerney *et al.*, 2001). On Earth, the magnetic features are distributed more or less uniformly over the planet. On Mars, the strong features are largely confined to a band that covers two-thirds of the southern highlands (Figure P33). They also reach an order of magnitude stronger than substantial terrestrial anomalies. An n = 90 spherical harmonic model (Cain *et al.*, 2003) gave an upper limit for the martian dipole six orders smaller than the geomagnetic dipole moment and close to the noise in the martian coefficients. However, between n = 20 and 40 the martian power spectrum is 40 times stronger than that of the Earth.

There have been discussions of the linear nature of the anomalies and the possibility that they record a seafloor-spreading-like mechanism on Mars (Acuna *et al.*, 1999) or terrane accretions (Fairen *et al.*, 2002). However, the evidence for seafloor-like anomalies has been questioned by Harrison (Harrison, 2000) and even the linear nature of the features has been disputed by Arkhani-Hamed (2001a). The possibility of reversals of the Martian dynamo is supported by calculations of paleomagnetic poles from isolated anomalies that turned out to be in similar locations, but of both polarities (Arkhani-Hamed, 2001b). More recent analyses have increased the resolution of the surveys and drawn attention to the presence of smaller anomalies in the northern plains and the possibility of the role of shock demagnetization associated with the major basin of Utopia (Halekas, 2003).

#### Discussion

The origin of the martian anomalies and the explanation of their distribution and strength remain unclear. However, it appears that there must have been a relatively strong surface magnetic field, at least comparable with that of the geomagnetic surface field, when the strong anomalies of the southern highlands were formed. The caveat discussed in reference to the lunar dynamo and the strength of the surface fields it may generate must also be remembered here. Hence, if the dipole moments generated by the martian and geodynamos are similar, say to order of magnitude, then the surface martian field would be stronger than terrestrial surface field simply due to the ratio of the radii of the planets. The strongest observed anomalies are about an order larger than those on Earth.

Numerous magnetic phases have been suggested to help in understanding the high remanent magnetization of the Martian crust: e.g., hematite (Dunlop and Kletetschka, 2001, Kletetschka *et al.*, 2000a, Özedmir and Dunlop, 2002), hematite-ilmenite solid solution (Kletetschka *et al.*, 2002, Robinson *et al.*, 2000), and low-temperature oxidation, or weathering to give maghemite, or hematite (Özdemir, 2000). Cooling experiments with iron-rich basalts were carried out and revealed the presence of titanium-rich cruciform titanomagnetites that were modeled as the source of the martian crustal anomalies (Hammer *et al.*, 2003). The role of pyrrhotite has been emphasized by Rochette *et al.* (2001). The most potent magnetic material that might give rise to these strongly magnetized rocks is generally recognized to be SD magnetite (e.g., Kletetschka *et al.*, 2000b).

Given the saturation magnetization of magnetite of  $4.9 \times 10^5$  A/m, the saturation remanent magnetization of a 0.5% dispersion of uniaxial, SD magnetite will be between  $1 \times 10^3$  A/m and  $2 \times 10^3$  A/m. Assuming a surface field intensity an order of magnitude greater than the geomagnetic field, the TRM, or indeed the chemical remanent magnetization

**Figure P33** Mars crustal magnetic anomalies from Connerney *et al.* (2001). Note that the strongest anomalies are in a band stretching some 60° of latitude, which is centered equatorially near 0° longitude and expands to cover most of the Southern Hemisphere near 180° longitude. Within the Southern Hemisphere, the anomalies are weak in Hellas and Argyre, and over the Tharsis region (With permission, Purucker).

(CRM), will give the  $\sim 10-20$  A/m required by the models for the Martian crustal fields. With a surface field comparable to the geomagnetic field, 0.5% of SD magnetite may be sufficient to give the required to depths of  $\sim 10$  km in parts of the Southern Hemisphere to meet the requirements of the models. The key point is that this magnetite must be in a SD state.

No matter what proves to be the explanation of the intensity of the martian anomalies, their distribution and in particular their confinement to a band largely in the Southern Hemisphere remains a puzzle (Figure P31). Moreover, there is strong evidence that beneath the younger surface material of the northern plains, there is cratered older material similar to that found in the Southern Highlands (Frey, 2003), so that the superficial difference in appearance of the two regions is not a sufficient explanation.

To explain the lack of strong anomalies in the north, hydrothermal activity has been invoked to demagnetize the features in the northern basin (Solomon *et al.*, 2002). Another possibility is that the strong magnetic anomalies are never formed in the Northern Hemisphere, but only in the Southern Highlands (Scott and Fuller, 2004). This idea is based on: (1) an early carbon dioxide rich atmosphere in which weak acids formed, dissolved iron from igneous rocks, depositing iron rich carbonates in the upper crust and (2) the fine magnetite that was then formed by decomposition of the siderite on subsequent heating due to intrusions. Given the observed correlation between water channels and magnetic anomalies in the Southern Highlands (Harrison and Grimm, 2000), this suggestion is consistent with the disposition of the anomalies. Only in these regions water was found to be present in the appropriate amounts to permit the necessarily intermittent dissolution and deposition processes to take place.

Another factor that has emerged with the newer analyses is the possible role of demagnetization caused by the impacts that formed the large basins in the Northern Hemisphere. In this view, it appears that just as in the absence of strong magnetization in the major basins on the Moon permits a simple model of magnetization of the lunar crust, so on Mars, the same absence of strong anomalies in Argyre, Hellas, and Utopia basin suggest a similar role of shock demagnetization on Mars. Indeed Hood et al. (2000) have argued that the size of the demagnetized region around Hellas corresponds to the region that would have experienced 2 GPa, the shock value required for pyrrhotite to pass through a transition into a nonmagnetic phase. If shock does play a dominant role of in determining not only the lack of anomalies associated with Argyre and Hellas, but also with even bigger features of Utopia in the Northern Hemisphere, then important aspects of the Martian crustal magnetic field may be modeled by similar demagnetizing effects to those utilized in the lunar model of Mitchell et al. (2003).

## Conclusion

The martian crustal anomalies, the magnetization of ALH840001, and other SNC meteorites suggest that a martian dynamo generated a global magnetic field early in martian history, but that it shut off sometime soon after 4.0 Ga. The strength of the surface anomalies may be partially explained by the smaller distance from the sources in the martian core to the surface, but their distribution on the martian surface requires an explanation. Clearly the role of shock demagnetization associated with large basin-forming events has played an important role in determining the observed distribution, but there appears to be a need for some additional explanation of the absence of anomalies in the Northern Hemisphere.

## Asteroid paleomagnetism

Prior to the 1990s our knowledge of the asteroids was from telescopic observations and interpretations of the sources of certain meteorites. With advent of the space era of exploration, observations by spacecraft with magnetometers onboard permitted estimates of the magnetic

fields and ultimately of the magnetization of a sampling of asteroids. Beginning with the flyby of 9969 Braille in 1991 by Deep Space 1 (DS1) (Richter *et al.*, 2001), there have been flybys of 951 Gaspra (Kivelson *et al.*, 1993) and 243 Ida by Galileo on its way to Jupiter, and of 433 Eros and of 253 Mathilde by the Near Earth Rendezvous Mission (NEAR) which subsequently landed on 433 Eros (Acuna *et al.*, 2001). With the exception of the observations on 433 Eros, estimates of the magnetic fields of the various asteroids rely on the interpretation of the interaction can reveal whether it is strongly and coherently magnetized, weakly and incoherently magnetized, or whether it is without remanent magnetization and simply has an induced magnetization dependent on the solar wind field. The results of such measurements constrain the origin and history of the asteroid and potentially have important bearing on the origin of the solar system.

The closest approach of DS1 of 28 km was achieved at 1.3 AU. Despite the strong magnetic noise from the ion propulsion unit of DS1, magnetic field measurements were made of 9969 Braille and yielded an estimate of its magnetic moment of  $2.1 \times 10^{11}$  A m<sup>2</sup> (Richter et al., 2001). The magnetometer on Galileo observed a disturbance of the solar wind field during the flyby of Gaspra consistent with the asteroid having a remanent magnetization (Figure P34). The intensity of magnetization was comparable with that of chondritic meteorites (Kivelson et al., 1993; Baumgartel et al., 1994). A similar effect was observed on the flyby of 243 Ida, although it was weaker. In contrast to these results, the magnetometer on the NEAR spacecraft on its approach to 433 Eros and after landing failed to detect a global magnetic field (Acuna et al., 2002). The upper limit on the field value was reported 0.005 A/m, giving a remanent magnetization of  $1.9 \times 10^{-6}$  A m<sup>2</sup>/kg. This is orders of magnitude smaller than those reported for 951 Gaspra and 9969 Braille and for meteorites likely to have come from this type of asteroid.

Taken at face value these results suggest that Gaspra and Ida have relatively strong coherent magnetization comparable in intensity to that seen in strongly magnetized chondrites (see below) to which they are most closely linked spectroscopically. This would be consistent with their S-type classification. Such a magnetization might have been acquired by initial cooling in a substantial magnetic field, or as a result of some subsequent event. On the other hand, the results from Eros, also an S-type, suggest cooling in the absence of a field, or random magnetization, such as might be acquired in a cold accretion process. The puzzling results from the asteroid magnetic field observations led to suggestions of random magnetization within 433 Eros (Wasilewski *et al.*, 2002) and to reconsideration of the possibility that the magnetization of chondritic meteorites might be randomly oriented. The latter will be discussed below.

#### Conclusion

The results from 9969 Braille, 951 Gaspra, and to a lesser extent 243 Ida suggest homogenous magnetization and hence magnetization recording the field of the planetesimal in which it was formed or some subsequent event in a field. In contrast, the results from 433 Eros suggest that its constituent magnetic phases either carried little intrinsic magnetization, or that they were not strongly heated in the accretion process.

## Meteorite paleomagnetism

#### Introduction

Meteorites provide a sampling of the oldest material in the solar system and even pre-solar grains. In addition they sample the moon, planets, and asteroids. Recently, the number of meteorites available for analysis has more than doubled because of the remarkable Antarctic meteorite collections obtained by recent Japanese and US expeditions, in which Prof. William Cassidy of the University of Pittsburgh played a key role. We thus have the possibility of studying the paleomagnetism,

Gaspra Encounter - IMF Rotated Coords, 4-sec Average Vectors

**Figure P34** Disturbance of solar wind field during Gaspra flyby and a model for its magnetosphere (With permission; Kivelson *et al.*, 1993).

as well as the petrology, chemical, and isotopic composition and age of this material, so fortuitously brought to Earth and preserved in a relatively pristine state. Meteorites are divided into chondrites, achondrites, stoney-irons, and irons. The irons are separated because they are metal rich. The chondrites and achondrites are separated according to the presence, or absence of chondrules, which are small spherules, 0.1-2 mm in size. The achondrites are differentiated, in contrast to the chondrites. McSween (1999) provides an excellent modern introduction to meteorites.

Chondrites are heterogeneous aggregates with radiogenic ages of 4.56 Ga, which is consistent with the presence in chondrites of products of short-lived radioactive isotopes such as <sup>26</sup>Al, and the similarity of their composition to that of the sun. Among the inclusions in chondrites are the refractory calcium aluminum inclusions (CAI). They formed between 1400 and 1100°C as condensates, or evaporative residues, or more complex mixtures of thermally processed material. As such, they are of great interest as a means of glimpsing early solar system magnetic fields, although the magnetic material in them formed somewhat later than the earliest condensates. The chondrule population in the chondrites, is the next most primitive material available to us, which probably formed a few million years after the CAIs, although their origin remains somewhat controversial. Unfortunately, the CAIs and chondrules have suffered either the varying degrees of aqueous alteration especially in the various carbonaceous chondrites, or the thermal metamorphism especially in the ordinary chondrites.

The achondrites in principle are simpler to understand than the chondrites because they are derived from the products of igneous differentiation similar to processes seen on the Earth. However, achondrites are also frequently brecciated, so that we find rarely anything like a pristine igneous rock. They crystallized at approximately 4.5 Ga.

The paleomagnetism of meteorites has been a major research area for more than half a century since the pioneering work of Stacey *et al.* (1961) and a comprehensive review appeared in the 1980s (Cisowski, 1987), as well as a very useful discussion in the *Rock Magnetism* text by Dunlop and Özdemir (1999). It is a rich field with the possibility of giving information about early solar system magnetic fields, and in addition key magnetic data for asteroids, the moon, and Mars. There are however major difficulties in the interpretation of the paleomagnetic record of meteorites that must be addressed before the data can be used with confidence (e.g., Wasilewski *et al.*, 2002). Magnetic studies have focused upon the chondrites, their inclusions, and achondrites. Yet, the complicated histories of these meteorites make the interpretation of their paleomagnetic record particularly tricky.

# Magnetic properties of different categories of meteorites

Irons contain dominantly Fe-Ni, in the form of the Ni poor alpha phase kamacite, and the Ni-rich gamma phase taenite. Irons have been classified according to their composition and the dimensions of the Widmanstatten pattern, which is related to their Ni content and cooling rate. Kamacite has an irreversible thermomagnetic curve with a Curie point of between 740 C and 770 C, whereas taenite has a range of Curie points dependent upon Ni content. As we noted in the discussion of the magnetic properties of the Apollo samples, on heating kamacite inverts to taenite with a sluggish return transition on cooling. This temperature is dependent upon Ni content. A plot of the fraction of the saturation magnetization due to the alpha Fe-Ni phase kamacite against the temperature of the gamma to alpha transition separates the various subgroups (Figure P35a) (Strangway *et al.*, 1970; Nagata *et al.*, 1972).

Because many chondrites contain metallic Fe-Ni, whereas achondrites do not, the subdividision into chondrites, or achondrites, has a natural magnetic expression. This is best seen if the fraction of the total saturation magnetization due to the alpha phase, or kamacite, is plotted against the total saturation magnetization of the meteorite (Figure P35b, P35c). Kamacite and taenite, alpha and gamma phases of NiFe dominate the magnetic properties of most meteorites. It is tetrataenite, the stable form of NiFe below 320°C that is seen for the most part in ordinary chondrites as was first pointed out by Wasilewski

**Figure P35** Magnetic classification of meteorites (a) the ratio of the saturation magnetization of the alpha phase to the total saturation magnetization plotted against the temperature of the gamma to alpha transition defines the various group of the irons H—hexahedrites, O—octahedrites, and A—ataxites. (b) the same ratio plotted against saturation magnetization defines the various groups of chondrites and (c) also separates the various groups of achondrites (Strangway *et al.*, 1970; Nagata *et al.*, 1972; Cisowski, 1987).

(e.g., 1988). Tetrataenite is remarkable for its extreme anisotropy and coercivity that can reach as much as 100 mT. The carbonaceous chondrites have multiple magnetic phases that are not yet completely understood.

Achondrites are the products of igneous differentiation and have in general much less metallic content than the chondrites. As Cisowski (1987) notes, they are somewhat analogous to lunar samples with eucrites and diogenites being similar to monomict lunar breccias. They too are conveniently divided in the same parameters as those used for the chondrites (Figure P35c).

The SNCs (Shergotites, Nahklites, and Chassignites) are a special group of meteorites from an evolved body with relatively recent volcanic activity that has been shown to be Mars. They contain magnetite, titanomagnetites, and pyrrhotite and have been discussed above in the section on Mars. A lunar origin has been demonstrated for certain meteorites. These have the characteristic mixes of metallic Fe and Fe-Ni found in lunar samples.

## Paleomagnetic record of meteorites

The prime interest in meteorite paleomagnetic studies is in the intensity of the fields in which the NRM was acquired and the possibility of gaining insight to early solar system magnetic fields, or in the martian and lunar meteorites to the history of the magnetic field of Mars and the Moon. Meteorites may be exposed to shock effects in their assembly or in their subsequent history, to radiation, and to temperature changes in space, and finally to heating as they come through the atmosphere. All these factors can have an effect on their paleomagnetic record, but they do not eliminate the possibility of some primary magnetization acquired at the time of their formation.

Iron meteorites can carry stable NRM, but the microstructure of the kamacite taenite intergrowths has been shown to control the direction of TRM, while the intensity of the TRM was not found to depend upon the field in which it was acquired (Brecher and Albright, 1977). For these reasons the paleomagnetic record of the irons has not been pursued strongly.

The paleomagnetic record of the chondrites and achondrites has been energetically investigated. Unfortunately, many of the meteorites collected in earlier times were contaminated by magnets used to recognize them as meteorites. Recently, and particularly with the Antarctic collections, care has been taken to maintain the meteorites in as pristine a condition as possible. In earlier work, plots of NRM versus IRMs were used to aid in the detection of contamination and in the interpretation of the origin of the NRM (Sugiura and Strangway, 1988). Wasilewski and Dickinson (2000) have recently suggested using the ratio of NRM:IRMs (or REM as they call it) as a preliminary indication of contamination, with values greater than 0.1 being indicative of exposure to a strong magnet.

The carbonaceous chondrites are some of the most intensely investigated of all meteorites with studies of individual CAIs, chondrules, and of bulk samples. The individual refractory inclusions and other chondrules are of particular interest because they may contain a record of solar system magnetic fields extant prior to the assembly of the meteorite. A necessary test for this is the demonstration that their magnetization was acquired before aggregation of the parent meteorites randomly oriented in the sample. This is an application of the classical conglomerate test of paleomagnetism, in which the clasts within a conglomerate are shown to be magnetized randomly within the conglomerate, whereas the matrix is coherently magnetized. Thus their magnetization may have been acquired prior to assembly into the conglomerate because they do not exhibit the coherent magnetization that might have been acquired during, or since the conglomerate was assembled. Unfortunately, this very direct test has been confounded by the random nature of the magnetization of the matrix and its virtual absence as a significant carrier of homogeneous NRM in some chondrites.

Paleomagnetic analyses of CAIs in Allende have been reported (Smethurst and Herrero-Bervera, 2002) and gave consistent values of 5.2–5.4  $\mu$ T by the Shaw method (Shaw, 1974) for the intensity of the field they record. Results from Allende chondrules are inconsistent: values range from hundreds of millitesla (Lanoix *et al.*, 1978) to 70 and 130 mT (Nagata and Sugiura, 1977). Moreover, Nagata and Sugiura (1977) obtained similar results from the matrix and from bulk samples as they had from chondrules in double heating experiments from 20 to 300 °C. This of course strongly suggests that the magnetization was a low-temperature overprint. Such information may be of interest as a means of estimating the temperature to which the meteorite was heated at the time of acquisition of the low-temperature overprint. In ALH 76009, 13 chondrules were found to have random orientation despite the matrix samples showing an overprint (Nagata and Funaki, 1981). Stepwise thermal demagnetization suggested

that the chondrules may have acquired their magnetization in a steady field within which they were rotating slowly.

The interpretation of the magnetization of carbonaceous chondrites, as opposed to the inclusions that they contain, is complicated by the discovery that the paleomagnetic record of the matrix is randomly oriented within some of these meteorites (e.g., Brecher, Stein, and Fuhrman, 1977). The magnetization of some carbonaceous chondrites such as Coolidge, Murray, and Yamato fall off slowly with AF demagnetization and exhibit directional stability. Investigations of multiple oriented samples from these meteorites to check for random magnetization would be of great interest. The presence of tetrataenite is suggested by extreme stability against AF demagnetization. Other carbonaceous chondrites show quite different behavior with NRM that falls off rapidly with the NRM decreasing by as much as an order of magnitude with AF to 10 mT. e.g., Tysnhes Island and Bushof (Gus'kova, 1963). Results are also available for samples that have been cycled through the low-temperature transition of magnetite at  $\sim 120$  K (Brecher and Arrhenius, 1974). Classical double heating intensity determinations have been carried out for Orgueil, Murchison, Leoville, with multiple determinations for Allende. The results fall in the range of tens and hundreds of microtesla. However, the bulk of the magnetization is blocked below 200°C and one must question how well such magnetization is likely to reflect fields more than 4 Ga old.

The magnetization of ordinary chondrites suffers from the same problem of the heterogeneity of the magnetization that is encountered with the carbonaceous chondrites. The phenomenon was investigated systematically by Morden and Collinson (1992). They demonstrated that the magnetism of subsamples of 8LL chondrites and 3L chondrites was randomly oriented down to the scale of millimeters, which was the smallest for which they could be confident of maintaining accurate orientation of subsamples (Figure P36). They also discovered a magnetic fabric, which they considered to be a primary structure formed during the final lithification of the various chondrites. The random paleomagnetic result was therefore interpreted as primary. However, this interpretation is not consistent with the strong metamorphic heating of some of these meteorites, unless magnetization took place before final aggregation. Subsamples of Bjurbole including were also found to be randomly magnetized (Wasilewski et al., 2002). This once again raises a general question of how homogeneous the magnetization of chondrite is and hence what size of sample can be regarded as giving an indication of any possible primary magnetization. Nevertheless numerous dual heating intensity determinations on bulk samples have been carried out. They have yielded values a little lower than the carbonaceous chondrites with values falling between a few µT and nearly 200 µT. The blocking temperatures are rather higher than in the carbonaceous chondrites with the pTRM acquired and the NRM demagnetized linearly related up to steps near to 400°C.

The interpretation of the magnetization of achondrites is in principle simpler than that of chondrites because achondrites originated by crystallization from a magma, or in the case of primitive achondrites, as the residues of partial melting. Therefore they are formed above the Curie points of any magnetic minerals they contain and should have acquired a primary NRM of thermal origin on the evolved body in which they were formed. However, unfortunately only very few achondrites appear to be unbrecciated igneous rocks. Rather achondrites mostly compare with the lunar suite of breccias with igneous clasts, whereas just a few may be true igneous rocks. The crystallization ages of the howardite, eucrite, diogenite clan (HED) are between 4.40 and 4.55 Ga

Figure P36 Demonstration of randomly directed remanent magnetization in ordinary chondrites (Morden and Collinson, 1992).

**Figure P37** Magnetization of Vredefort impact crater samples. Strong random magnetization of shocked basement after (a) AF demagnetization, and (b) thermal demagnetization. (c) and (d) TRM like magnetization in dykes and melt rock recording earth's field, (e) orientation of minimum susceptibility axes (Carporzen *et al.*, 2005).

and thus appear to have come from a parent body that had a brief and active history. The shergottites, nahklites, and chassignites (SNC) meteorites, although achondrites were discussed above because of their demonstrated martian origin.

Not a lot of paleomagnetism has been done on the achondrites other than the SNC meteorites. Some exhibit directionally stable NRM that is resistant to AF demagnetization and to some degree against thermal demagnetization. Some have ratios of NRM:IRMs so high that according to the criterion suggested by Wasilewski *et al.* (2002) contamination must be suspected. One dual heating intensity determination has been done on an Antarctic achondrite (Yamato 7038) and yielded a field intensity of less than 10  $\mu$ T.

Recent work has produced important results, which bear on the studies of randomly directed remanent magnetization in meteorites and on the role of shock in many meteorites. The first result comes from a study of the Vredefort meteorite impact crater by Carporzen et al. (2005). Rocks such as the dykes and pseudotachylites carrying TRM are acquired during cooling after the impact was magnetized coherently with small scatter between samples (Figure P37c,d). In contrast, shocked granitoid basement rocks are magnetized randomly (Figure P37a, b). These shocked rocks also have anomalously high intensities of magnetization. This magnetization of the shocked rocks is interpreted to have been acquired in the intense fields of the plasmas generated by the shock event. The anisotropy of these samples was also determined and the minimum susceptibility axes found to be randomly oriented. In individual samples the anisotropy was related to the remanence direction, indicating that both were caused by the shock events. In other related work, it has been demonstrated that the foliation of chondrites does indeed have an impact origin. Gattacecca et al. (2005) showed that the magnitude of the susceptibility anisotropy is correlated with shock level (Figure P38). These two results call in to doubt again the use of randomly directed magnetization as an indication of magnetization acquired prior to meteorite assembly, demonstrate that foliation can be shock generated, and make the interpretation of paleointensities obtained from meteorites more problematical.

**Figure P38** The relation between fabric and shock demonstrated by the correlation of magnetic anisotropy with shock level (Gattaccea *et al.*, 2005).

#### Discussion

The paleomagnetic record of meteorites is probably the most difficult of all paleomagnetic records to interpret. In particular, the record in CAIs and chondrules is difficult because they are later incorporated in chondrites and so one must separate the history prior to accretion from postaccretion history in the meteorite. Nevertheless there are standard techniques for doing this and progress is being made, despite the difficulties discussed above. In some cases, CAIs and chondrules may carry a record of the fields experienced prior to accretion, but much of the magnetization is probably a postaccretional low-temperature overprint. The magnetization of carbonaceous chondrites and ordinary chondrites may well have been acquired on the surface of the parent body and yielded, respectively, fields of hundreds and tens of microtesla. The NRM of achondrites and primitive achondrites may have been acquired at different depths on an evolved parent body. Only a single double heating experiment was available that yielded a value in the single microtesla range.

The interpretation of these results in terms of early solar system fields is not easy. The fields in which CAIs and chondrules were formed must have been very early solar system fields and Strangway et al. (1988) suggested that these may have been strong fields associated with T-Tauri winds. However, as we have seen that care needs to be taken in while interpreting these field estimates. The fields recorded by carbonaceous and ordinary chondrites are presumably due to surface processes on the parent bodies and modern studies are increasingly recognizing the difficulty of interpreting these results (Gattacceca et al., 2003). Achondrites and primitive achondrites may vield values for different depths in short-lived parent bodies in the form of planets or planetesimals, that might had active dynamos. The question of parent bodies of meteorites a major research area discussed in McSween (1999). For the present purposes, we simply note that S-type asteroids have similar spectra, but not identical to ordinary chondrites, whereas C-type asteroids have features in their spectra characteristic of hydrated minerals typical of the aqueous alteration exhibited by carbonaceous chondrites. It is therefore interesting that S-type asteroid Gaspra appears to have an intensity of magnetization comparable with chondrites, but puzzling that Eros, which is also an S-type asteroid, has a very low magnetization.

#### Conclusion

A remarkable extraterrestrial paleomagnetic record has been found to be associated with the Moon, Mars, the asteroids, and the meteorites. Observations from spacecraft provide evidence that suggests that just as the Earth and Mercury have dynamos generating magnetic fields at the present, the Moon and Mars may have had similar dynamos in the past PALEOMAGNETISM, EXTRATERRESTRIAL

that generated comparable fields. They also suggest that there were magnetic fields in the solar system at the time of origin of chondrites and achondrites, but the records of the chondrules in carbonaceous chondrites and of the primitive CAIs remain hard to interpret in these observations.

# PALEOMAGNETISM, OROGENIC BELTS

Orogenic belts are the key signature of Plate Tectonics at the sites of plate convergence. At these margins the consumption of ancient ocean basins culminates in the collision of blocks of continental crust and this is responsible for deforming broad tracts of crust on either side of the site of collision (*suture*). The deformed rocks are mostly marine

sediments and the products of the preceding phases of ocean development. After collision they are squeezed into increasingly tight folds that may ultimately become overfolded and develop shear planes along which wedges of crust are transported horizontally for large distances as *nappes*. Slices of young, light, and buoyant ocean crust may also become incorporated in this process and emplaced (*obducted*) into the deformed crust as *ophiolites* instead of being subducted back into the mantle.

Orogenic deformation is concentrated mainly within the rock wedges accreted to the peripheries of the continents during the preceding phase of ocean growth, which deform in a semiplastic way. The ancient, relatively cold metamorphic and igneous basements to the continental crust act as the rigid indenters and the inherited shapes of these blocks of old hard crust ultimately control the shape of the orogenic belt. Further from the site of the suture, the sedimentary covers on the continents may be deformed by collision into open folds with amplitudes and wavelengths declining away from the collisional zone. This cover is typically folded independently of the underlying basement by slipping along detachment zones (decollements). Such detachments are also developed within the orogenic belt where rocks deform by contrasting mechanisms controlled by their ductility and bedding. This deformation is constrained between the limiting parallel case where the folding layers in the rock section preserve their thickness but not their shape, and the similar case where they preserve their shape but not their thickness.

The compressional phases of orogenic deformation lead in turn, to crustal thickening, isostatic rebound and uplift. The thickened wedge of deformed rocks becomes topographically unstable and flows outwards as a viscous medium on a geological timescale in a secondary phase of plate collision known as orogenic collapse. Compressional deformation then gives away to extensional deformation that may be regarded as a later phase of a single Plate Tectonic cycle. The development of the Basin and Range Province in western North America during Tertiary times for example, followed compression and crustal thickening during the Laramide Orogeny in Late Cretaceous times. Extensional deformation in the continental crust can occur by two mechanisms. Pure shear attenuates a viscous crust (McKenzie 1978) leading to a change in shape with little or no rotation. In contrast, deformation by simple shear develops a low-angle detachment zone through the crust (Wernicke et al., 1987). As this crust attenuates, the changing thickness balance of crust to mantle lithosphere causes partial uplift of the basement and rotation of blocks above the detachment about horizontal axes; the upper zone (hanging wall) may dissect into fault blocks that rotate about horizontal axes in a domino fashion and, if the detachment extends right through the crustal section, both upper and lower (*footwall*) sections may rotate with respect to each other.

Following continental collision, the rate of convergence of the two converging continents decelerates but relative movements may not cease altogether. One continental margin may then drive under, and uplift, the orogenic belt as in the case of India beneath Tibet. If the indenter has an irregular shape, or there is ocean basin to one side, blocks of the orogen defined by major vertical faults are extruded laterally by *tectonic escape*. This latter phenomenon also occurs when the subduction of ocean crust is oblique to the orogenic margin. It is responsible for the tectonics of the Cordilleran margin of western North America where terranes are slipping differentially northwards along the continental margin until they become locked into a dumping ground in Alaska. In the orthogonal continent-continent collision of the Alpine-Himalayan Belt the tectonic escape defines the last phase of the orogenic cycle.

The ability of rocks to record the direction of the ancient magnetic field provides the key quantitative information for unraveling tectonic deformation in orogenic belts. Geological indicators such as bedding directions, stratigraphic variations and dyke intersections can be used only rarely to provide data of comparable significance, and they are unconstrained to a paleogeographic orientation. The orogenic environment, however, causes specific problems to the analysis of the magnetism in rocks due to the effects of strong deformation and temperature increase. Rocks in this environment are more likely to have their primary magnetism partially or completely overprinted by magnetizations linked to the deformation. Partially set against this disadvantage, the deformed nature of the rocks means that the paleomagnetic fold test is more readily applied to constrain the geological ages of the magnetizations than would be possible in less deformed settings. The study of rock-units may include fault flakes up to a few kilometers in size rotating within fault zones, thrust sheets in interior zones of strong deformation and blocks of crust on a 10–100 km scale bounded by major near vertical faults called *terranes*; only if the terrane extends to the base of the continental lithosphere can it properly be referred to as a *microplate*.

Paleomagnetic analysis assumes that the mean direction of magnetization recovered from the rock-unit is a record of the time averaged dipole field source at the time of magnetization. The cumulative deformation can then be resolved by comparing this direction with the predicted direction at the study location at the time of magnetization. These predicted directions are usually calculated from the *apparent polar wander paths (APWPs)* of the adjoining continental indenter. In the case of the Alpine-Himalayan orogenic belt for example, they would be calculated from APWPs of continental Africa, Arabia, India, or Eurasia. Usually the difference is the resultant of more than one episode of deformation and in favorable circumstances it can be decomposed using geological evidence or from studying the paleomagnetism of rocks of different ages.

The angular deformation is usually considered in terms of differences of declination and inclination with respect to the reference direction from the stable plate. The difference between the observed and expected directions is described in terms of rotation and flattening. A difference in declination implies rotation (R) of a crustal block about a quasivertical axis and is usually calculated by the method of Beck (1980). Both observed and reference directions have confidence limits ( $\Delta D$  and  $\Delta D_{ref}$ , respectively) and Beck (1980) proposed a confidence limit on R' defined by  $\Delta R' = \sqrt{(\Delta D^2 + \Delta D_{ref}^2)}$ . From a statistical analysis of this proposed confidence limit, Demarest (1983) concluded that this value overestimates errors and showed that, provided  $\alpha_{95}$  is small and preferably less than 10°, a standard correction factor is applicable. For a direction derived from  $n \ge 6$  or more samples, the correction factor lies between 0.78 and 0.80. Then  $\Delta R'$  is derived from the equation  $\Delta R' = 0.8\sqrt{(\Delta D^2 + \Delta D_{ref}^2)}$  and only, if  $R' > \Delta R'$  can tectonic rotation be regarded as significant.

A difference in inclination(I), or flattening(F), is also subject to error limits ( $\Delta I$  and  $\Delta I_{ref}$ , respectively). Following Demarest (1983) it is given by  $\Delta F = 0.8\sqrt{(\Delta I^2 + \Delta I_{ref}^2)}$  but provided that  $F > \Delta F$  the flattening may be regarded as significant. F has two possible explanations. Firstly, it could result from rotation of crustal blocks about near horizontal axes. This contribution can usually be isolated if references to the paleohorizontal, such as sedimentary bedding, are present. Secondly, the continental block could have moved through latitude since the time of magnetization. This latter interpretation of F has proved more contentious than the interpretation of R, in part because there is often structural or paleogeographic evidence with which the paleomagnetic analysis can be tested independently. It has been found that inclination differences within the Alpine-Himalayan Belt are often too large to be attributed to continental movement through latitude alone. The anomalies are more important in sedimentary rocks and imply that inclination shallowing during compaction and lithification is a factor here (Bazhenov and Mikolaichuk, 2002). However, Tertiary inclinations from igneous rocks also appear to be too shallow to be accommodated solely by latitudinal movement (Beck et al., 2001). The difference is probably to be explained in terms of small departures from the geocentric axial dipole assumption and a full explanation for this anomaly currently limits the usefulness of flattening in tectonic analysis.

The values of F and R need to be interpreted in terms of the scale of the crustal blocks undergoing deformation and temporal setting of the deformation within the orogenic cycle. Two examples from the

Anatolian sector of the Alpine-Himalayan orogenic belt illustrate contrasts in scale (see Figures P39, P40). Figure P39 shows an example of rotation across an intracontinental transform, the North Anatolian Fault Zone, separating the Eurasian and Anatolian plates. The crust on either side of this fault zone shows comparable regional anticlockwise rotation. This occurred before the initiation of the transform plate boundary in Late Pliocene times. Within the transform fault zone, small fault blocks <10 km in size are being rotated clockwise in ball bearing fashion between master faults at rates of the order of 1° per 10 ka. Figure P40 shows a large-scale example of deformation in which blocks on a scale of  $\sim$ 50–200 km are being rotated as Anatolian crust is being extruded outwards to the west by the impingement of the Arabian indenter into a collage of terranes accreted to the Eurasian margin during closure of the Tethyan Ocean in Mesozoic and Early Tertiary times. Most of these rotations are concentrated within the last few millions of years and are thus a record of the last phase of orogenic development (tectonic escape) following continental collision and crustal thickening. Both these examples illustrate deformation during late stages of orogenic deformation following collision, folding and crustal thickening. Within the Alpine-Himalayan Belt, they fall into the timescale of postcollisional events described as neotectonic to distinguish it from the pre and syn collisional history described as paleotectonic.

In principle there are two aspects to the earlier history of orogenesis that paleomagnetic study can aim to quantify. Firstly, there is the phase of ocean closure in which latitudinal convergence of the two continental margins is recorded by a decline in the difference between paleomagnetic inclinations from either margin. In the Anatolian case, for example, this is identified by progressive reduction in flattening as the Afro-Arabian crust has moved northwards to close the Tethyan Ocean (Kaymakci *et al.*, 2003). Secondly, the plastic deformation associated with continental collision is responsible for nappe emplacement and Ris a measure of the differential rotation between the nappe and the footwall beneath the thrust. Figure P41 shows directions of magnetization resolved from Late Cretaceous rocks, mostly passive margin limestones, in the overthrust front of the Apenninic and Silcilian nappes of southern Italy (Channell *et al.*, 1980). The distribution of declinations is a composite of rotation during nappe emplacement and of differential rotations during the opening of the Tyrrhenian Sea to form the Calabrian arc of southern Italy.

The large-scale deformation shown in Figures P40, P41 producing a radial distribution of paleomagnetic directions over hundreds of kilometers of continental crust is often referred to as "orogenic bending." One of the best documented examples is the Japanese Arc (see Figure P42) where magnetic declinations in north east Japan are rotated anticlockwise and directions in south west Japan are rotated clockwise. The relative rotation between these two regions appears to have occurred over a relatively short interval of time ( $\sim$ 16–20 Ma) during the opening of the Japan Sea by back-arc spreading (Otofuji *et al.*, 1985). However, the actual deformation mechanisms operating in such arcs are certainly complex (Randall, 1998). They no doubt vary from region to region and are likely to involve both small block rotations

**Figure P39** Deformation across an intracontinental dextral transform in the Niksar sector of the North Anatolian Fault Zone in northern Turkey. The arrows with 95% confidence cones are normal polarity directions. Rapid clockwise rotation of small blocks between the master faults is identified in Brunhes chron lava units with ages defined by high-precision K-Ar dating at ca. 520 ka. After Piper *et al.* (1997).

**Figure P40** Rotation of blocks within the accretionary collage in central Anatolia formed by closure of the Neotethys Ocean prior to the termination of suturing  $\sim$ 12 Ma ago and defined by paleomagnetic directions (here shown with common reversed polarity). The neotectonic magnetizations are less than 12 Ma in age and the rotations are an expression of block rotation during tectonic escape to the west as the Arabian indenter is continuing to impinge into the weak continental crust of Anatolia and the Eurasian margin in the east. After Piper *et al.* (2003).

and differential slip along major lineaments such as the "D" zones in the Calabrian example shown in Figure P41a.

Rotation can occur within an orogenic belt either during translation of nappes over a low-angle thrust (Figure P41) or in response to strike slip fault movement within the seismogenic upper crust. The stress conditions for strike slip faulting occur when the maximum ( $\sigma_1$ ) and minimum ( $\sigma_3$ ) principal stresses are in the horizontal plane. Whilst this ideally generates two sets of subvertical faults that are conjugate to one another, one fault set always becomes dominant over time. Vertical axis rotation is demonstrably a major component of crustal deformation within orogenic belts although the kinematics of in situ vertical axis rotations in the upper crust is still controversial due to uncertainties relating to the ways in which continental crust deforms. Limiting models consider the deformation to be continuum or discrete with the division between them based on the driving mechanism for the rotation rather than the type of deformation produced. In continuum models, the rotating blocks are considered to be significantly smaller than the size of the deforming zone and occur passively in response to motion of a ductile lower crust. Shear is distributed across a wide zone with creep and diffusive mass transfer accommodating the deformation. Paleomagnetic directions will be rotated by an amount that diminishes away from the main fault (McKenzie and Jackson, 1983).

In the discrete case the strain is localized into bands and deformation involves the rotation of rigid blocks with slip between them accommodated by fault movement. The blocks themselves are internally undeformed although space constraints imply that they may be expected to undergo tectonic erosion at some peripheries and *spheochasm* formation to open conduits to the lower crust at others. Whilst the evidence indicates that continental lithosphere as a whole deforms on a large scale as a fluid medium with a behavior that can be modeled as a thin viscous sheet (England and Jackson, 1989), pervasive deformation in the upper crust can only occur if there is a sufficient highlevel heat source to promote ductile deformation and permit diffusive mass transfer so that strain is not focused. As Figure P39 demonstrates, this condition does not pertain in the brittle upper crust, even adjacent to intracontinental transform faults. Deformation here takes the form of intense rotation confined between master faults and realistic models to explain rotations must therefore invoke a discrete mechanism. The base of this upper crust is evidently decoupled from a viscous lower crust obeying power law behavior. This detachment is defined by an abrupt reduction in seismicity in the depth range 10-20 km over most of the continental crust. It correlates with the combined effects of increase in temperature and in relatively weak pyroxene and plagioclase feldspar mineral assemblages, which combine to produce a rapid reduction in the strength of the crust below this level.

In discrete models the deformation is taken up on rigid crustal blocks with a length comparable to the width of the deforming zone (Figure P43). The rotation and deformation is the response to shear applied along the edges of the blocks by strike slip faults. All blocks and block bounding faults within the same fault domain will rotate by the same amount in the same direction. An exception to this rule will occur when the strike slip faults form two domains and the sense of rotation will then be opposite within each domain (Ron *et al.*, 1984). It is usually considered that rotation will be clockwise in regions of net right lateral shear and anticlockwise in regions of net left lateral shear (Nelson and Jones, 1987) as shown in Figure P43a. However, the sense of fault motion on the block bounding faults controlling the rotation need not necessarily be the same as the motion sense on the system

**Figure P41** (a): Mean directions (reversed polarity) in Late Cretaceous rocks of the Apenninic and Sicilian nappes and the bordering autochthonous zones of Apulia and Iblei in southern Italy. (b) Schematic reconstruction showing the opening of the Tyrrhenian Sea in Early Pliocene times responsible for the large-scale regional differences in magnetic declination in (a) Compiled from Channell *et al.* (1980).

**Figure P42** (a): Mean paleomagnetic field directions from rock-units older than 20 Ma in age in northeast and southwest Japan. (b) Explanation for the difference between the regional directions shown in (a) in terms of rotation of the two sectors of Japan away from the Asian margin as a result of the fan-shaped opening of the Japan Sea. After Otofuji *et al.* (1985).

**Figure P43** The origin of clockwise and anticlockwise rotations defined by paleomagnetic study of small blocks influenced by major vertical faults cutting through the thickness of the seismogenic upper crust when the deformation is (a) distributed and (b) discrete. Adapted from Randall (1998) and Tatar *et al.* (2004).

bounding faults (Randall, 1998). The sense of rotation is controlled by the initial orientation of the block bounding faults with respect to the system bounding faults, and whether the system bounding faults are acting as the margins of a wide shear zone (Figure P43a) or as discrete faults either side of the rotating blocks (Figure P43b). If the block bounding faults have the same sense of motion to the discrete system bounding faults (Figure P43b) the blocks rotate in the direction opposite to that suggested by the bulk shear on the deformation zone. Examples of both types of rotation have been reported from application of paleomagnetism to orogenic belts and are evidently a signature of the distributed or discrete character of the causative major strike slip zones.

In general there are two scales of tectonic rotation observed in orogenic belts. Large and rapid rotations are present within, or adjacent to, the intracontinental transform faults defining the conservative boundaries of the plates; Figure P39 is an example of this kind of deformation. More modest and slower rotations are present where terranes are being pushed laterally by oblique subduction or tectonic escape, or nappes are being emplaced by an advancing fold belt. Figures P39 (remote form the intracontinental transform) and P40 are examples of this scale of deformation.

A further important aspect of orogenic paleomagnetism is the study of remagnetization events directly related to orogenesis. A burial related heating that partially or completely remagnetizes preexisting ferromagnetic minerals may cause these overprints. More commonly they reside in chemical remanent magnetizations (CRMs) carried by new minerals that have either been transformed from the preexisting minerals (diagenesis) or have been precipitated from fluids (authigenesis). Comparison of the pole position with the APWP of the adjoining indenters may then allow diagenetic and authigenic events to be dated. In addition progressive unfolding of remagnetized rocks within fold structures can constrain this event within a pre, syn or postfolding timeframe. The most commonly invoked mechanism for regional CRMs in the vicinity of orogenic belts is lateral migration of preexisting connate brines within the deforming rock assemblage as it is loaded and heated within the orogenic belt. Forced migration of these orogenic fluids along ancient aquifers under a temperature and pressure gradient is considered to be a plausible explanation for the widespread distribution of CRMs away from some orogenic belts such as the Appalachians, although evidence for the link is still in part circumstantial (Elmore et al., 2000). Precipitation of new ferromagnetic minerals will be controlled by the availability of ions, and the temperature, pH and Eh of the ambient environment. Oxidizing conditions will

favor precipitation of hematite whereas alkaline and mildly reducing environments favor precipitation of magnetite. In more strongly reducing conditions, the ferromagnetic pyrrhotite is precipitated and can produce important late stage CRMs within the orogenic belt where abundant mudrocks originally containing pyrite are present or where mineralizing fluids have been able to permeate. Thus, in addition to applications of the primary or early tectonic paleomagnetic record for resolving the scale of deformation, the study of chemical magnetic overprints can constrain the age and regional extent of important later events in the development of orogenic belts.

## PARKINSON, WILFRED DUDLEY

### Twentieth century scientist

Wilfred Dudley Parkinson (see Figure P44) was an internationally prominent geomagnetician of the 20th century (Barton and Banks, 2002). His origins in geomagnetism were classical, and he was active through the remarkable period that saw observing apparatus change from mechanical to modern electronic, and recording methods change from paper chart and photographic paper to electronic memory. Data analysis methods changed from graphical and hand-calculated to the full range of numerical, modeling and inversion methods, which were possible with electronic computers by the end of the century. Parkinson was a dedicated and effective teacher at the University of Tasmania, and his book *Introduction to Geomagnetism* (Parkinson, 1983) reflected the benefits of being based on an excellent lecture course.

His research contributions, together, thus very much appear as a period piece of his time. The International Geophysical Year (IGY), which spanned the 18 months from July 1, 1957 to December 31, 1958 (Bates *et al.*, 1982) promoted the observation of the geomagnetic time-varying field at an enhanced density of observatories relative to the then standard global network, and focussed attention on the spatial pattern of these time-varying fields. It was from an analysis of the fluctuating fields observed at Australian stations that Parkinson first observed the "coast effect" for which he became well known, and

which he characterized by graphically constructed "Parkinson vectors" (also called "Parkinson arrows" see induction arrows).

The time of his activity, plus his natural skills, meant Parkinson led in pioneering much Australian geophysics. In pursuits promulgated by his national government employer, the Bureau of Mineral Resources, he was a pioneer in the construction of magnetic maps of the Australian continent, in developing the aeromagnetic survey method for Australia, and in instituting geomagnetic measurements in Antarctica.

However he is best known for his widely used "Parkinson arrow" contribution.

### Brief biography

Parkinson was born in 1919 into a family active in geomagnetism, as his father worked for the Carnegie Institution of Washington (CIW), and was assistant observer at the Watheroo Observatory in Western Australia. Parkinson thus traveled extensively with his family in connection with geomagnetic activities. He received his first degree (BSc hons in mathematics) from the University of Western Australia, and then following service with the CIW at Huancayo Observatory in Peru he studied for his PhD at Johns Hopkins University in the United States of America. After some time in USA, he returned to Australia in 1954 to join the then Bureau of Mineral Resources. In 1967 he joined the Department of Geology at the University of Tasmania. He was promoted to Reader in Geophysics and spent the rest of his career at that university, traveling internationally to other places active in geomagnetism during his sabbatical leave periods.

Hobart and environs had been significant in the history of geomagnetism and Parkinson played an important role both in the celebration of the bicentenary of the year 1792 D'Entrecasteaux expedition (Lilley and Day, 1993), and in ensuring appropriate recognition of the site and history of the 1840 Rossbank Magnetic Observatory.

As a leader in Australian geomagnetism, he was an important figure at four Australian Geomagnetic Workshops which were convened in Canberra by C.E. Barton and F.E.M. Lilley in the years 1985, 1987, 1993, and 2000. It was appropriate that he was the invited guest speaker at the last workshop he was to attend, in 2000—the year before his death in 2001.

Dudley Parkinson, as he was widely known, was survived by his wife Mary, two sons Charles and Richard, and four grandchildren.

**Figure P44** Wilfred Dudley Parkinson 1919–2001 (photo taken 1990, by F.E.M. Lilley).

Recognition of the coast effect, Parkinson arrows, and crustal conductivity structure

From his familiarity with magnetic observatory data, in the 1950s Parkinson had noticed that commonly for coastal observatories the vertical component of the fluctuating field had an evident correlation, best seen during magnetic storm activity, with the onshore horizontal component. Parkinson realized that from some starting point, the vectors of magnetic field change, reckoned at intervals of say half-an-hour, tended to lie on a plane in space. Parkinson called this plane the "preferred plane."

In investigating the phenomenon, Parkinson developed a graphical method for determining the plane at a particular observatory. To characterize the effect he plotted the horizontal projection of the (unitlength) downwards normal to the plane on a map, at the observatory site. The plane became known as the "Parkinson plane," and the horizontal projection of the downwards normal became known as the "Parkinson vector."

Subsequently, usage of the term Parkinson arrows was adopted to avoid any implication that Parkinson vectors of structures considered in isolation could necessarily be added vectorially to produce the effect of the structures in combination. Later Parkinson supported use of the term "Induction arrow", out of respect for others who had developed similar ideas.

Remote from a coastline, such arrows generally point to the high conductivity side of any conductivity structure present in the regional geology. (Note that in some conventions, such as that attributed to Wiese, the arrows are plotted in the opposite direction.) Plotted for an array of stations, the arrows demonstrated that electrical conductivity contrasts within continents, as well as at continent-ocean boundaries, could thus be mapped. The realization that the phenomenon was controlled by Earth electrical conductivity structure guided much of Parkinson's research for the rest of his career.

### Chronicle of publications

Parkinson's published work provides a representative chronicle in geomagnetic research for the later half of the 20th century. Thus Parkinson (1959) describes recognition of the "preferred plane," and Parkinson (1962) introduces the Parkinson vector technique. In Parkinson (1964) a laboratory model comprising copper sheeting for the seawater of the world's oceans is described—Parkinson's "terrella"—in an attempt to test whether induction in the seawater alone is sufficient to account for the coast effect. The coast effect is reviewed further in Parkinson and Jones (1979).

Parkinson (1971) addresses an analysis of the Sq variations recorded during the IGY. These observations had been a prime objective of the IGY global network of observatories, and Parkinson's analysis was one of the first to exploit the power of electronic computers, which were developing rapidly in the 1960s. This thread is picked up again in Parkinson (1977), Parkinson (1980) and Parkinson (1988).

Dosso *et al.* (1985), Parkinson *et al.* (1988), and Parkinson (1989) see attention given again to local induction, and the discovery of the Tamar conductivity anomaly in northeast Tasmania. The Australian island State proved a productive field area for Parkinson and his students, based in Hobart. In Parkinson (1999) several earlier pursuits are brought together, in addressing the influence of time-variations on aeromagnetic surveying. Parkinson and Hutton (1989) is a major review, bringing together threads of earlier research contributions.

Coast Effect of Induced Currents Electromagnetic Induction (EM) Geomagnetic Deep Sounding

## PEREGRINUS, PETRUS (FLOURISHED 1269)

Virtually nothing is known of the life or wider circumstances of the Frenchman Peter, Pierre, or Petrus Peregrinus, beyond what he wrote in his *Epistola Petri Peregrini de Maricourt*, from the camp of the army besieging Lucera in Apulia, Italy, and dated August 8, 1269. Most probably, he was a native of Méharicourt, Picardy, in north-east France, and from his fascination with all kinds of machines and self-acting devices, he could have been a military engineer. His honorific title "Peregrinus," no doubt stemming from the Latin *peregrinator*, or wanderer, could have derived from his having been on pilgrimage or Crusade, though there is no evidence to back the legend that he was a monk or priest. Whether he was the same "Master Peter" referred to as a mathematician of brilliance by his English contemporary Friar Roger Bacon is uncertain but possible.

Peter's historical importance, however, derives from his being the first significant author on magnetism. His *Epistola* of 1269 was widely circulated across Europe in manuscript form, and in the 16th century

was acknowledged by no less a figure than William Gilbert in *De Magnete* (1600). The *Epistola* recounts that magnetic phenomena was already familiar to Europeans by 1269 (for knowledge of the compass, originally obtained from China, had already been used for direction finding in the West for about 100 years by Peter's time), along with new experiments and insights, which could well have been Peter's own. What Peter does, however, is producing a coherent treatise that surveys the current state of magnetic knowledge in Europe by 1269, before going on to describe his own experiments.

Peter experimented with different types of magnets, including elongated pieces of magnetite stone, with what seem to have been spherical magnets (probably carved from blocks of magnetite) and with the transfer of magnetism from the natural stone to pieces of iron or steel. While there was some conjecture amongst scholars as to whether he was the first person to use the term "pole" with relation to magnetism, he was certainly familiar with the concept of the north and south terminations of all magnetic bodies. When using what seems to have been a spherical magnet, for instance, he describes employing the natural orientation of needles upon its surface to trace lines that would converge in polar points.

He also conducted experiments in the breaking in two of natural magnets, and found that when a piece of magnetic stone was so divided, the ends of the two broken pieces suddenly acquired north and south polar characteristics of their own. Yet if one rejoins the broken pieces and cemented them together, then the two magnetic fields seemed to recombine and form one magnet again. Peter's experiments showed that like poles repel and unlike poles attract. Heavy pieces of magnetite with an apparently homogenous composition were more powerful attractors of iron than the light-weighted and less pure pieces of the stone.

Needles and pieces of iron (or steel), under the right conditions and by bringing them into contact with natural magnets, themselves become magnetic, and display all the characteristics of the natural magnets from which they were derived.

Peter Peregrinus described several experiments with floating magnets which he had placed in cups that were then made to float in water-the pieces of magnetite, indeed, being like passengers in a boat. He found that when placed in an unrestricted environment of this kind, the magnets always oriented themselves north-south by the Earth's own astronomical poles. An advancement on this experiment was made when he encased an elongated piece of magnetite in wood, so as to make it float. First, he proposed that if the rim of the water-containing vessel was divided into the cardinal points and the whole vessel into 360°, then one had an instrument which would allow an observer or navigator at sea to determine the exact rising and setting points of astronomical bodies on the horizon, with reference to the north pole. Next Peter proposed a dry compass, where instead of water, the balanced needle rotated upon a vertical pin, but which still allowed astronomical bearings to be read off against a graduated edge. This would have been a very early version of a marine azimuth compass.

But in addition to his more practical experimental work, Peter was interested in the source of the magnet's power. First, he dismissed what seem to have been a series of folk myths about magnetism. For instance, magnetism could *not* have been a uniquely north-polar phenomenon because the north pole is too cold to be inhabited and hence there can be no people there to mine the magnetite familiar to scholars. Peter reminds us that magnetite deposits occur in many places in Europe that are many degrees south of the north polar regions, while—let us not forget—the needle also points south. And while Peter, like all educated medieval men who were heirs to the classical tradition, knew that the Earth itself was a sphere. In 1269 no European knew anything for certain about the nature, inhabitants, or geography of the Southern Hemisphere.

As an educated man who had clearly received some training in the classical sciences of astronomy, geometry, and arithmetic, and had no doubt encountered the increasingly influential ideas of Aristotle (all of which were part of the undergraduate *Quadrivium* of Europe's universities in the 13th century), he would have taken it as axiomatic

that the Earth rested motionless at the center of the universe and that the heavens revolved about it. In this way of thinking, the Earth was associated with cosmological stability, whereas the heavens were imbued with motion. So it was probably this line of reasoning which led Peter to attribute the motion inducing capacity of the magnet to the heavens. This also prompted him to suggest the devising of a piece of apparatus to demonstrate the phenomenon. He proposed that if a spherical magnet were mounted upon its polar points in some sort of bearing, and the north and south poles exactly oriented to correspond with those of the Earth (in what would now be called an Equatorial Mount), then the sphere would rotate of its own accord. It would do so in accordance with the natural rotation of the heavens, the sphere's own magnetism simply responding to its celestial source. Peter never reported any success with this experiment as the reasons seem to be obvious.

But Peter's obvious interest in inventions next led him to join that band of medieval men who were fascinated with perpetual motion. Yet whereas his 12th-century fellow-Frenchman, Villard de Honnecourt, and others like him saw their machines as powered by arrangements of falling weights, Peter's proposed perpetual motion machine was set in train by an oval magnet the north-seeking properties of which actuated the teeth of a denticulated wheel.

What is so tantalizing about Peter is that we know nothing of him beyond his Epistola of August 8, 1269. His very fleeting passage across the pages of history, therefore, begs more questions than it answers. For how many educated men were there in medieval Europe who traveled, possibly crusaded, worked as military engineers, and were fascinated by mechanical invention? And let us not forget that the Epistola was sent not to a Bishop or university corporation, but to "Sygerum de Foucaucourt, Militem", or "Sygerus... the Soldier". Did ingenious military engineers conduct experiments into magnetism and investigate astronomy and other branches of science on those long tedious days in camp, when they were not supervising storming engines? Indeed, 13th- and 14th-century Europe was vibrant with mechanical invention: improved wind and water mills, iron founding machinery, daring Gothic cathedrals, early gun founding and explosives manufacture, the ship's rudder, and soon after 13th century the first geared mechanical clocks, many of which possessed elaborate automata. To see medieval Europe as technologically primitive is just as much a myth of our own time as was Peter's refutation of the existence of a great lump of ironstone at the north pole. And it was this ingenious culture, which produced the first experimentally based treatise on magnetism.

Allan Chapman

## PERIODIC EXTERNAL FIELDS

### Definition

The lines of force of the Earth's magnetic field extend upwards from the surface of the Earth to the magnetopause, which is the boundary at great altitudes within which the solar wind confines the Earth's magnetic field. At an altitude of 100 km the atmospheric pressure is low and

molecules dissociate to form a conducting layer called the ionosphere. When lower layers of the atmosphere are heated by sunlight and caused to move, the motion is propagated in all directions. Electromotive forces are formed everywhere in the moving atmosphere, where from Lenz's law,  $E = \mathbf{v} \times B$ . In the electrically conducting ionosphere, electrical currents flow, and the magnetic field of these currents forms the external periodic magnetic variation. On magnetically quiet days this variation is called the solar quiet day variation, denoted Sq.

In every month of the calendar, five days are denoted as disturbed days, and another five as quiet days. The difference between the magnetic field, hour after hour, on the quiet and disturbed days, is called the disturbance daily variation, denoted SD, and it is another periodic field of external origin.

The gravitational force of the Sun and the Moon causes tidal movements in the oceans, the atmosphere and the solid Earth. The tidal movements of the ionosphere caused by the Moon lead to the lunar magnetic daily variations. Solar tides are much smaller than lunar tides and the corresponding solar tidal magnetic effect is difficult to discern from the magnetic variation arising from solar heating of the atmosphere.

The deep oceans in tidal movement also give rise to magnetic variations. The separation of oceanic and ionospheric components in the analysis of solar and lunar daily magnetic variations is based on the assumption that there is no ionospheric current flow at local midnight.

Because of their ionospheric origin, the regular daily variations at the surface of the Earth have an external component that is greater than the corresponding induced internal component, and the results are used for the modeling of the distribution of electrical conductivity within the Earth's interior land eigenmodes of atmospheric oscillation.

### Magnetograms

In geomagnetism, the declination, denoted D, refers to the angle between the direction of the compass needle and true north, positive towards the east. The horizontal intensity, H, of the magnetic field is that component of the field in the direction of true north, and the vertical intensity, Z, is the vertically downwards component. Magnetic variations are recorded in these three elements at magnetic observatories throughout the world. Satellite magnetic data from low-Earth-orbiting satellites at an altitude of approximately 400 km, above the ionosphere, record the main field components and the determination of daily variations from satellite magnetic data has only just begun.

Magnetograms of the declination of the Earth's magnetic field recorded at Canberra magnetic observatory are given in Figure P45 with one calendar month to each row and 12 monthly rows for the year 1999. The most prominent feature of the daily magnetograms is the regular daily change that occurs on each day throughout the year, with a daily range that is smaller in local winter months.

The monthly mean values of the magnetic elements show a small annual, one cycle per year, external, periodic variation of the order of 10 nT, and it is necessary to use several years of data to get a significant result. This variation is thought to arise from the seasonal displacement of the ring current from the equatorial plane. The accurate analysis of long-period terms such as the annual variation and the 11 year cycle, is plagued by a number of difficulties, amongst which are baseline problems arising from small errors in instrument calibration.

### Hourly mean values

For many years the daily variations in the magnetic field were given as hourly mean values that had been prepared manually from magnetogram photographic traces, and given in Universal Time centered midway between the hours. The results were published in yearbooks, usually three elements, month by month, after a long delay, often of some years. With modern three component vector magnetometers (see *Magnetometers*) providing samples every 10 s with a resolution of 0.1 nT, it is now possible to have 1-min values transmitted within minutes via the Intermagnet program. In 2001 about half of the world's magnetic observatories contributed to the Intermagnet program, and since that time the number of observatories contributing has increased.

### Fourier analysis

The Fourier analysis of solar and lunar magnetic tides from observatory hourly mean values has a number of technical difficulties, such as noncyclic variation, but in every case, harmonic analyses of either 24-hourly mean values or 1440 one-minute values are required. The fast Fourier transform can be used, although for relatively small calculations the Goertzel algorithm (Goertzel, 1958) is useful and easily programmed. For the analysis of lunar magnetic tides, each day is "tagged" with an integer, usually from 1 to 12, called a "character number," based on a linear combination of the astronomical parameters denoted s, h, and p, by Bartels (Bartels, 1957, 747, see Bartels, Julius). These represent the east longitudes of the Moon, the Sun and the Moon's perigee respectively, from January 1, 1900. For the lunar variations, the character number is determined from the angular measure of 2s - 2h, and seasonal sidebands are determined using character numbers 2s - h and 2s - 3h. Hourly values from days with the same tag provide an average daily sequence, and the 12 groups are called "group sum sequences."

The Chapman-Miller (Chapman and Miller, 1940), (see *Chapman, Sydney*) method analyses the 12 groups of 24 values, by a modified two-dimensional Fourier analysis, with adjustments for the daily noncyclic variation. By using the variability of Fourier coefficients determined for the 12 groups, reasonable estimates of standard deviations for computed coefficients are obtained. The Chapman-Miller method has the great advantage of being able to deal effectively with missing days of data, or the rejection of days because of magnetic disturbance.

The Chapman-Miller method can be adapted (Malin, 1970) to separate the lunar magnetic variations into parts of ionospheric and oceanic origin.

The Fourier analysis of the elements X, Y, and Z, being the northward, eastward, and vertically downward components, respectively, of the Earth's magnetic field, over a sphere of radius a, leads to the following Fourier series:

$$\begin{aligned} X(a,\theta,\phi) &= \sum_{M=1}^{4} [C_{XM}(\theta,\phi)\cos Mt + D_{XM}(\theta,\phi)\sin Mt], \\ Y(a,\theta,\phi) &= \sum_{M=1}^{4} [C_{YM}(\theta,\phi)\cos Mt + D_{YM}(\theta,\phi)\sin Mt], \\ Z(a,\theta,\phi) &= \sum_{M=1}^{4} [C_{ZM}(\theta,\phi)\cos Mt + D_{ZM}(\theta,\phi)\sin Mt]. \end{aligned}$$
(Eq. 1)

Spherical harmonic analysis of the Fourier coefficients  $C_{XM}$ ,  $C_{YM}$ , and  $C_{ZM}$  gives internal field coefficients  $g_{NCI}^{mM}$ ,  $h_{nCI}^{mM}$ , and external field coefficients  $g_{NCe}^{mM}$ ,  $h_{nCe}^{mM}$ , in the potential function  $V_C^M(r, \theta, \phi)$ , where

$$V_C^M(r,\theta,\phi) = a \sum_n \sum_m \left[ \left(\frac{a}{r}\right)^{n+1} \left( g_{nCi}^{mM} \cos m\phi + h_{nCi}^{mM} \sin m\phi \right) + \left(\frac{r}{a}\right)^n \left( g_{nCe}^{mM} \cos m\phi + h_{nCe}^{mM} \sin m\phi \right) \right] P_n^m(\cos\theta).$$
(Eq. 2)

It is the usual practice to do a spherical harmonic analysis of the Fourier coefficients  $D_{XM}$ ,  $D_{YM}$ , and  $D_{ZM}$ , giving the two sets of spherical

**Figure P45** Daily change of the compass needle at Alice Springs, 1999. The daily range is smaller in local winter months, the lunar changes appear as a small, fortnightly modulation. (From the Australian Geomagnetism Report, 1999. Magnetic Observatories, vol. 47, Part 1, 2001).

harmonic coefficients, but leaving the researcher with the difficult task of deciding which coefficient is which, and of separating the westward and eastward moving terms.

However, by using the g and h coefficients from  $V_C^M(r, \theta, \phi)$  to represent the potential  $V_D^M(r, \theta, \phi)$  for the D coefficients in the form:

$$V_D^M(r,\theta,\phi) = a \sum_n \sum_m \left[ \left(\frac{a}{r}\right)^{n+1} \left( h_{nCi}^{mM} \cos m\phi - g_{nCi}^{mM} \sin m\phi \right) + \left(\frac{r}{a}\right)^n \left( h_{nCe}^{mM} \cos m\phi - g_{nCe}^{mM} \sin m\phi \right) \right] P_n^m(\cos\theta)$$
(Eq. 3)

the potential function based on both  $V^M_C(r,\theta,\phi)$  and  $V^M_D(r,\theta,\phi),$  namely

$$\begin{aligned} V_C^M(r,\theta,\phi)\cos Mt + V_D^M(r,\theta,\phi)\sin Mt \\ &= a\sum_{n=1}^N\sum_{m=0}^n \left\{ \left(\frac{a}{r}\right)^{n+1} \left[g_{nCt}^{mM}\cos(m\phi+Mt) + h_{nCt}^M\sin(m\phi+Mt)\right] \right\} \\ &+ \left(\frac{r}{a}\right)^n \left[g_{nCe}^{mM}\cos(m\phi+Mt) + h_{nCe}^M\sin(m\phi+Mt)\right] \right\} P_n^m(\cos\theta) \end{aligned}$$
(Eq. 4)

consists entirely of westward moving terms. The actual numerical analysis is based on Eqs. (2) and (3) together. The terms for which m = M are local time terms. It is a simple matter to construct an expression corresponding to Eq. (3), which will give the results for eastward moving terms, which analysis shows to be much smaller than the westward moving terms.

Amplitudes and phase angles for internal and external fields are needed for conductivity studies, so that results of Eq. (4) should be provided in the form

$$a\sum_{n=1}^{N}\sum_{m=0}^{n}\left\{\left(\frac{a}{r}\right)^{n+1}A_{nCi}^{mM}\cos(m\phi+Mt+\epsilon_{nCi}^{mM})+\left(\frac{r}{a}\right)^{n}A_{nCe}^{mM}\cos(m\phi+Mt+\epsilon_{nCe}^{mM})\right\}P_{n}^{m}(\cos\theta).$$
 (Eq. 5)

Note particularly that the phase angles  $\epsilon_{nCi}^{mM}$  and  $\epsilon_{nCe}^{mM}$  in Eq. (5) are given for cosine functions.

No general method of analysis for periodic external variations from satellite magnetic data is available. Significant orbital drift through local time is required, and the more rapid the drift, the better.

### Ionospheric current systems

It is very convenient to represent the vector field of external (ionospheric) origin by a scalar "stream function" whose contours run parallel to the lines of flow of electrical currents in the thin conducting shell used to represent the ionosphere. This scalar function  $W(\theta, \phi)$ , A, in Eq. (6), is determined from the *external* field coefficients only. The surface current density  $\mathbf{K}(\theta, \phi)$ , A/m, is

$$\mathbf{K}(\theta,\phi) = \nabla \times [\mathbf{e}_r \Psi(\theta,\phi)] = -\mathbf{e}_r \times \nabla W(\theta,\phi),$$
  
=  $\frac{1}{R} \left( \frac{1}{\sin\theta} \frac{\partial W}{\partial \phi} \mathbf{e}_{\theta} - \frac{\partial W}{\partial \theta} \mathbf{e}_{\phi} \right), A/m.$  (Eq. 6)

The current function  $W(\theta, \phi)$ , A, for a shell of radius *R*, relative to a reference sphere of radius *a*, is given by

$$W(\theta, \phi) = \sum_{n=1}^{N} \sum_{m=0}^{n} \left[ W_{gn}^{m} \cos(m\phi + Mt) + W_{hn}^{m} \sin(m\phi + Mt) \right] P_{n}^{m} (\cos \theta)$$
(Eq. 7)

with coefficients  $W_{gn}^m$  and  $W_{hn}^m$  as given originally by Maxwell (Maxwell, 1873, p. 672),

$$W_{gn}^{m} = -a_{km} \frac{10}{4\pi} \frac{2n+1}{n+1} \left(\frac{R_{km}}{a_{km}}\right)^{n+1} (g_{nCe}^{mM})_{nT},$$
  
$$W_{hn}^{m} = -a_{km} \frac{10}{4\pi} \frac{2n+1}{n+1} \left(\frac{R_{km}}{a_{km}}\right)^{n+1} (h_{nCe}^{mM})_{nT}.$$
 (Eq. 8)

Contours in kiloamperes of the current function for the solar quiet day variation are given in Figure P46.

### Ionospheric dynamo theory

An article by Stewart (1883) in the 9th edition of the *Encyclopedia Britannica*—in a subsection of the article, "Meteorology"—proposed a dynamo in the upper atmosphere as the only plausible theory for the regular solar daily magnetic variation. Schuster (1889) analyzed Sq from four Northern Hemisphere observatories, and then used the theory of electromagnetic induction (see *Electromagnetic induction* and *Price, Albert Thomas*) in a uniformly conducting sphere as derived by Lamb (in an appendix to Schuster's 1889 paper) to determine the electrical conductivity models of the Earth's interior. The theory, for a uniformly conducting sphere, uses phase angle differences and amplitude ratios of internal and external components. Schuster (1908) took the process a step further, inferring upper atmosphere wind velocities from global representations of atmospheric pressure. In particular he represented the components of electric force by a potential function  $S(\theta, \phi)$  and a stream function  $T(\theta, \phi)$ ,

$$E_{\theta} = -\frac{1}{a} \left( \frac{\partial S}{\partial \theta} - \frac{1}{\sin \theta} \frac{\partial T}{\partial \phi} \right),$$
  

$$E_{\phi} = -\frac{1}{a} \left( \frac{1}{\sin \theta} \frac{\partial S}{\partial \phi} + \frac{\partial T}{\partial \theta} \right).$$
 (Eq. 9)

Schuster included an analysis of the seasonal change of Sq. His theory provided a solid foundation for ionospheric dynamos, adapted in more recent times by using the eigenfunctions of the Laplace tidal equation to represent the forced and free atmospheric oscillations and wind velocities.

Chapman (1919) (see *Chapman, Sydney*) developed the ionospheric dynamo theory (see *Ionosphere*) of the magnetic daily variations, of solar and lunar origin, using atmospheric velocities given as the gradient of a scalar potential. Mathematical expressions for the lunar magnetic variations, and the Chapman-Miller method for their analysis developed gradually over many years.

In the following sections,  $r, \theta, \phi$ , will denote radial distance, colatitude, and east longitude in a spherical polar coordinate system. Subscripts will be used to denote the  $r, \theta, \phi$ , components of vectors. For wind movements in the high atmosphere, the radial component  $v_r$  is assumed to be negligibly small, relative to the horizontal components,  $v_{\theta}$  and  $v_{\phi}$ . In a magnetic field with magnetic flux density components ( $B_r, B_{\theta}, B_{\phi}$ ), the dynamo electric field  $\mathbf{v} \times \mathbf{B}$  has spherical polar components

$$E_r = v_{\theta} B_{\phi} - v_{\phi} B_{\theta},$$
  

$$E_{\theta} = v_{\phi} B_r,$$
  

$$E_{\phi} = -v_{\theta} B_r.$$
 (Eq. 10)

Consider the dipole term only in the geomagnetic potential, V, where

$$Y = a \left(\frac{a}{r}\right)^2 g_1^0 \cos\theta, \qquad (\text{Eq. 11})$$

so that the components of magnetic flux density from  $\boldsymbol{B} = -\nabla V$  at r = R, are,

$$B_{r} = -\frac{\partial V}{\partial r}\Big|_{r=R} = 2G_{1}^{0}\cos\theta,$$
  

$$B_{\theta} = -\frac{1}{r}\frac{\partial V}{\partial\theta}\Big|_{r=R} = G_{1}^{0}\sin\theta,$$
  

$$B_{\phi} = -\frac{1}{r\sin\theta}\frac{\partial V}{\partial\phi}\Big|_{r=R} = 0,$$
 (Eq. 12)

where  $G_1^0 = (a/R)^3 g_1^0$ .

l

With the Schuster representation of the electric field, in Eq. (9), the currents driven in the direction of the gradient of the function  $S(\theta, \phi)$  will go towards maxima or minima of the function, which act as sinks or sources. In a conducting thin shell, these currents have nowhere to go and an electrostatic field is set up so that no current

Figure P46 Equivalent external ionospheric current system for annual average Sq, 1964–1965. Contour interval and extrema in kiloamperes (from Winch, 1981).

flows. The stream function, or toroidal component  $T(\theta, \phi)$ , drives a stream function electrical current parallel to the contours of  $T(\theta, \phi)$  in the thin spherical shell representing the ionosphere. Thus, backing off the electrostatic field from the dynamo field,

$$E_{\theta} + \frac{1}{R} \frac{\partial S}{\partial \theta} = \frac{1}{R \sin \theta} \frac{\partial T}{\partial \phi}, \quad E_{\phi} + \frac{1}{R \sin \theta} \frac{\partial S}{\partial \phi} = -\frac{1}{R} \frac{\partial T}{\partial \theta}.$$
 (Eq. 13)

From the current function  $W(\theta, \phi)$ , determined from observatory data, the components of surface current density are  $J_{\theta}, J_{\phi}$ , where

$$J_{\theta} = \frac{1}{R \sin \theta} \frac{\partial W}{\partial \phi}, \quad J_{\phi} = -\frac{1}{R} \frac{\partial W}{\partial \theta}.$$
 (Eq. 14)

Therefore, by Ohm's law in the form  $E = J/\sigma(\theta, \phi)$ ,

$$\frac{1}{\sigma(\theta,\phi)R\sin\theta}\frac{\partial W}{\partial\phi} = \frac{1}{R\sin\theta}\frac{\partial T}{\partial\phi},$$
$$\frac{1}{\sigma(\theta,\phi)R}\frac{\partial W}{\partial\theta} = -\frac{1}{R}\frac{\partial T}{\partial\theta}.$$
(Eq. 15)

Therefore, from Eqs. (10) to (15), ignoring self-induction,

$$2\nu_{\phi}G_{1}^{0}\cos\theta - \frac{1}{R}\frac{\partial S}{\partial\theta} = \frac{1}{\sigma(\theta,\phi)R\sin\theta}\frac{\partial W}{\partial\phi},$$
  
$$2\nu_{\theta}G_{1}^{0}\cos\theta + \frac{1}{R\sin\theta}\frac{\partial S}{\partial\phi} = \frac{1}{\sigma(\theta,\phi)R}\frac{\partial W}{\partial\theta}.$$
 (Eq. 16)

Eliminating the electrostatic function  $S(\theta, \phi)$  from Eq. (16) gives

$$\frac{2G_1^0}{\sin\theta} \left[ \frac{\partial \nu_{\phi}}{\partial \phi} \cos\theta + \frac{\partial}{\partial \theta} (\nu_{\theta} \sin\theta \cos\theta) \right]$$
  
=  $-\frac{1}{\sigma(\theta,\phi)R} \left[ \frac{1}{\sin^2\theta} \frac{\partial^2 W}{\partial \phi^2} + \frac{1}{\sin\theta} \frac{\partial}{\partial \theta} \left( \sin\theta \frac{\partial W}{\partial \theta} \right) \right]$   
 $-\frac{1}{\sigma^2(\theta,\phi)R} \left[ \frac{\partial \sigma}{\partial \phi} \frac{1}{\sin\theta} \frac{\partial W}{\partial \phi} + \frac{\partial \sigma}{\partial \theta} \frac{\partial W}{\partial \theta} \sin\theta \right].$  (Eq. 17)

In the special case of constant conductivity  $\sigma(\theta, \phi) = \sigma$ , Eq. (17) can be written

$$\frac{2G_1^0}{\sin\theta} \left[ \frac{\partial v_{\phi}}{\partial\phi} \cos\theta + \frac{\partial}{\partial\theta} (v_{\theta} \sin\theta \cos\theta) \right] = -\frac{1}{\sigma R} \nabla_H^2 W(\theta, \phi),$$
(Eq. 18)

where  $\nabla_{\rm H}^2$  is the horizontal Laplacian operator,

$$\nabla_{\rm H}^2 W = \frac{1}{\sin\theta} \frac{\partial}{\partial\theta} \left( \sin\theta \frac{\partial W}{\partial\theta} \right) + \frac{1}{\sin^2\theta} \frac{\partial^2 W}{\partial\phi^2}.$$
 (Eq. 19)

Wind velocities in the upper atmosphere will be governed by the Laplace tidal equation, and the components of the equation can be used to simplify the expression on the left of Eq. (18).

### Laplace tidal equation

Taylor, in his paper on oscillations of the atmosphere (Taylor, 1936), showed that when the temperature of the atmosphere is a function only of height above the ground, free oscillations are possible which are identical with those of a sea of uniform depth H, except that the amplitude of the oscillations is a function of the height.

Movements of the upper atmosphere are governed by the Laplace tidal equation, which includes Coriolis forces and conservative forces. In vectorial form

$$\frac{\partial \mathbf{v}}{\partial t} + 2\Omega \times \mathbf{v} = -\nabla F \tag{Eq. 20}$$

If  $v_{\theta}$  and  $v_{\phi}$  denote the southward and eastward components of velocity relative to the surface of the rotating Earth of radius *a*, the horizontal components of Eq. (20) are

$$\frac{\partial v_{\theta}}{\partial t} - 2\Omega v_{\phi} \cos \theta = -\frac{1}{R} \frac{\partial F}{\partial \theta},$$
  
$$\frac{\partial v_{\phi}}{\partial t} + 2\Omega v_{\theta} \cos \theta = -\frac{1}{R \sin \theta} \frac{\partial F}{\partial \phi},$$
 (Eq. 21)

The function F is the scalar potential of conservative forces,

$$F = \delta p / \rho + V. \tag{Eq. 22}$$

With  $e^{iMt}$  time dependence, Eq. (21) can be written

$$iMv_{\theta} - 2\Omega v_{\phi} \cos \theta = -\frac{1}{R} \frac{\partial F}{\partial \theta},$$
  

$$iMv_{\phi} + 2\Omega v_{\theta} \cos \theta = -\frac{1}{R \sin \theta} \frac{\partial F}{\partial \phi}.$$
 (Eq. 23)

With  $e^{im\phi}$  longitude dependence, the Laplace tidal equation in the form of Eq. (23) can be solved for  $v_{\theta}$  and  $v_{\phi}$ ,

$$v_{\theta} = \frac{iM}{4R\Omega^2(f^2 - \cos^2\theta)} \left(\frac{\partial F}{\partial \theta} + \frac{m}{f}F\cot\theta\right), \quad (\text{Eq. 24})$$

$$v_{\phi} = \frac{-M}{4R\Omega^2(f^2 - \cos^2\theta)} \left(\frac{\cos\theta}{f}\frac{\partial F}{\partial\theta} + \frac{m}{\sin\theta}F\right)$$
(Eq. 25)

where  $f = M/2\Omega$ .

From Eqs. (24) and (25), the divergence of the velocity is

$$\frac{1}{\sin\theta} \left[ \frac{\partial v_{\phi}}{\partial \phi} + \frac{\partial}{\partial \theta} (v_{\theta} \sin \theta) \right] = \frac{iM}{4R\Omega^2} LF$$
 (Eq. 26)

where the operator L is defined by

$$LF = \frac{1}{\sin\theta} \frac{\partial}{\partial\theta} \left( \frac{\sin\theta}{f^2 - \cos^2\theta} \frac{\partial F}{\partial\theta} \right) - \frac{1}{f^2 - \cos^2\theta} \left[ \frac{m}{f} \frac{f^2 + \cos^2\theta}{f^2 - \cos^2\theta} + \frac{m^2}{\sin^2\theta} \right] F, \quad (Eq. 27)$$

where  $f = M/2\Omega$ . Eigenfunctions  $F(\theta)$  of the operator L, are denoted  $\Theta^M(\theta)$  and have  $e^{im\phi}$  longitudinal dependence, and  $e^{iMt}$  time dependence,

$$L\Theta^M = -(4R^2\Omega^2/g\,h^M)\Theta^M. \tag{Eq. 28}$$

For specific values of M, the eigenfunctions  $\Theta^M$  form an orthogonal set. The eigenvalue  $4R^2\Omega^2/gh^M$  is chosen to correspond to the theory of the oscillations of a shallow ocean of depth  $h^M$  on a rotating sphere of radius R.

Eliminating the scalar potential  $F(\theta, \phi)$  in Eq. (23) leads to the remarkable simplification required in Eq. (18), namely

$$\frac{1}{\sin\theta} \left[ \frac{\partial v_{\phi}}{\partial \phi} \cos\theta + \frac{\partial}{\partial \theta} (v_{\theta} \sin\theta \cos\theta) \right] \\ = \frac{iM}{2\Omega} \frac{1}{\sin\theta} \left[ \frac{\partial v_{\theta}}{\partial \phi} - \frac{\partial}{\partial \theta} (v_{\phi} \sin\theta) \right]$$
(Eq. 29)

### Longuet-Higgins calculation

Longuet-Higgins (1968) used spectral analysis of tidal modes of "stream function" and "potential" function type for a shallow ocean on a rotating sphere. Tarpley (1970) pointed out the need to use wind velocities based on the Laplace tidal equation, and not just the gradient of a scalar potential. He showed the influence of the various tidal modes in the combinations of spherical harmonic coefficients obtained by analysis of global distributions of hourly mean values.

The horizontal components of velocity with potential and stream function components,  $\Phi$  and  $\Psi$ , respectively, are

$$v_{\theta} = \frac{\partial \Phi}{\partial \theta} + \frac{1}{\sin \theta} \frac{\partial \Psi}{\partial \phi},$$
  
$$v_{\phi} = \frac{1}{\sin \theta} \frac{\partial \Phi}{\partial \phi} - \frac{\partial \Psi}{\partial \theta}.$$
 (Eq. 30)

In particular, the eigenvalues of the Laplace tidal equation yield eigenfunctions for  $\Phi$  and  $\Psi$  simultaneously. It follows from Eq. (30) that

$$\frac{1}{\sin\theta} \left[ \frac{\partial v_{\phi}}{\partial \phi} + \frac{\partial}{\partial \theta} (v_{\theta} \sin \theta) \right] = \nabla_{\mathrm{H}}^{2} \Phi, \qquad (\text{Eq. 31})$$

$$\frac{1}{\operatorname{in}\theta} \left[ \frac{\partial v_{\theta}}{\partial \phi} - \frac{\partial}{\partial \theta} (v_{\phi} \sin \theta) \right] = \nabla_{\mathrm{H}}^{2} \Psi, \qquad (\text{Eq. 32})$$

where  $\nabla_{\rm H}^2$  is the horizontal Laplacian, defined in Eq. (19).

s

When  $\Phi(\theta, \phi)$  and  $\Psi(\theta, \phi)$  are represented as a series of associated Legendre functions,

$$\Phi(\theta,\phi) = \sum_{n=m}^{\infty} A_n^m P_n^m(\cos\theta) e^{i(m\phi+Mt)},$$
  
$$\Psi(\theta,\phi) = \sum_{n=m}^{\infty} i B_n^m P_n^m(\cos\theta) e^{i(m\phi+Mt)},$$

then Eqs. (31) and (32) lead to the equations for the eigenvalues  $h^M$ , and eigenfunctions, namely, in which the coefficients  $A_n^m$  and  $B_n^m$  are calculated simultaneously.

From Eqs. (26), (28), and (31), for the horizontal divergence of the flow, the horizontal Laplacian of the potential flow is proportional to the eigenfunctions  $\Theta^M$ 

$$\nabla_{H}^{2} \Phi = -\frac{iM}{4R\Omega^{2}} L \Theta^{M} = -\frac{iMR}{gh^{M}} \Theta^{M}.$$
 (Eq. 33)

From Eqs. (18), (29), and (32), the velocity stream function term  $\Psi(\theta, \phi)$ , is given in terms of the current function  $W(\theta, \phi)$ , which has been calculated by spherical harmonic analysis of geomagnetic data:

$$\nabla_{\rm H}^2 \Psi = \frac{i\kappa\Omega}{aMG_1^0} \nabla_{\rm H}^2 W(\theta,\phi). \tag{Eq. 34}$$

Equations (33) and (34) are valid only for an ionosphere with constant conductivity, whereas the ionospheric conductivity will be small during nighttime hours and large during daylight hours. For this particular approximation, Eq. (34) indicates that from the known current function  $W(\theta, \phi)$ , the coefficients  $B_n^m$  of the stream function component  $\Psi(\theta, \Phi)$  of wind velocity can be obtained. These coefficients are determined by eigenvalue calculation at the same time as coefficients  $A_n^m$  of the potential function component  $\Phi(\theta, \phi)$  of wind velocity and allow a direct determination of wind velocity modes from the magnetic field daily variation current function. See, for example, Winch (1981).

### Ionospheric conductivity

The electrical conductivity of an ionized gas in the presence of a magnetic field is no longer uniform, but depends on the relative orientation of the applied electric field and the magnetic flux density B. The electric field can be resolved into three components. Thus component of E parallel to B is denoted  $E_0$ ; the component of E perpendicular to B in the plane containing both E and B is denoted  $E_1$ ; the component of E in the direction  $B \times E$  is denoted  $E_2$ . The current density J is given by

$$\boldsymbol{J} = \sigma_0 \boldsymbol{E}_0 + \sigma_1 \boldsymbol{E}_1 + \sigma_2 \boldsymbol{E}_2. \tag{Eq. 35}$$

in which  $\sigma_0$  is the longitudinal conductivity,  $\sigma_1$  the Pedersen conductivity, and  $\sigma_2$  the Hall conductivity.

Thus, if **b** is used to denote a unit vector in the direction of the magnetic flux density **B**, then if  $\chi$  is used to denote the magnetic dip, being the angle that the magnetic needle dips below the horizontal, the spherical polar components of the unit vector **b** are

$$\boldsymbol{b} = -\sin\chi\,\boldsymbol{e}_r - \cos\chi\,\boldsymbol{e}_\theta. \tag{Eq. 36}$$

Spherical polar components of the electric field  $E_0, E_1$  and  $E_1$  are

$$E_{0} = (E \cdot b)b,$$

$$= (E_{r} \sin \chi + E_{\theta} \cos \chi) \sin \chi e_{r} + (E_{r} \sin \chi)$$

$$+ E_{\theta} \cos \chi) \cos \chi e_{\theta}$$

$$E_{1} = E - E_{0},$$

$$= (E_{r} \cos \chi - E_{\theta} \sin \chi) \cos \chi e_{r} - (E_{r} \cos \chi - E_{\theta} \sin \chi)$$

$$\times \sin \chi e_{\theta} + E_{\phi} e_{\phi},$$

$$E_{2} = b \times E,$$

$$= -E_{\phi} \cos \chi e_{r} + E_{\phi} \sin \chi e_{\theta} + (E_{r} \cos \chi - E_{\theta} \sin \chi) e_{\phi}.$$
(Eq. 37)

The spherical polar components of current are

$$J_r = (\sigma_0 \sin^2 \chi + \sigma_1 \cos^2 \chi) E_r + (\sigma_0 - \sigma_1) \sin \chi \cos \chi E_\theta$$
  

$$-\sigma_2 \cos \chi E_\phi,$$
  

$$J_\theta = (\sigma_0 - \sigma_1) \sin \chi \cos \chi E_r + (\sigma_0 \cos^2 \chi + \sigma_1 \sin^2 \chi) E_\theta$$
  

$$+\sigma_2 \sin \chi E_\phi,$$
  

$$J_\phi = \sigma_2 \cos \chi E_r - \sigma_2 \sin \chi E_\theta + \sigma_1 E_\phi.$$
 (Eq. 38)

At the dip equator,  $\chi = 0$ , and Eq. 38 reduces to

$$\begin{aligned} J_{r}|_{\chi = 0} &= \sigma_{1}E_{r}|_{\chi = 0} - \sigma_{2}E_{\phi}|_{\chi = 0}, \\ J_{\theta}|_{\chi = 0} &= \sigma_{0}E_{\theta}|_{\chi = 0}, \\ J_{\phi}|_{\chi = 0} &= \sigma_{2}E_{r}|_{\chi = 0} + \sigma_{1}E_{\phi}|_{\chi = 0}. \end{aligned}$$
(Eq. 39)

At the dip equator, the fluid velocity v and the magnetic flux density B are both horizontal, and the dynamo electric field  $v \times B$  will be a purely radial field  $E_r|_{\chi=0}$ . By the first of Eq. (39), and electrostatic field  $E_{\phi}|_{\chi=0}$  appears,

$$E_r|_{\chi=0} = \frac{1}{\sigma_1} J_r|_{\chi=0} + \frac{\sigma_2}{\sigma_1} E_\phi|_{\chi=0}.$$
 (Eq. 40)

Substitution of Eq. (40) into  $J_{\phi}\Big|_{\chi=0}$  of Eq. (39) gives

$$J_{\phi}\Big|_{\chi = 0} = \frac{\sigma_2}{\sigma_1} J_r \Big|_{\chi = 0} + \sigma_3 E_{\phi}\Big|_{\chi = 0}$$

in which  $\sigma_3$  is the Cowling conductivity, defined at the dip equator by

$$\sigma_3 = \sigma_1 + \frac{\sigma_2^2}{\sigma_1} = \frac{\sigma_1^2 + \sigma_2^2}{\sigma_1},$$
 (Eq. 41)

which is clearly greater than the Pedersen conductivity  $\sigma_1$ .

### Equatorial electrojet

At observatories within one or two degrees of the magnetic equator, particularly at Huancayo in Peru, the regular daily variations in horizontal intensity are larger than at observatories further away from the magnetic equator. The section of the equivalent ionospheric current system that is responsible for this variation was first called the equatorial electrojet by Chapman (Chapman, 1951), and it is a narrow band of current flowing eastward along the magnetic dip equator in the sunlit section of the ionosphere. Baker and Martyn (Baker and Martyn, 1953) showed that "thin-shell" approximation, in which the radial component of current generated by the ionospheric dynamo is inhibited, leads to an effective enhancement of conductivity in a narrow band along the dip equator.

Vector component data from the Magsat satellite of 1980, in an orbit that remained on the dawn and dusk terminators in the ionospheremagnetosphere region, allowed modeling of the morning and afternoon structure of the equatorial electrojet. The more recent CHAMP and Ørsted satellites, moving steadily through a range of local times, provide information on the longitudinal distribution and local time variation of the equatorial electrojet. Studies also continue at observatories in India, Africa, and Vietnam that are along, and in lines directly across the magnetic equator.

### Thin-shell approximation

From the first of Eq. (38) use

$$(\sigma_0 \sin^2 \chi + \sigma_1 \cos^2 \chi) E_r$$
  
=  $J_r - (\sigma_0 - \sigma_1) \sin \chi \cos \chi E_\theta + \sigma_2 \cos \chi.$  (Eq. 42)

to eliminate  $E_r$  in Eq. (38) to obtain

$$J_{\theta} = \frac{(\sigma_0 - \sigma_1)\sin\chi\cos\chi}{\sigma_0\sin^2\chi + \sigma_1\cos^2\chi} J_r + \sigma_{\theta\theta}E_{\theta} + \sigma_{\theta\phi}E_{\phi},$$
  
$$J_{\phi} = \frac{\sigma_2\cos\chi}{\sigma_0\sin^2\chi + \sigma_1\cos^2\chi} J_r - \sigma_{\theta\phi}E_{\theta} + \sigma_{\phi\phi}E_{\phi}.$$
 (Eq. 43)

The tensor conductivity components are

$$\sigma_{\theta\theta} = \frac{\sigma_0 \sigma_1}{\sigma_0 \sin^2 \chi + \sigma_1 \cos^2 \chi},$$
  

$$\sigma_{\theta\phi} = \frac{\sigma_0 \sigma_2 \sin \chi}{\sigma_0 \sin^2 \chi + \sigma_1 \cos^2 \chi},$$
  

$$\sigma_{\phi\phi} = \frac{\sigma_0 \sin^2 \chi + \sigma_3 \cos^2 \chi}{\frac{\sigma_0}{\sigma_1} \sin^2 \chi + \cos^2 \chi}.$$
(Eq. 44)

At the dip equator,  $\chi = 0$ , the conductivity  $\sigma_{\phi\phi}$  reduces to the Cowling conductivity,

 $\sigma_{\phi\phi}\Big|_{\chi=0} = \sigma_3. \tag{Eq. 45}$ 

In the ionosphere,  $\sigma_0 \approx 800\sigma_1$ , and this tends to keep the conductivity  $\sigma_{\phi\phi}$  much smaller than the Cowling conductivity  $\sigma_3$  in all regions except those where the magnetic dip is small. In a narrow band along the dip equator, corresponding to the equatorial electrojet,  $\sigma_{\phi\phi}$  is approximately equal to the Cowling conductivity.

### Disturbance daily variation

The disturbance daily variation is simply the daily variation that occurs when the Earth rotates about the geographic axis when it is surrounded by a ring current system symmetric about the geomagnetic axis.

### Annual variation

Walker, in his Adam's Prize essay of 1866 (Walker, 1866) includes a chapter on the annual variation, recording that Cassini noted an annual variation in the direction of the compass needle in 1786. Modern analyses show that there are both annual and semiannual components. Spherical harmonic analysis shows that the annual term is dominantly a zonal quadrupolar term, and the semiannual term is a zonal dipolar term. Determination of these long period terms is difficult due to aliasing by shorter period variations. For example, a calculation based on midnight values only will detect the K1 tide, a sidereal time variation, as an annual term. The precise origin of these terms is still debated, but annual changes in the Sun-Earth geometry have been proposed, together with the corresponding changes in the influences of the solar wind on the Earth's magnetosphere and ring current.

## PLATE TECTONICS, CHINA

Our Earth is a layered planet with a dense iron core, a surficial crust of light rock, and between them, a solid silicate, convecting mantle. Plate tectonics is the surface manifestation of mantle convection. This activity gives rise to seafloor spreading, continental drift, earthquakes, and volcanic eruptions. Specifically, plate tectonics is the theory and study of plate formation, movement, interactions, and destruction, with seafloor spreading ridges, transform faults, and subduction zones as the plate boundaries. Today, many displaced continental blocks have been found in the world, and the original locations of some have yet to be worked out. Nevertheless, the concept of continental drift is now accepted as a necessary consequence of plate tectonics, and the complexity of mountain belts is well recognized as the product of the great mobility of lithospheric plates.

Paleomagnetism, which is the study of the ancient magnetism of the Earth, has played a central role in this developing view of the dynamic Earth. In the 1950s and early 1960s, scientists collected rocks on land all over the world and determined their magnetism and ages in order to reconstruct the history of the Earth's magnetic field. This worldwide effort led to the discovery of reversals of the geomagnetic field, and thus the realization that the seafloor acts as a tape recorder of the Earth's magnetic reversals, and polar wandering (McElhinny and McFadden, 2000). In particular, polar wandering is an interpretation given to the observation that the magnetic pole-and the geographic pole-has moved extensively in the geologic past. In the absence of any external influences, however, the direction of the Earth's axis of rotation cannot shift but remains fixed in space for all the time due to the law of conservation of angular momentum. The only way out of this dilemma is-the continents have to be moved relative to the axis of rotation. Thus, polar wandering is actually a manifestation of the mobility of the lithospheric plates. There are two principal ways of summarizing paleomagnetic data for a given region. One approach is to construct paleogeographic maps of the region for different geologic periods. These maps are mostly useful for comparison with relevant information, but not easy to view overall variations over different geologic time intervals. A much simpler and convenient way is to plot successive positions of paleomagnetic pole for a given continent from epoch to epoch on the present latitude-longitude grid. Such a path, traced out by the paleomagnetic poles and relative to the continent, is called the apparent polar wander path (APWP).

### Fundamental principles in paleomagnetism

The first assumption of paleomagnetism is that the time-averaged geomagnetic field is produced by a single magnetic dipole at the center of the Earth and aligned with the Earth's rotation axis (McElhinny and McFadden, 2000). Thus, the calculated paleomagnetic pole coincides with the geographic pole. This geocentric axial dipole (GAD) hypothesis means that, when averaged over time, magnetic north is geographic north and there are simple relationships between the geographic latitude and the inclination of the field, which are the cornerstones of paleomagnetic methods applied to plate reconstruction and paleogeography. Paleomagnetic data can be used to find latitude and north-south orientation of the paleocontinents. Paleolatitude can be also checked with paleoclimate records (Irving, 1964). Although it is not possible to assign longitudinal position to the paleocontinents, the relative positions of the continents around the globe can often be pieced together by matching the shapes of apparent polar wander paths.

The configuration of the Earth's field today is modeled fairly closely by a geocentric dipole inclined at 11.5° to the rotation axis, but the field for most of the Tertiary, when averaged over periods of several thousand years, agrees well with the GAD model (Merrill et al., 1996). During the 1950s and early 1960s, many questioned the validity of the GAD hypothesis during the Paleozoic and Mesozoic. With the expansion of paleomagnetic data and development of plate tectonics studies, the validity of the GAD hypothesis as a good working approximation now appears to be on solid ground (McElhinny and McFadden, 2000). Rigorously selected paleomagnetic data are in quite good agreement with plate tectonic reconstructions and also internally self-consistent under the assumption of a GAD field (Besse and Courtillot, 2002). Moreover, paleolatitude changes calculated from paleomagnetic data are consistent with paleoclimatic changes: the distribution of various paleoclimatic indicators is latitude dependent (Irving, 1964; Ziegler et al., 1996).

The second assumption of paleomagnetism applied to plate tectonics is that one can use rocks as fossil compasses that record the Earth's ancient field. Study and experiments have proved that igneous and sedimentary rocks acquire primary magnetization when they were formed (McElhinny and McFadden, 2000). But determining whether the natural remanent magnetization of rocks is primary is often problematical and challenging. The original magnetization may be unstable to later physical or chemical processes and partially or completely overprinted over geologic time. Some sedimentary rocks have been shown to record paleomagnetic directions significantly shallower than the ancient field direction, a phenomenon termed inclination error (Tauxe, 1998, 2005). An important factor in making meaningful tectonic interpretations from volcanic rocks is the need to sample many separate flows that span many thousand years, a requirement that cannot always be fulfilled. The reason for this is the necessity of averaging out secular variation of the magnetic field, which typically produces a 10-20° angular dispersion of instantaneous directions, so as to obtain the time-averaged, GAD field direction (McElhinny and McFadden, 2000).

### Supercontinent Gondwanaland and its dispersion

The past existence of the Gondwanaland supercontinent, a huge landmass comprised of over half of the world's present continental crust, is now clearly confirmed by paleomagnetic and paleobiogeographic data (Li, 1998). Late Precambrian to Early Paleozoic paleomagnetic data suggest that the Gondwanaland supercontinent had assembled just before the end of Early Cambrian (520 million years ago, Ma) as a result of collision between proto East Gondwanaland (Antarctica, India, Australia) and proto West Gondwanaland (Africa, Arabia, South America, and possibly Madagascar). For at least 100 Ma during the Late Devonian to Middle Carboniferous, Gondwanaland is thought to have remained over the south pole, as indicated by the available paleomagnetic data (Li and Powell, 2001) and southern cold-water fauna (Yin, 1988) and cool-climate flora (Runnegar and Cambell, 1976; Ziegler, 1990). By 320–310 Ma, Gondwanaland had collided with Laurussia to form a single supercontinent named Pangea, which stretched from pole to pole. The fragmentation of Pangea occurred as a result of plate tectonics and continental drift over Late Paleozoic, Mesozoic, and Cenozoic time to form the modern continents and oceans (Metcalfe, 1999).

Starting in Late Paleozoic time, fragmentation of Pangea (and former Gondwanaland continents) and the concomitant expansion of Eurasia have occurred repeatedly. The latest example is the addition of India to Eurasia in Early Cenozoic time (McElhinny and McFadden, 2000). Indeed, this global geographical reorganization is still in progress, as evidenced in part by the continued movement of Australia northward toward Asia (White, 1995). The ability of modern science to reconstruct this paleo-supercontinent is truly impressive. Earth scientists are continuing to sort out more details of this complex jigsaw puzzle, whose individual pieces change shape over geologic time.

### Tectonic framework of China

China, which covers 9.6 million square kilometers (6.5% of the Earth's land surface) in eastern Asia, is complex and interesting from both tectonic and paleogeographic standpoints. In its simplest form, China consists of three large Precambrian continental cratons, namely, the Tarim, North China Blocks, and South China Blocks (NCB and SCB), separated by Paleozoic and Mesozoic accretionary belts, as well as several smaller blocks or terranes (Tibet, Junggar and Qaidam basins, and the Alashan/Hexi Corridor, see Figure P47). Several recent studies favor the hypothesis that these continental blocks and terranes were derived from Gondwanaland (Wang et al., 1999). A close biogeographic association of South China with Australia has been recognized for both the Cambrian and Devonian, suggesting that South China may have been part of Gondwanaland in Early and Middle Paleozoic time (Burrett and Richardson, 1980; Long and Burrett, 1989). Some paleontological data from Tarim show that Cambrian and Ordovician Bradoriida fossils are very similar to those of South China, which in turn would suggest that Tarim was also part of Gondwanaland in the Early Paleozoic (McKerrow and Scotese, 1990; Shu and Chen, 1991). But it is less clear whether North China belonged to Gondwanaland or not during this same period. Early Cambrian fauna from North China show affinity with Australia, but Ordovician benthic trilobite assemblages in North China show more similarity with those of Siberia and North America (Burrett et al., 1990). Comparative studies of the tectono-stratigraphy, paleontology, and structural geology of the various terranes in the Tibetan Plateau suggest that they were all derived directly or indirectly from Gondwanaland (Metcalfe, 1999) and added successively to the Eurasian plate during the Mesozoic and Cenozoic eras (Burg and Chen, 1984).

If, indeed, these Chinese blocks and terranes were associated with Gondwanaland during the Early Paleozoic, then the key questions would be, when and in what sequence did these blocks rift off from Gondwanaland and stitch as they are at present. As outlined below, geologic data germane to these questions are sparse and subject to conflicting interpretations (e.g., Klimetz, 1983; Mattauer *et al.*, 1991; Hsu *et al.*, 1988).

### North China block

The North China block is bounded on the north by the Central Asian Fold Belt and on the south by the Qilian-Qingling-Dabie Shan ("shan" = mountain in Chinese). The Tancheng-Lujiang (more often referred to by the Chinese contraction "Tanlu") fault runs through the eastern part of the NCB, and sharply cuts the Qinling belt at its eastern end. There is considerable debate as to whether or not the fault represents the eastern boundary of the NCB, and its origin and history of development. The oldest basement rock was dated as  $3670 \pm 230$  Ma, which is possibly the oldest age in China (Li and Cong, 1980). The oldest unmetamorphosed sedimentary cover has been dated at 1700 Ma (Wang, 1993).

**Figure P47** Simplified map (after Halim *et al.*, 2003) of Eastern Asia showing the main sutures and faults (KF, Karakorum fault; MBT, Main Boundary Thrust). The major blocks are: Afg, Afganistan; Eur, Eurasia; Inc, Indochina; Ind, India; Jun, Junggar; Kaz, Kazakhtan; Kun, Kunlun; Mon, Mongolia; NCB, North China block; Qa, Qaidam; Qi, Qiangtang; Sib, Siberia; SCB, South China block; ST, Shan Tai; and Tar, Tarim. Also indicated are the main locations where Cretaceous paleomagnetic data are available. Declination is indicated by arrows (a thin line indicates geographic north, it is vertical because of the projection selected). Open arrows are for areas suspected of major local scale deformation or unreliable paleomagnetic data. Solid arrows are thought to be representative of the individual blocks at a larger scale.

The Paleozoic sections of the NCB are dominated by Lower Paleozoic marine carbonates and characterized by a great sedimentary hiatus from the Late Ordovician through Early Carboniferous, although rare strata within this age span apparently exist on its western boundary. This remarkable hiatus has led many geologists to the conclusion that the NCB was separated from currently adjacent blocks during much of Paleozoic time. From the Late Permian onwards, its sediments are of continental origin.

The Korean Peninsula is situated east of the NCB. Traditionally, Korea has been incorporated with the NCB into a single craton (Sino-Korea) based on the close similarity of Paleozoic stratigraphy. Depending on the significance of Tanlu fault movement, it is possible that the Korean Peninsula (or part of it) was formerly located close to the South China Block, a question that is still intensively debated.

Geological estimates of the age of accretion of the NCB with Siberia to the north are also controversial. It is assigned a Middle Paleozoic age (end of Devonian and Hercynian Orogeny), while Klimetz (1983) ascribes it to the Mesozoic. By analyzing paleobiogeographic data, Laveine *et al.* (1989) argued that the Chinese blocks must have

been close to Europe in the Late Carboniferous, as shown by plant migration routes.

### South China block

The South China Block is bounded on the north by the Qinling and Dabie Shan, which mark the suture between the SCB and NCB (see Figure P47). Exposures of basement rocks are limited, but a U-Pb ziron date of 2860 Ma was reported for migmatitic granite in Guangxi province, indicating that the block may have formed in the late Archean. The basement of the SCB was finally consolidated around 850–800 Ma. The Paleozoic and Mesozoic strata consist mainly of marine carbonate and clastic sediments, with continental lava flows in the Late Permian. The Cenozoic strata are mainly red beds.

In the eastern part of the Qinling-Dabie Mountains, ultrahigh-pressure, coesite- and diamond-bearing metamorphic rocks crop out. Ages from U-Pb dating of zirons from eclogites range from 250 to 220 Ma, which correspond to the time when sedimentation in the SCB changed from marine to continental. This change was heralded by the voluminous eruption of the Emeishan basalts in southwestern China around 250 Ma. Great quantities of Jurassic red beds in the Sichuan Basin indicate that large neighboring mountains were being eroded at that time. Northeast of the Dabie Shan in eastern Shandong Peninsula lies another ultrahigh-pressure coesite-bearing metamorphic suite. Similarities in mineralogy of the Shandong and Dabie Shan metamorphic assemblages suggest they were once part of the same belt that was later displaced about 500 km by the Tanlu fault in a left-lateral sense. There are widely different estimates on the timing of collision between the SCB and NCB based on geologic data. These estimates vary from the Precambrian and Middle Paleozoic to the end of the Paleozoic and earliest Mesozoic.

The SCB is commonly segregated into the Yangtze block to the northwest and mobile belts to the southeast. In general, the division between the Yangtze block and exotic terranes is demarcated south of the exposed Meso- to Neoproterozoic low-grade metamorphic rocks called the Jiangnan old land. Jiangnan rocks include ophiolite and thick argillaceous turbidites that extend for over 1000 km. Using Sm (samarium) and Nd (neodymium) isotopes, two laboratories have dated two of the ophiloite suites at 1024  $\pm$  24 Ma and 935  $\pm$  34 Ma, and 1034  $\pm$  24 Ma and 935  $\pm$  10 Ma, respectively. Li et al. (1995) and Li (1998) suggested that the Yangtze Block and fold belts to the southeast were amalgamated in the late Proterozoic at around 1000 Ma and are separated by a failed intracontinental rift activated during the breakup of Rodinia at around 700 Ma. There is no welldocumented evidence of a Phanerozoic suture in the SCB. Hsu et al. (1988) proposed a Mesozoic age collision model based on the discovery of Mesozoic thrust structures in south China. This new interpretation of south China tectonics has since led intensive debate.

### Tarim and Junggar basins

Tarim is a rhombic-shaped basin, bounded by the Tianshan, ("Celestial Mountains"), Kunlun and Altyn Tagh mountain ranges, with Precambrian basement (3.3 Ga) exposed along its periphery (Hu and Rogers, 1992), attesting to an extensive geologic history for the block. Tarim became an inland basin since the beginning of the Mesozoic and it is presently covered by the Takalamagan (Takla Makan) desert, with Paleozoic rocks occurring mostly along its northern and southern margins. Cambrian and Ordovician strata are distributed mainly along the northern periphery of the basin, whereas the Silurian, Devonian, Carboniferous and Permian are mainly distributed in the northwestern part of the basin (Keping area). The lithologies of these Paleozoic sequences are mainly dolomitic limestone and red and yellow siltstones. The Mesozoic and Cenozoic strata consist mainly of green sandstone and red mudstone and are distributed in the northeast part of the basin (Kuche depression). A late Paleozoic (Hercynian) orogeny was responsible for a general unconformity between Paleozoic and Mesozoic formations.

Of the three major blocks that compose the tectonic framework of China, Tarim, being the most inboard must have arrived at its present position at least as early as any of the more outboard blocks and terranes. There is no clear suture zone between Tarim and the NCB. Indeed, some geologists considered the NCB and Tarim to have formed a rigid block since the Neoproterozoic because an almost continuous—"Hexizoulang", equivalent to "Hexi Corridor"—of Precambrian and Paleozoic formations connects the NCB and Tarim. This idea has been abandoned because available paleomagnetic data suggest that these two blocks did not assume their present configuration for sometime in the Mesozoic.

The Junggar Basin, often considered to be the southeast extremity of the Kazakhstan Block, sits in a complicated region squeezed between the Tarim Basin on the south, the Kazakhstan Block on the west, and Siberia to the northeast. Unlike the Tarim Basin, there are no known exposures of Precambrian rocks along the Junggar Basin margins. However, some researchers have suggested that Junggar is underlain by Precambrian crystalline basement, based entirely upon gravimetrically determined depths to the Moho (e.g., Ren *et al.*, 1987). Other workers believe that it is underlain by a basement of structurally imbricated Ordovician to Lower Carboniferous accretionary metasedimentary rocks and oceanic crustal fragments. The oldest rocks in this region are of Late Cambrian age ( $508 \pm 60$  Ma). Middle Devonian strata consist of spilitic pillow lavas interlayered with radiolarian cherts and associated limestone horizons. Carboniferous units consist mainly of marine to continental volcanic rocks interbedded with clastics. Potassium-rich granitic plutons and their extrusive equivalents, which have Permian K-Ar ages and Middle to Late Carboniferous U-Pb ages are common in west Junggar. Permian rocks are mainly continental clastics and volcanic extrusive. At many localities igneous dikes of Permian age intrude the Carboniferous formations. Triassic and Jurassic sequences are all continental clastics.

Collision between Tarim and Junggar along the Tianshan Range has been inferred to be Early Permian in age, based on geological features such as the termination of andesitic volcanism, the development of unconformitites between late Early Permian and underlying units, the intrusion of widespread syncollisional to postcollisional granites in the Tianshan and the mixture of Angaran and Cathaysian flora across the Tianshan.

### Alashan/Hexi Corridor terrane

Situated west of Ordos, the Alashan/Hexi Corridor terrane is bounded on the north by Central Asian Fold Belt and is separated from the Qaidam terrane by the Qilian Shan fold belt to the south. The western boundary with the Tarim is not clearly delineated but is thought to be within the northern Qilian Shan.

The oldest rock of the Alashan/Hexi Corridor terrane is Precambrian (about 1850 Ma), as the Precambrian Longshoushan Formation in the southern part is intruded by granites 1789 Ma in age (Yang *et al.*, 1986, p. 244). The first most recognized regional uncomformity in southern Alashan area is between Middle and Late Cambrian (the Xianshan Formation), which can be correlated to the coeval unconformity the Ordos basin, one of the most stable parts of the NCB. In contrast, this geologic pattern never penetrated into the Central Asian Fold Belt, indicating the latter indeed is the geologic/block boundary. Because of these geological observations, Alashan/Hexi Corridor terrane is believed to be part of the NCB at least since the Late Cambrian and was still receiving deposition while most other parts of the NCB were standing higher during Late Ordovician to Early Carboniferous time.

### Tibet and Qaidam basin

Tibet is a collage of continental terranes that accreted onto Eurasia ahead of India. From north to south, the Tibetan terranes are the Kunlun, Songpan-Ganze, Qiangtang, Lhasa, and Himalaya terranes, the latter being actually part of the Indian subcontinent (see Figure P47). Geologic studies suggest that these terranes collided with Eurasia at times progressively younging southward (Dewey et al., 1988; Yin and Harrison, 2000; Davis et al., 2002). The amalgamation of the Kunlun and Songpan-Ganze terranes is marked by a broad Early Paleozoic arc on which was later superposed a Triassic arc (Burchfield et al., 1992). The Qiangtang terrane accreted to the Songpan-Ganze terrane along the Jinsha suture during the Late Triassic or Early Jurassic (Xiao et al., 2002), followed by the docking of the Lhasa terrane against the Qiangtang block along the Bangong-Nujiang suture during the Late Jurassic (Dewey et al., 1988), although the precise age of suturing and subsequent reactivation by other collisions are still debated. The Indian subcontinent in turn collided with these terranes along the Yarlung-Zangbo suture during Late Cretaceous to Eocene time (Murphy et al., 1997).

The Qaidam Basin is relatively a lower elevation region of the northeast Tibetan Plateau bounded by the Altyn Tagh fault to the northwest, the Kunlun fault to the south, and the Nan Shan fold-andthrust belt to the northeast. The nature of Qaidam's basement is not known because it is buried under thick cover strata and still no sufficient borehole or geophysical data are available. Cover strata consist of Cenozoic clastics of terrestrial facies. Tertiary continental sediments in the Qaidam Basin reach several kilometers and serve as the main oil producing layers in the basin. Qaidam's mountain ranges probably formed as ramp anticlines stacked upon a crustal-scale thrust fault. However, compared to complexly deformed surrounding areas, the Qaidam Basin shows only limited deformation of Cretaceous to Tertiary sedimentary cover.

In summary, these geological observations provide fundamental constraints on tectonics models of Chinese blocks. Although the geology of the fold belts between these major Chinese blocks and terranes has the potential of constraining the times of collisions more tightly than the geology of the blocks themselves, the complexity of these fold belts has led to widely different views of the tectonic history of the region. With Gondwanaland in high southern paleolatitudes during the Late Paleozoic and the Chinese blocks nowadays situated at midnorthern latitudes, paleomagnetism is obviously an ideal tool by which to test various Paleozoic paleogeographic models and to unravel the later northward relative motions of these blocks and terranes if they were part of Gondwanaland. As explored below, paleomagnetism offers an independent—and complementary—source of constraints in terms of the style of convergence and timing of amalgamation of individual continental blocks.

## Paleomagnetic constraints on tectonic history of major chinese blocks

The tectonic relationship between crustal blocks can be constrained by comparison of their paleomagnetic poles. If reliable poles of the same age from two blocks are significantly different, one must conclude that the two blocks have moved relative to one another sometime after remanent magnetization was acquired. The converse is not necessarily true, since it is not possible to assign longitudinal position to the paleocontinents according to the GAD model.

Paleomagnetic investigation in China began in the early 1960s. Great development in the acquisition of paleomagnetic data has been made since early 1980s. In particular, the Cretaceous is well-studied paleomagnetically both in terms of data quality and area distribution (see Figure P47). The Global Paleomagnetic Data Base nowadays has included studies from the Chinese literature, but there is still a large variation in quality and reliability of the poles. Detailed reviews of paleomagnetic poles ("paleopoles" for short) for Chinese blocks have been given in several papers and books (e.g., Lin et al., 1985; Zheng et al., 1991; Enkin et al., 1992; Zhao and Coe, 1987; Van der Voo, 1993; Zhao et al., 1996, 1999; McElhinny and McFadden, 2000; Zhu and Tschu, 2001; Yang and Besse, 2001). Several additional paleopoles have become available since 2001. Up to 2003, a total of 415 paleomagnetic poles have been published for Chinese blocks and terranes. Some of these poles are still subject to debate and interpretation. Any serious use of paleomagnetic data from China should always involve independent evaluation and assessment of each study. Thus, our intention is not to list the detailed references for these 415 paleopoles and discuss exhaustively the significance of data. Readers are referred to the Global Paleomagnetic Data Base Version 4.6 (www.tsrc.uwa.edu.au/data\_bases) for more information. These paleomagnetic poles, from both Chinese and English language journals and books, are briefly outlined below.

### Paleomagnetic studies in the North China block (+Hexi Corridor and Korea): 118 Poles

### Quaternary (3 poles)

The Quaternary is represented by only three paleomagnetic poles: two studies on the Chinese Loess Plateau in Shaanxi province and one study on basalt flows in Shandong province.

## Tertiary (7 poles)

Little work has been done on Tertiary rocks in North China as well: Only a total of seven paleopoles have been reported from volcanic and sedimentary rocks from Inner Mongolia, Hebei, Shandong, Shanxi, and Gansu provinces. Most of the results passed reversal tests, although the reliability of some of the studies can still be argued. The scarcity of reliable paleomagnetic poles for these younger geologic time intervals seems to be a result of the low research priority given to them.

### Cretaceous (16 poles)

Twelve Cretaceous paleopoles have been reported from Ningxia, Gansu, Shaanxi, Shanxi, Henan, Shandong, and Inner Mongolia of the NCB. In addition, four studies on Cretaceous rocks from South Korea have been published in the literature. These Cretaceous-aged poles obtained from widely separated regions are consistent with each other, suggesting that these areas occupied the same relative positions in terms of paleolatitudes since the Cretaceous. Clockwise vertical-axis block rotations of 30° of Korea relative to the NCB, however, are implied by the Cretaceous data for Korea.

#### Jurassic (12 poles)

Only one Early Jurassic pole is available from Shaanxi province. Four Late Jurassic poles have been published from three areas of Inner Mongolia and Shanxi provinces and six paleopoles are available for the Middle Jurassic that were derived from sedimentary rocks in Shaanxi and Shanxi provinces. One Late Jurassic pole was reported from Korea, again showing the region has rotated clockwise with respect to China. There is still a worldwide deficiency of Early Jurassic paleomagnetic poles, and North China is no exception.

### Triassic (23 poles)

The Late Triassic in the NCB has only been studied in one region of Shanxi province (2 poles). Nine paleopoles were reported from Middle Triassic formations in Shaanxi and Shanxi provinces. Twelve paleopoles are available for the NCB from the Early Triassic sections in Liaoning, Shandong, Shanxi, and Shaanxi provinces, but five of them are clearly questionable.

#### Permian (26 poles)

A total of 19 Late Permian poles have been obtained from 14 sections distributed over Hebei, Shanxi, Shaanxi, and Inner Mongolia. There are also four Late Permian paleopoles available for Korea. In contrast, only three Early Permian paleopoles are available from Shaanxi and Shanxi province, which are significantly different from each other. Like the Early Triassic, the distribution of the Late Permian paleomagnetic poles is streaked along a small circle centered on the NCB, indicating significant internal deformation that has caused local rotations.

### Carboniferous (6 poles)

Two studies have reported Middle-Late Carboniferous results from Shanxi and Shaanxi province for the NCB. None of them was considered reliable (Zhu and Tschu, 2001), underscoring that more paleomagnetic study of Carboniferous rocks should be a future research focus. Four preliminary Late Carboniferous paleomagnetic poles were reported from Korea.

### Devonian and Silurian (5 poles)

Because of the great sedimentary hiatus during the Devonian and Silurian for the NCB, three studies were conducted in the Alashan/Hexi Corridor in the Ningxia Hui Autonomous region on Middle to Late Devonian and Silurian red beds. Two Middle to Late Devonian and three Middle to Late Silurian paleopoles have been published from these studies.

### Ordovician (10 poles)

Nine paleopoles have been obtained from Liaoning, Hebei, Shandong, Shaanxi provinces and the Ningxia Hui Autonomous region that are distributed along a small circle centered on the NCB, indicating local rotations. One Early Ordovician pole was obtained from Korea. There was a dispute on the magnetic polarity of the stable magnetization from the Ordovician rocks in China, which was resolved by a recent magnetostratigraphic study on rocks spanning the Cambrian/ Ordovician boundary and into early Ordovician.

### Cambrian (10 poles)

Ten Cambrian paleopoles have been reported for the NCB that were derived from rock formations from Liaoning, Shandong, Shanxi, Shaanxi, and Ningxia. These poles can be grouped into three clusters. One group (3 poles) is close to the Triassic pole of the NCB and without stability tests. These poles are suspicious because they may have been remagnetized in the Triassic. Poles in the second group fall near the equatorial area of the western Atlantic while those in the third group are in the eastern Atlantic. The scatter of paleopoles may result from the local rotation of sampling areas or unsatisfactory removal of a second magnetization component.

## Paleomagnetic study in the South China block: 204 poles

### Quaternary (5 poles)

Early Quaternary poles were obtained from a basalt formation in Jiangsu (1 pole) and clays from Yunnan (4 poles). No details concerning sampling sites and laboratory work were given.

### Tertiary (24 poles)

Tertiary paleomagnetic data are numerous for the SCB. A total of 24 paleopoles are available for the SCB, which come from red beds and basalt formations in Yunnan, Guangdong, Sichuan, Hubei, Hunan, Zhejiang, and Jiangsu provinces.

### Cretaceous (26 poles)

Of the 26 paleopoles determined for the Cretaceous, 12 come from sedimentary rocks in Sichuan province. The rest are obtained from red beds and mudstones in Guangxi, Fujian, Yunnan, and Guangxi provinces. There are two poles obtained from volcanic rocks in Zhejiang and Hong Kong, respectively.

### Jurassic (31 poles)

Fourteen poles have been published for the Late Jurassic of the SCB, which were obtained from sandstone and mudstone formations in Zhejiang, Sichuan, Anhui, and Yunnan provinces. The Middle Jurassic is represented by 11 paleopoles that come from sedimentary and volcanic rocks from Guangxi, Hubei, Anhui, Sichuan, Guizhou, and Hong Kong. Six paleopoles from sandstone formations in Sichuan, Hubei, Anhui, Guangxi, and Yunnan are available for the Early Jurassic.

### Triassic (49 poles)

Fifteen Late Triassic poles have been isolated from siltstone sites in Sichuan and Yunnan provinces. Nine Middle Triassic poles were reported from limestone and red sandstone in Hubei, Jiangsu, Guizhou, Sichuan, Hunan, and Guangxi provinces. Most of poles from the Early Triassic limestone formations are from Sichuan. It is important to note that Early Triassic poles from limestone and sandstone formations of Jiangsu and Zhejiang in the eastern extreme of the block are coherent with the poles from west (Sichuan), suggesting that the SCB has behaved more or less rigidly since at least this period.

## Permian (30 poles)

Many high-quality paleomagnetic data for the Late Permian have been presented since McElhinny et al.'s (1981) pioneering paleomagnetic paper on the Emeishan Basalt from Sichuan. Those poles are now from both the Emeishan basalt from Yunnan and Guizhou provinces and red limestone and sandstone from Hubei, Zhejiang, Guangdong, and Sichuan. In contrast, only one Early Permian pole is reported from a limestone section in Hubei province. It is worth mentioning that, like many other fields in Earth sciences, progress in the paleomagnetic data of China has grown through repeated trials, criticisms, and improvements. Some studies may encompass entire lifetimes of devoted work. The debate on the age of magnetization of the Late Permian Emeishan Basalt from the SCB is a case in point. Debate has continued for the last 15 years as to whether the observed magnetic direction is primary or secondary. Although a reported positive conglomerate test by Huang and Opdyke (1995) effectively refuted the suspicion that the directions from the Emeishan Basalt may represent a remagnetization of Triassic or even Jurassic age, it may still require more extensive investigations to unequivocally settle the question.

### Carboniferous (5 poles)

Out of the 5 Carboniferous poles published from limestone and mudstone formations in Zhejiang, Yunnan, and Fujian provinces, none of them, however, can demonstrate the age of magnetization with certainty, reflecting the still insufficient inventory of Chinese paleomagnetic data.

### Devonian (5 poles)

Five poles of Devonian age for the SCB are reported from sandstone formations in Zhejiang, Jiangsu, Yunnan, and Sichuan. The data set is relatively small and also subject to debate. Only one pole was selected by McElhinny and McFadden (2000) to be included in their book.

### Silurian (8 poles)

Silurian poles for the SCB were reported from red beds, sandstone, and limestone in Guizhou, Zhejiang, Hubei, Yunnan, and Sichuan provinces. These poles have been all determined using the modern methods and analytical techniques.

#### Ordovician (8 poles)

Eight Ordovician paleomagnetic poles have been reported for South China that were derived from limestone and sandstone in Zhejiang, Hubei, Yunnan, and Sichuan province. These poles generally have poor quality.

### Cambrian (5 poles)

The collected Cambrian poles were derived from rocks from Zhejiang, Hubei, and Yunnan provinces. The poles are very different from Cambrian poles of the NCB, suggesting that North and South China were two different continental blocks during Cambrian.

## Paleomagnetic study in the Tarim and Junggar basins: 52 poles

### Quaternary (1 pole)

Only one study of Quaternary basalt from the southeast of the Tarim Basin has been published. The age of the basalt is still in dispute, but it seems reasonable for it to represent the Quaternary.

### 822

### Tertiary (11 poles)

Tertiary paleomagnetic poles for Tarim were mainly obtained from the Aertushi region of western Tarim, the Kuche depression of northwest Tarim, and the Maza Tagh range in the central Tarim Basin. Up to 1990, the paleomagnetic database for Tarim was very sparse. The last 13 years saw a major increase in the number of paleomagnetic data for Tarim, which is rather fortunate because tectonic rotations caused by the Indian collision might be constrained by such data.

### Cretaceous (10 poles)

Eight Cretaceous poles were reported for Tarim, all of them from the Kuche depression in northwestern Tarim. Of the eight poles, six were derived from red beds and two were from basalt formations in the Tuoyun area of western Tarim. Two Cretaceous poles were published for the Junggar basin, which are close to Cretaceous poles for Tarim.

## Jurassic (4 poles)

One Late Jurassic and three Middle Jurassic pole are available for Tarim. Both were derived from red bed formations in southwestern Tarim. No coeval pole is available for the Junggar basin.

### Triassic (3 poles)

The Triassic of Tarim is represented by three poles (one each in the Late, Middle, and Early Triassic). Among them, only the Late Triassic was well studied through a magnetostratigraphic investigation.

### Permian (14 poles)

Permian paleomagnetic poles for Tarim are mainly from volcanic rocks in the Aksu, Keping, and Kuche areas of western Tarim, with 7 poles for Late Permian and 5 poles for the Early Permian. Two Late Permian poles have been reported for the Junggar Basin, which is concord with the Permian poles for Tarim. The number and quality of Permian paleopoles for Tarim is quite impressive, suggesting one should treat these poles seriously. No paleopoles older than Permian were reported from the Junggar basin.

#### Carboniferous (4 poles)

Four Carboniferous paleopoles are available for Tarim, which were all derived from sedimentary rocks (limestone and sandstone) from South western Tarim.

#### Devonian (3 poles)

Three Devonian paleomagnetic poles were reported for the Tarim, obtained from both the north and south rims of Tarim.

### Silurian (3 poles)

There are three middle Silurian poles for Tarim. The magnetization is dominated by an extremely weak, recent-field component of magnetization that was carried by goethite. Clearly, these poles are unacceptable for tectonic study.

### Ordovician (1 pole) and Cambrian (1 pole)

Although the number of poles for these two periods is extremely sparse, the reported poles each pass fold and reversal tests and place Tarim in low paleolatitudes during Cambrian and Ordovician.

## Paleomagnetic studies in the Tibet and Qaidam basin: 38 poles

Since the early 1980s, paleomagnetic investigation has been an important aspect of all the major geologic expeditions conducted on the Tibetan plateau. While paleomagnetic investigations of the Cretaceous and younger rocks from the plateau have yielded useful constraints for the Lhasa and Qiangtang terranes (Achache *et al.*, 1984; Lin and Watts, 1988; Otofuji *et al.*, 1989; Huang *et al.*, 1992; Chen *et al.*, 1993), studies on the Paleozoic formations were often hampered by lack of favorable lithology, multiphase deformation, and metamorphism that has obliterated the primary magnetization (Lin and Watts, 1988; Otofuji *et al.*, 1989; Huang *et al.*, 1992). Triassic and Jurassic paleomagnetic directions also tend to be remagnetized (Chen *et al.*, 1993). As a result, there are a total of 8 Tertiary and 13 Cretaceous paleomagnetic poles for Tibet.

Among the Late Cretaceous paleomagnetic results from Tibet, those reported from south Tibet (Achache et al., 1984), east Qiangtang (Huang et al., 1992), and west Qiangtang (Otofuji et al., 1989; Chen et al., 1993) appear to have high quality, each with positive fold test result. However, there is a serious problem in interpreting these Late Cretaceous data in terms of paleolatitude. The study on the Late Cretaceous Takena red beds and Paleocene andesites of the Lhasa Block yielded a paleolatitude of 15-20° N for Lhasa. It should be pointed out that the Paleocene Lingzizong volcanics in the Lhasa area give consistent result (with positive fold and reversal test) with the underlying Cretaceous strata (Achache et al., 1984) and provide a notable example that both red beds and volcanic rock in the Lhasa area recorded the same ancient magnetization. Lin and Watts (1988) sampled the Takena formation in the Linzhou area as well as Late Cretaceous volcanic units in Nagqu and Qelico. Their data pass a fold test and give slightly lower paleolatitudes (7.6  $\pm$  3.5°N), but still similar to the results of Achache *et al.* (1984). If we use the mean of these three results, the paleolatitude of Lhasa in the Late Cretaceous would be about 12.5°N. A comparison of this value with that predicted by the reference pole (Besse and Courtillot, 1991) would confirm the conclusion of Achache et al. (1984, p. 10335) that crustal shortening of the order of 2000 km has occurred between Lhasa and Eurasia since the Late Cretaceous. Calculations of shortening using the Early Tertiary Linzizong volcanic rocks yield a similar amount of northward displacement of the Lhasa terrane. This is compatible with other geophysical and geological estimation that India has moved about 2500 km northward about 50 Ma (e.g., Dewey et al., 1988). However, when comparing the paleolatitude of Lhasa with that of west Qiangtang (Chen et al., 1993) and Tarim/Junggar (Li et al., 1988; Chen et al., 1991), the data suggest that there is no net crustal shortening between Lhasa and west Qiangtang/Tarim/Junggar from the Late Cretaceous to present. In other words, the entire 2000 km of northward displacement of the Lhasa block suggested by the Late Cretaceous paleomagnetic data would have to be taken up in the region to the north of Junggar. This would conflict with existing understanding of the formation of the Tibetan plateau by either the crustal shortening model (Dewey et al., 1988) or the tectonic extrusion model (Tapponnier et al., 2001), or a combination of the two (Harrison et al., 1992). In addition, there is no geologic evidence to suggest a candidate place between Siberia platform and Junggar/Tarim to accommodate crustal shortening of this magnitude in the Tertiary. If the configuration for most or all of the Tibetan plateau has been created by the India/Asia collision, then the Late Cretaceous paleomagnetic results from Lhasa and west Qiangtang /Tarim/Junggar cannot both be correct. Obviously, further work is badly needed to solve this problem, and a reliable paleomagnetic pole from central Qiangtang would provide a direct test.

For the Qaidam Basin, there are 5 Jurassic, 3 Cretaceous, and 9 Tertiary poles reported from paleomagnetic investigations of the basin. These studies were designed to detect possible clockwise rotation of Qaidam basin, as implied by extrusion models. Rotation within the Qaidam-Altyn Tagh region is very controversial, and existing paleomagnetic data are contradictory. Halim *et al.* (2003) presented one Late Jurassic pole from red beds in Huatugou of Qaidam basin. This pole indicates negligible northward convergence of the Qaidam block with respect to Tarim since Late Jurassic times, but implies a significant relative clockwise rotation of the studied area with respect to Tarim (~16°). Similarly, Chen *et al.* (2002) reported that three widely spread areas in Qaidam exhibit 20° clockwise rotations during the Late Oligocene-Late Miocene time. However, recent study from the east end of the Altyn Tagh fault by Gilder *et al.* (2001) shows that area has rotated  $27^{\circ} \pm 5^{\circ}$  counterclockwise with respect to the Eurasian reference pole during the last 19 Ma. Otofuji *et al.* (1995) also suggest that their sampling sites along the Altyn Tagh fault showed  $7.4^{\circ} \pm 5.2^{\circ}$  counterclockwise rotation during the last 1.0 Ma. On the other hand, Dupont-Nivet *et al.* (2002, 2003) and Rumelhart *et al.* (1999) argue for no significant Neogene vertical-axis rotation in northern Tibet since Eocene. These results would contradict extrusion models which imply clockwise rotation of Qaidam basin at rates approaching  $1^{\circ}/Ma$ .

### Paleo-positions of Chinese blocks

Although a great number of Late Mesozoic and Cenozoic paleomagnetic results are available, the current paleomagnetic data base for China is still limited to allow a satisfactory interpretation of the questions concerning the paleogeography of China and the implications for Gondwanaland. Because many studies are performed at a single locality or over a small region and are of variable quality, paleomagnetists must critically assess and update the previously published data from China and Eurasia in order to better understand the tectonic relationship between the Chinese blocks and their relative motions with respect to Eurasia (i.e., Europe, Siberia, and Kazakhstan) during the Phanerozoic. Basic criteria for an acceptable paleomagnetic pole determination should include (i) age of the magnetization; (ii) structural control; and (iii) paleomagnetic laboratory treatment (demagnetization) of sufficient samples.

After such evaluations and assessments of each published study, the current state of paleomagnetic knowledge can be synthesized as follows: during Early (~530 Ma) and early-middle Late Cambrian (505 Ma), the paleolatitudes of South China, Tarim, and Australia permit them to be next to each other. North China can be placed between Siberia and Australia. All these blocks were in the area around the equator. Between late Middle to early Late Cambrian (~505 Ma), Tarim, North and South China Blocks lay closer to Australia and shared close trilobite affinities until Late Cambrian (~490 Ma). The counterclockwise rotation of Gondwanaland during the Cambrian was reversed during the Ordovician. The change in sense of rotation occurred at the Cambro-Ordovican boundary. The North and South China Blocks, and Tarim, remained in low latitudes, and rotated sinistrally along the Cimmerian margin of Gondwanaland towards positions they are inferred to have occupied later on the basis of faunal relationships.

By Early Silurian time (430 Ma) Siberia remained in the vicinity of the equator but has moved slightly northward to a position north of the equator. Gondwanaland appears to have moved southward and rotated clockwise. North China may also have rotated clockwise and appears to be compatible with a position next to the northern margin of Australia, which also fits the distribution of freshwater fish fauna on the two continents. While South China remains in roughly the same position, Tarim appears to have rifted off the SCB by rapid clockwise rotation and northward displacement.

At Middle Devonian time ( $\sim$ 380 Ma) the location of South China suggests that it may have rifted off Australia. Tarim is continuing its northward journey. Siberia has also drifted northward and rotated clockwise. North China, on the other hand, is still on the equator. The development of highly endemic vertebrate faunas on both the North and South China Blocks indicates that these two blocks were separated from Gondwanaland during Early-Middle Devonian.

Later at the Late Devonian time ( $\sim$ 354 Ma), Gondwanaland began to drift rapidly across the south pole, and by mid-Carboniferous (320–310 Ma), it has collided with Laurussia to start assemblage the supercontinent Pangea. It was for the first time that Australia had been drifted close to the south pole during the Paleozoic. The major Chinese blocks remained in low and medium paleolatitudes and started to develop their distinctive Cathaysia flora. The Late Carboniferous poles

for Tarim and Eurasia are in agreement, suggesting that these regions could have started the process of accretion by Late Carboniferous time.

The paleogeography of the Early Permian ( $\sim 280$  Ma) remained more or less the same as the mid-Carboniferous, except that Siberia collided with Laurussia along the Urals. Mongolian terranes accreted to the North China, the first phase of continental collision between the NCB and SCB at their eastern ends started soon. Supercontinent Pangea was complete at this time.

Pangea endured from ~280 Ma to ~175 Ma when the first seafloor spreading began in the North Atlantic Ocean. During this time, several Tibetan terranes (Kulun, Songpan-Ganze, and Qiangtang) accreted to Eurasia. The apparent polar wander paths for Eurasia and North and South China converge during the Late Jurassic (~150 Ma) and are tightly grouped throughout the Cretaceous and Tertiary, implying that large relative motion (translation and/or rotation) between the blocks was accomplished by Late Jurassic. On the other hand, although the paleolatitudes for Tarim and Eurasia have been similar since Carboniferous time, a close inspection reveals that there is a significant difference between the Late Permian, Early Triassic and Late Jurassic through Cretaceous poles for Eurasia/Siberia and Tarim, indicating relative motions between Tarim and Eurasia.

### Tectonic models inferred by the paleomagnetic data

The paleomagnetic results available from China allow plausible tectonic models to be constructed for the amalgamation of the Chinese blocks with themselves and with Eurasia (Zhao and Coe, 1987; Zhao *et al.*, 1996). The collision between Siberia/Eurasia and the Mongolia-NCB initially occurred in the Permian near the western end of their boundary in the Irtysh-Zaysan region ( $50^{\circ}$  N,  $75^{\circ}$  E), which is near the edge of the Kazakhstan Block (in today's geographical frame). Suturing progressed eastward as the Mongolia-NCB rotated counterclockwise about 90° in relation to Eurasia during the Early Mesozoic with a scissors-like motion (see Figure P48). The amalgamation of North and South China took place in the Late Permian by a similar but antithetic mechanism, with collision first occurring near the eastern end (about 30° N, 120° E) of the Qinling Fold belt and diachronously suturing from east to west due to a clockwise rotation of 65° of South China relative to North China.

Early Triassic paleomagnetic poles for all continental blocks are very similar to those for the Late Permian, consistent with the same scissor model discussed above and reinforcing the tectonic model. Reliable Middle and Late Triassic paleomagnetic data for the NCB, SCB, and Eurasia are still relatively sparse. Little change appears to have taken place by Middle Triassic time, with about 65° of rotation still left between Eurasia and the NCB to reconcile their poles.

In the Early Jurassic, more than half of the Qinling Sea between the NCB and SCBs was subducted, and so was the Mongol-Okhotsk Ocean between Eurasia and the NCB. Therefore, paleomagnetic data suggest that most of the relative rotation between the Chinese blocks took place during the Late Triassic and Early Jurassic. By the Middle Jurassic, the Qinling Sea is almost completely closed, although this may not be entirely correct due to the relatively large uncertainty in the SCB poles. The Late Jurassic and Early Cretaceous paleomagnetic poles for the NCB and SCB are statistically indistinguishable at this time, suggesting that accretion between the two blocks was accomplished some time between the Middle and Late Jurassic. However, the Chinese blocks were still significantly south of Siberia, with ~1000 km of the Mongol-Okhotsk Ocean to be closed north of Mongolia. The final closure of the Mongol-Okhotsk Ocean took place sometime in Cretaceous.

The tectonic model mentioned above contradicted widely held views at the time that the NCB and SCB were joined by the Devonian at the latest and that the Central Asian Fold Belt, which runs across North China just north of 40°N, is the zone where China was sutured to Siberia in Permian time. Rather, the paleomagnetic evidence suggested that in both cases suturing was completed much later, in Mid-Mesozoic time,

**Figure P48** Schematic reconstruction of Mongolia-North China (MON-NC), Europe-Siberia-Kazakhstan (EUR-SIB-KAZ), Tarim (TAR), Junggar Basin (JB), South China block (SCB), Africa (AFR), Arabian Shield (ARA), India (IND), Australia (AUS), Antarctic (ANT), the East Qiangtang (EQ), Lhasa (LS), Indochina (IC), and Shan-Thai (ST) blocks in Late Permian time. Mecator Projection. After Zhao *et al.* (1990).

and that it was a composite Mongolia-North China plate, not the NCB, that became sutured to Siberia Mesozoic time in a zone much further north along what is termed the South Siberian Fold Belt. Furthermore, the paleomagnetic data suggested in both cases a very simple mechanism involving a scissors-like closing of the intervening ocean basins by antithetic senses of rotation about the points of initial collision at the eastern and western ends of the convergence zones of the southern and northern suture zones, respectively. These paleomagnetic models have been reinforced by many later studies and backed up by reinterpretation of relevant geological information, such as the propagation of abrupt regional and local changes from marine to continental basin deposition and of syncollisional to postcollisional alkalic granites in the collision zone. Therefore, here is a case where paleomagnetism has again provided first-order contributions in deciphering continental collision and amalgamation.

## Paleomagnetic implications concerning tectonic controversies in China

## Implications for the duration of continent-continent collisions

As noted above, the scissor model of NCB-SCB collision based on paleomagnetic data matches the change in sedimentary style from marine to continental on the northern margin of the SCB. Both paleomagnetic and geologic data agree that the onset of collision occurred in Permian to Triassic time. The data sets diverge, however, regarding the end (duration) of the collision, with the paleomagnetic data suggesting younger estimates (Middle Jurassic) than geological indicators (Late Triassic) by 20–30 Ma. Part of the discrepancy could be the lack of more reliable Late Triassic to Middle Jurassic paleomagnetic data from both blocks. Further studies could show that the paleomagnetic poles of Early Jurassic or Late Triassic age are indistinguishable, thereby bringing the paleomagnetic and geological data sets closer into agreement. On the other hand, it is possible that the rotation suggested by the paleomagnetic data also includes postcollisional shortening between the two blocks. Taking the ongoing India-Asia collision as an example of typical continent-continent collisions, deformation and shortening could continue at least 50 Ma after initial contact of the two plates. Such postcollision shortening could also potentially lead the age of initial India-Asia collision based on paleomagnetic data to be somewhat younger than those based on stratigraphic data.

### Tertiary low-paleolatitude dilemma of western China

As the Chinese paleomagnetic database grows, several research teams are continuing to discover the outstanding regional disagreement between the observed and predicted Cenozoic paleomagnetic directions from red bed formations in western China. The inclinations of stable magnetization in Cretaceous red beds from Tarim and surrounding region's are somewhat shallower than expected using Besse and Courtillot (2002) APWP Cretaceous reference pole for Eurasia, whereas the Tertiary red beds are even more shallow using the corresponding Tertiary reference pole. The inclinations translate to anomalously low

paleolatitudes. If all these paleomagnetic data, the ages, and the GAD hypothesis were correct, then in the Cretaceous Tarim would have been somewhat further south with respect to Eurasia compared to its present situation, relatively even further south when the Tertiary red beds were magnetized, and then had to move to its present more northerly relative position after that time. This implies a southward (extensional) relative displacement away from Eurasia in the period between the times when the Cretaceous and Tertiary redbeds were magnetized, and significantly more northerly (compressional) relative displacement toward Eurasia after the Tertiary red beds were magnetized, a scenario that is geologically indigestible. Recent results from Cretaceous red beds in the Hexi-Corridor (central China) show that there is no evidence that red beds there suffered the same inclination shallowing as the neighborhood Cenozoic red beds to the west (Sun et al., 2001; Chen et al., 2002). A review of published poles also confirms previous analyses that red beds from South and North China do not reveal the shallow inclination and these blocks (plus Mongolia) and Siberia have not undergone very significant internal deformation since the Cretaceous (Besse and Courtillot, 2002). It appears that some red beds suffer from inclination error, and others do not. The task is thus to develop ways to identify which of the Tertiary red beds do and do not undergo inclination shallowing.

The most direct way would be to obtain reliable Tertiary paleomagnetic results from volcanic rocks and compare them with inclinations of coeval red beds in the same study area. Two such studies have reported contrasting results: (1) the Paleocene Lingzizong volcanics in the Lhasa area give consistent result (with positive fold and reversal test) with the underlying Cretaceous strata (Achache *et al.*, 1984), providing a notable example that both red beds and volcanic rock in the Lhasa area recorded the same ancient magnetization; and (2) Early Cretaceous red beds and underlying basalt flows from Tarim and central Asia fold belt (Gilder *et al.*, 2003) have directions that pass both fold and reversal tests, but the mean paleolatitude of the Early Cretaceous red beds is 11° lower than that of the Early Cretaceous basalts. Obviously, more studies should be conducted on Tertiary volcanic and red sedimentary rocks from the same area.

#### Tectonic affiliation of the Korean peninsula

The question about the Korean Peninsula's affinities with both the NCB and SCB is one of the highly charged controversies in Asian tectonics. The lack of knowledge about this question hampers our understanding concerning the models of collision of eastern Asian blocks and their paleogeographic settings. Pre-Cretaceous paleomagnetic poles for Korea are all different from each other and make it difficult to compare the coeval poles from the NCB and SCB. At first glance, Triassic and Jurassic paleomagnetic poles for Korea published prior to 1994 are indeed somewhat similar to coeval ones from the SCB, and this was perhaps the reason to lead some workers to suggest that Korea and South China may have behaved as a single tectonic block since the Triassic. However, all these poles that apparently correspond to the SCB poles were derived from rocks within the Okchon zone, which is known to be a site of severe deformation in the Mesozoic. In fact, Cretaceous remagnetization of Carboniferous rocks has been concluded for several previous published results. Although detailed structural analysis and mapping are still insufficient to unravel the kinematic history of the Okchon fold belt and assess its effects on these paleomagnetic poles, the proximity of these poles to the SCB poles may be a coincidence.

If one leaves out these poles derived from the Okchon zone and merely retains those poles derived from areas bordering the Okchon, a striking feature between the Korean and NCB poles emerges: the Late Permian, Early Triassic, and Late Jurassic poles for Korea are systematically displaced some 30° eastward with respect to the coeval poles of the NCB. A 30° clockwise rotation of Korea about a vertical axis brings these poles into general coincidence with those coeval poles for the NCB. Thus, paleomagnetic study suggests that the whole region was part of the North China landmass at least as early as Late Permian and rotated clockwise by about  $30^{\circ}$  with respect to the NCB during the Cretaceous (Zhao *et al.*, 1999).

It is apparent that the rotated (or corrected) poles show large apparent polar wander motion of Korea between Early Triassic and Late Jurassic, replicating those found in the paleomagnetic results from the NCB. Late Jurassic paleomagnetic poles for the NCB, SCB, and Korea are statistically indistinguishable, reinforcing the hypothesis that the accretion of the NCB and SCB was finished at this time. Thus, the NCB-Korea connection is not only consistent with the majority geologic observations, suggesting affinities between the two blocks, but also consistent with the collisional tectonic history of the eastern Asian margin derived from paleomagnetic data.

### Terrane accretion between east and west Qiangtang

Comparison of paleomagnetic data obtained from east and west Qiangtang shows a problem that obstructs our understanding of terrane accretion in Tibet. The Cretaceous paleolatitudes of Otofuji et al. (1989) and Huang et al. (1992) in the Markam area of east Qiangtang are similar to the expected paleolatitudes for the sampling locality. The data would suggest that east Qiangtang was  $21^{\circ} \pm 10^{\circ}$  farther north than expected for Lhasa and  $22^{\circ} \pm 11^{\circ}$  farther north than expected for western Qiangtang. Taken at face value, these data would suggest that no significant crustal shortening has taken place north of east Qiangtang since at least the Late Cretaceous. The 2000 km shortening of Lhasa must have been accommodated between the Qiangtang and Lhasa blocks in the Tertiary. On the other hand, west Qiangtang must be close to the Lhasa trerrane in Late Cretaceous time, so there should be a suture between east and west Qiangtang. Huang et al. (1992) interpreted their paleomagnetic observation in terms of a giant rightlateral transpressional zone advocated by Dewey et al. (1998). Chen et al. (1993), on the other hand, suggested that east Qiangtang may have belonged to South China or to a block that was separated from western Qiangtang.

### Tectonic rotational history of northern Tibet

A closely related question is the tectonic rotational history of northern Tibet, which is often related to uplift and deformation. Magnetic declinations, which are not typically affected by depositional compaction, can be compared to expected magnetic directions to assess the extent to which regions within the northern Tibetan plateau have rotated about vertical axes with respect to stable Eurasia. In eastern Tibet, Cretaceous and Tertiary paleomagnetic data indicate large amountsin the order of 40°-of clockwise rotation in the eastern Himalayan syntaxis (e.g., Achache et al., 1984; Huang et al., 1992), which is consistent with right-lateral simple shear and associated oroclinal bending. However, paleomagnetic data obtained from Cretaceous and Tertiary red sedimentary rocks of western Qiangtang (Chen et al., 1993) show no significant Neogene vertical-axis rotation in northern Tibet since the Late Cretaceous. Thus, all paleomagnetic data for tectonic rotations are not in agreement; some of them are apparently contradicting extrusion models that imply clockwise rotation of the region. These existing results, however, should be incorporated with forthcoming new results to advance our understanding of the growth history of the Tibetan plateau.

### Summary

Plate tectonics views the whole Earth as a dynamic system in which the internal heat drives lithospheric plates in relative motion with respect to each other. Paleomagnetism enables geologists to view important aspects of continental movements in the past namely, changes in latitude and orientation relative to the geographic poles. It is important to realize the crucial role that paleomagnetic studies in China have played in providing the tectonic framework that guides geological investigation and interpretation. Until McElhinny *et al.*'s pioneering paleomagnetic paper in 1981 revealed discrepancies in Late 826

Permian paleolatitudes on the order of 20°, literally all geological interpretation concurred (incorrectly) that North and South China had been in place as part of the Eurasian landmass since the Early Permian or before. For some years after, with a notable exception (Klimetz, 1983), few geologists took these paleomagnetic results seriously enough to question the prevailing view. Meanwhile, additional paleomagnetic data began to accumulate in support of McElhinny et al.'s findings: discrepancies not only in Late Permian and but also in Early Mesozoic poles between South China and Siberia (Opdyke et al., 1986), between North and South China, and between North China (including Mongolia) and Eurasia (see Enkin et al., 1992 for references). It was on the basis of paleomagnetic evidence that the proposal was first made that South and North China collided at the eastern end of the Qinling belt at the close of the Permian and sutured progressively westward by relative rotation in the Mesozoic (Zhao and Coe, 1987), then backed up by reinterpretation of relevant geological information from the literature. Likewise, paleomagnetic evidence was the original basis of the similar mechanism of opposing sense (collision in the west followed by progressive rotation and suturing to the east) proposed for the incorporation of northern China into Eurasia in the Mesozoic (Zhao and Coe, 1989; Zhao et al., 1990)

Although paleomagnetism has already made a dramatic contribution to the tectonics of China, this is just the beginning. By carefully gathering the available paleomagnetic, geological, and geophysical data and integrating them, Earth scientists are testing new hypotheses about smaller scale, intracontinental deformation. The tectonics of China will continue as a fruitful focus in the study of the dynamics of the Earth.

Xixi Zhao and Robert S. Coe

Geomagnetic Polarity Reversals Magnetosphere of the Earth Paleomagnetism

### POGO (OGO-2, -4 AND -6 SPACECRAFT)

The Polar Orbiting Geophysical Observatories (POGO) were the low altitude half of the Orbiting Geophysical Observatories (OGO) intended to carry a large number of instruments to observe the physical environment of the Earth's magnetosphere and outer ionosphere (Jackson and Vette, 1975). The characteristics of the three POGO spacecraft are shown in Table P1 and the spacecraft design is shown in Figure P49. The magnetometers were each a pair of optically pumped rubidium vapor units whose output signal strength had a sin  $\theta \cos \theta$  dependence, where  $\theta$  is the angle between the optical axis and the observed magnetic field vector (Farthing and Folz, 1967). Each then had equatorial and polar "null zones" relative to their optical axes where the signals were too weak to measure. The equatorial

Table P1 The POGO spacecraft

ones were less than  $7^{\circ}$  half angle, and the polar zones less than  $15^{\circ}$ . The two instruments were mounted with their optical axes at  $55^{\circ}$  to each other so the combined output signal was available except for the two small angular areas where these zones overlapped.

The maximum altitude of the OGO-2 spacecraft was planned to be only 900 km but the tracking devices had lost its contact at launch due to the early morning fog, so it burned its full load of fuel to attain the high apogee seen in the table. The spacecraft also experienced problems soon after the operation began because its horizon sensors were found to be too sensitive; confusing temperature gradients in clouds with those at the horizon. It had utilized its full load of control gas within ten days of launch. It was then put into a slow spin mode. In April 1966 both batteries failed; so operation thereafter was limited to sunlit periods of the orbit. Nevertheless, there were some 306 days of observations. The OGO-4 spacecraft experienced far fewer problems and operated almost continuously until the tape recorders failed in January 1969. Because the orbits of both of these spacecraft drifted earlier in local time (5.5 min/day for OGO-2 and 6.1 for OGO-4) it was possible for the first time during September and early October 1967 to obtain magnetic field data simultaneously in two differing local time planes. OGO-6 was equally successful as OGO-4 though the data collection after August 1970 was sporadic. Having a lower inclination, the orbital drift with local time was higher-earlier by 8 min/day.

The magnetometer data from these three spacecrafts were the most accurate and continuous of any to that date, though the analysis was limited to use of the scalar field. A proposal to add vector instruments to OGO-6 by J.P. Heppner was not accepted by NASA, thus missing an opportunity to observe field-aligned currents in the polar regions for the first time. Initially, it was thought that accurate scalar observations would be sufficient to map the internal field as well as to study the *in situ* electrical currents. However, it was shown mathematically by Backus (1970) that there was one example of different vector

Spacecraft	Dates of operation	Inclination (degrees)	Perigee (km)	Apogee (km)	Sample interval (s)
OGO-2	Oct 14, 1965-Oct 2, 1967	87.3	410	1510	0.5
OGO-4	July 28, 1967-Jan 19, 1969	86.0	410	910	0.5
OGO-6	June 5, 1969-June 1971	82.0	400	1100	0.288

**Figure P49** Typical OGO spacecraft in deployed configuration. The spacecrafts were of the order of 18 m long on the *Y*-axis. They were maintained in Earth orientation using gyroscopic reaction wheels with corrections as needed with gas jets. The *Z*-axis was toward the Earth and the direction of travel was along *X*-axis.

fields that could not be distinguished by observations of the scalar magnitude. Hurwitz and Knapp (1974) first demonstrated that models based only on scalar magnitude have larger vertical intensity errors in equatorial regions. Nevertheless, the data, especially for OGO-4, have been shown to be accurate to better than 4 nT, including the effects of orbital errors of position (Sabaka *et al.*, 2004).

The data from OGO-2 were used as a standard in establishing the first International Geomagnetic Reference Field (IGRF) (Cain and Cain, 1971), and those from all three spacecrafts are the best control over the main field for the 1965–1971 epochs (Sabaka *et al.*, 2004). Although Benkova *et al.* (1973) believed that Cosmos 49 measurements showed the presence of broad-scale magnetic anomalies, the noise in the data and orbital positions were too great to bring them out clearly. Until the POGO magnetic data were analyzed, the first accurate global magnetic anomaly map (Regan *et al.*, 1975) could not be constructed.

The POGO data also allowed study of the field sources external to the Earth. Cain and Sweeney (1973) were the first to observe the equatorial electrojet from above the ionosphere. OGO-2 and OGO-4 were the first spacecrafts to operate simultaneously in different local time planes. Olsen *et al.* (2002) used data from a brief period in 1967 to show how such multispacecraft observations could help in obtaining a detailed picture of ionospheric current systems. Important contributions were also made to the understanding of high latitude external magnetic variations (Langel, 1974a) and their relation to the interplanetary field (Langel, 1974b) as well as the low energy plasma environment about the Earth (Langel and Sweeney, 1971).

Information about the POGO series spacecraft, experiments, and data sets can be obtained from the Master Catalog at the National Space Science Data Center Web site http://nssdc.gsfc.nasa.gov/nmc/sc-query.html by entering a query for the spacecraft name "pogo" and then following the response. Other internet sources include: http://www.spacecenter.dk/data/magnetic-satellites/ and http://core2.gsfc.nasa.gov/CM/.

## POLARITY TRANSITION, PALEOMAGNETIC RECORD

### Early work on the Matuyama-Brunhes transition field

The last change of geomagnetic polarity, bringing about an end to the Matuyama Reverse Chron and the onset of the Brunhes Normal Chron, occurred between 790 and 780 ka. This age was determined by both orbital tuning of marine sediment records (e.g., Tauxe *et al.*, 1996) and by  $4^{40}$ Ar/ $3^{9}$ Ar age determinations on transitionally-magnetized lavas (e.g., Singer and Pringle, 1996). Being the most youthful field reversal, it has always been associated with the largest number of available paleomagnetic records (see e.g., Love and Mazaud, 1997). One reason for this is that sedimentary records, often obtained from marine cores, penetrate this reverse-to-normal (R-N) polarity change before all others. It is no wonder then that the Matuyama-Brunhes (M-B) reversal was the first polarity transition to be associated with the availability of synchronous records from distant sites. These multiple recordings facilitated an initial attempt to better understand global characteristics of a transitioning field and the dynamo process that causes field reversal.

In 1976 the path of the virtual geomagnetic pole (VGP)-that is, the north geomagnetic pole position calculated by assuming each recorded paleodirection to be associated with a geocentric dipole-from a M-B record recovered from the dry sediments at Lake Tecopa, California, was compared by Hillhouse and Cox to the detailed, exposed marine sediment record published five years earlier (Niitsuma, 1971) from the Boso Peninsula, Japan. What was found was that the two VGP paths traced quite distinct tracks over Earth's surface from the geographic south polar region to the north polar region (see Figure P50), an observational finding that suggested for the first time that the transitioning field becomes largely nondipolar during, at least, this particular polarity change. On the other hand, if the two VGP tracks were quite similar, such a finding would be compatible with a transitioning field that remained dominantly dipolar. However, for this case, the VGP paths were found in the Atlantic and the west Pacific, respectively. Much later, the Lake Tecopa sediments became the focus of a second study by Valet et al. (1989) that attempted to confirm the earlier findings. This study found a far more complex VGP path, one that encompassed a significant portion of the central-to-east Pacific. Although these later findings still suggested a significant nondipole contribution to the transitioning M-B field, this study made clear that a complete understanding of even the most basic aspects of field geometry during such events would require a much larger database of contemporaneous records.

As the number of reversal records associated with the M-B transition steadily grew, so did the number of analyses that attempted to better define the structure of the transitional field. In 1981 a phenomenological model (Hoffman, 1981) was applied to available M-B datasets, an approach that assumed a reversal to begin at a particular locality within the core and then proliferate, or "flood," this "reversed" magnetic flux throughout the dynamo until completion of the process. This flooding model appeared to generally account for the M-B VGP paths that were available at the time.

**Figure P50** The path of the virtual geomagnetic pole (VGP) corresponding to the first two acquired paleomagnetic records of the Matuyama-Brunhes transition. Given the very different pathways, Hillhouse and Cox (1976) concluded that the M-B transition field was predominantly nondipolar.

### Questions regarding the role of Earth's mantle

A decade later research regarding the last reversal took a new and exciting turn: Clement (1991) found that VGP paths associated with M-B records contained in a more complete database of published results displayed a significant bimodal distribution of transitional poles in geographic longitude. More specifically, the M-B VGPs appeared to preferentially lie within two particular antipodal bands, one running through the Americas, the other through East Asia and Australia

(Figure P51a). This finding nearly coincided with another study—the results of which can be seen on the cover of a 1991 issue of *Nature* magazine—which found the same geographical bandings of transitional VGPs associated with several records of paleomagnetic reversals going back in time into the Miocene (Laj *et al.*, 1991).

This rather surprising result implied that, for the last several millions of years, and, in particular, during the time of the M-B event, transitional VGPs ran along "preferred" pathways. This, for the first time,

**Figure P51** Geographical distribution of M-B transitional VGPs. (a) *after* Clement's (1991) finding of a bimodal distribution in longitude. (b) *after* Hoffman's (2000) global histogram.

suggested that Earth's mantle was intimately involved in the process of field reversal. That is, it was argued that such recurrence of field behavior had to be tied to physical conditions about the lowermost mantle, the variations of which imposing a control on the manner in which magnetic flux can emerge from the fluid outer core during reversals. Since the time of these two seminal papers by Clement (1991) and Laj *et al.* (1991), the question as to whether or not field behavior during successful reversals as well as during other transitional events—like, say, an aborted attempt—is largely influenced by such lower mantle heterogeneities, has been hotly debated (see e.g., Jacobs, 1994; Merrill and McFadden, 1999).

An alternative explanation put forward was that the apparent preferential behavior-rather than having a geomagnetic basis-was, in fact, an artifact related to limitations in the way sediments acquire their remanent magnetization (e.g., Rochette, 1990; Valet et al., 1992; Langereis et al., 1992). However, during the following year an analysis (Hoffman, 1992) of transitional field behavior recorded in volcanic sequences having ages running back to the Miocene-rocks that, typically, provide the most accurate spot recordings of the paleofield vector-showed, not preferred banding of VGP paths, but rather preferred groupings, or clusters. Interestingly, these clusters resided within the hypothesized preferred longitudinal bands. Hence, this "preferred patch" finding implied virtually the same geomagnetic basis as proposed for sediment records. Yet, the correspondences and differences between what was observed in distinct rock types broadened the debate, while raising it to a new level. If preferred VGP behavior is assumed to be a manifestation of a dynamo process controlled by the lower mantle, could the apparent discrepancy observed in sediment and lava records-that is, preferred bands and preferred patches, respectively-be explained through the known differences in the manner these two types of rocks become magnetized? And, if so, could long-lived transitional field states during which time the field direction at a given site, although transitional, remained essentially stationary, produce both observations?

### The MBD97 database

In 1997, the first rigorous attempt was made (Love and Mazaud, 1997) to distinguish which records of the full M-B database may be

considered reliable, and, hence, worthy of inclusion in a robust analysis. Nearly 62 M-B records from sites about the globe were found in the literature, and each was subjected to a number of strict reliability criteria. Of these records only 11 satisfied this scrutiny and were admitted to the so-called *MBD97* database. These records now separated from less reliable records, were analyzed in an attempt to answer the primary question regarding the existence or not of preferential VGP behaviour during the last geomagnetic reversal. The findings by the authors of the *MBD97* database suggested a statistically significant answer in the affirmative. Specifically, they argued that the distribution of transitional M-B VGPs showed some degree of preferred longitudinal behavior compatible with the hypothesis that the bias was, in fact, a real geomagnetic phenomenon.

Other analyses of the MBD97 database followed. One study (Gubbins and Love, 1998) raised the point that the VGP behavior, when viewed in a global sense, was associated with a dependence on the site of observation, and that each individual VGP path was compatible with inferred symmetry conditions within the core dynamo. Still another investigation of the MBD97 database (Hoffman, 2000) produced a global histogram of transitional M-B VGPs (Figure P51b). This analysis, although again confirming a longitudinal bimodal nature of virtual poles, demonstrated that very few VGPs existed in the database at low latitudes near the equator. From this result it was argued that during the M-B transition considerable time was spent by the reversing field in particular configurations. Specifically, clusters of sequential VGPs near Australia, and in the South Atlantic, were found to exist in the database-data that was observed in records from sequences of lavas as well as sediments. Yet, the question regarding whether or not the VGP migrated across the equator along preferred longitudinally-confined pathways, remained unresolved.

### **Further work**

Since the construction of the *MBD97* database, records of the Matuyama-Brunhes obtained from deep-sea sediments in the West Pacific (Oda *et al.*, 2000) and the North Atlantic (Channell and Lehman, 1997; Channell *et al.*, 2004), have found their way to publication. In particular, the several parallel records from North Atlantic high deposition-rate drift deposits are particularly noteworthy (see examples shown in Figure P52). These data sets, all displaying remarkably similar,

**Figure P52** Three examples of VGP paths associated with parallel M-B marine sediment core records from the North Atlantic. Note the remarkable similarity of detail. After Channell and Lehman (1997).

though complex, field behavior, are arguably the most detailed and complete records of the M-B reversal presently available. In some contrast to the most reliable records obtained from mid-latitudes, these high latitude North Atlantic records show little in the way of VGP clustering near Australia, yet contain clusters both in the South Atlantic and northeast Asia (Channell and Lehman, 1997; Channell *et al.*, 2004). If it is the case that VGP cluster localities are dependent on the site of observation, then the associated long-held field states must be largely nondipolar.

Constable (1992) was the first to show a link between preferred VGP path behavior and the modern-day geomagnetic field. Specifically,

**Figure P53** Aspects of the modern-day field. (*Top*) VGP pathways associated with numerous sites from about the globe for simulated normal-to-reverse (N-R) and reverse-to-normal (R-N) polarity transitions in which only the axial dipole is assumed to be involved in the process. After Constable (1992). (Middle) Intensity of the vertical component of the field at Earth's surface following synthetic removal of the axial dipole from the modern-day field (hence, the NAD-field). The two locations in white-near west Australia and in the South Atlantic-are the most intense, having at least 90% of the most intense value found. (Bottom) Two grids of sites defining regions that, when subjected to the modern-day NAD-field, would possess paleomagnetic directions corresponding to VGPs found in either of the two shaded localities (also found to be areas of the most intense NAD-field). The smaller and larger grids correspond to north-VGPs in the South Atlantic and south VGPs in the west Australian shaded regions, respectively after Hoffman and Singer (2004).

it was shown (see Figure P53, *top*) that if a polarity reversal simply involved the decay, vanishing, and reemergence of the axial dipole having opposite sign—keeping the remainder of the field constant— VGP pathways for sites from around the globe would preferentially lie along the same antipodal longitudinal bands proposed by Laj *et al.* (1991) and Clement (1991). The field configuration for which only the axial dipole has been removed is commonly termed the nonaxial dipole or, *NAD*-field (although it is sometimes also called the *sans*-axial dipole, or *SAD*-field, translated from French as to be "without" the axial dipole). Such a field state must occur during a successful change in polarity. That is, the axial dipole must vanish before it can change sign.

Interestingly, the primary locations of observed M-B clustered VGPs from available paleomagnetic records near western Australia, in the southwest Atlantic, and within Siberia, are not only sites within the two proposed preferred bands, but also correspond to the three locations at Earth's surface which possess the most intense vertical component of the modern-day field after synthetic removal of the axial dipole (i.e., the NAD-field) from the calculated spherical harmonic analysis (Figure P53 middle). Moreover, if VGPs are calculated for sites from around the globe when assumed to be experiencing the modern-day NAD-field, one finds that in the Southern Hemisphere, the very same Australian and South Atlantic localities are the most preferred regions (Figure P53 bottom). Thus, available paleomagnetic transition data appear to be linked to the field of today, suggesting that primary features of the modern-day NAD-field remain virtually stationary over times in order of 10<sup>6</sup> or, perhaps, 10<sup>7</sup> years (Hoffman and Singer, 2004). If so, this is a definite sign of a controlling influence by the lowermost mantle on flux emerging from the fluid outer core.

### Duration of the Matuyama-Brunhes transition

Recently, the duration of the M-B transition has been under study. The investigation of paleodirectional records obtained from several marine sediment cores (Clement, 2004) found a clear dependence of reversal time on the latitude of the site of observation. Specifically, the duration varied from about 2000 years at low latitudes to 10000 years at high latitude sites. However, the complete temporal process of field reversal appears from other studies to be rather complex and require a significantly longer span of time: an earlier analysis by Hartl and Tauxe (1996) of several marine sediment cores that recorded the M-B found a significant decrease in field strength some 15 ka prior to a second weakening associated with the actual change in polarity. The first decrease of this "double-dip" in intensity was explained by the authors as a precursory geomagnetic event to the subsequent successful reversal.

Following this finding, a recent geochronological study in which several precise <sup>40</sup>Ar/<sup>39</sup>Ar ages were determined for transitionally magnetized M-B lavas from volcanic sequences at four mutually distant sites found a bimodal age distribution consistent with such a precursor (Singer et al., 2005). The initial instability, associated with the first of the two decreases in field intensity, was found to have occurred 18 ka prior to the polarity switch. The Australian and South Atlantic VGP clustering (Figure P54) appears now to be associated with the precursor, and thus suggests that the beginning of the period of dynamo instability may be simply explained by a process which essentially destroys the axial dipole, leaving the transitional field to have the configuration of the NAD-field at that time. Singer et al. (2005) further suggest that it is such a two-stage process that may be required for a given reversal attempt to be successful. Whether these characteristics of the M-B, the last reversal of Earth's magnetic field, are common to earlier polarity transitions (see e.g., Coe and Glen, 2004), and hence, typical of a fundamentally systematic process, requires the availability of considerably more paleomagnetic reversal data.

Matuyama-Brunhes

**Figure P54** Matuyama-Brunhes VGPs and precise <sup>40</sup>Ar/<sup>39</sup>Ar ages for sequences of transitionally-magnetized lavas from each of four mutually distant sites. Note that those sites associated with VGP clusters near Australia and the South Atlantic/South American regions (indicated with an asterisk) correspond to lavas that were erupted some 18 ka prior to the actual change in polarity that was recorded on Maui, Hawaii. After Singer *et al.* (2005).

# POLARITY TRANSITIONS: RADIOISOTOPIC DATING

The Plio-Pleistocene Geomagnetic Polarity Time Scale (GPTS) developed beginning in the early 1960s as Cox et al. (1963) and McDougall and Tarling (1963) used K-Ar ages and magnetic remanence data from volcanic rocks to propose a sequence of normal and reverse polarity "epochs" now called Chrons (Opdyke and Channell, 1996). A large set of K-Ar ages were acquired, mainly from lavas, that defined the lengths of Chrons, but if few, these lavas showed transitional directions of remanent magnetization, the timing of the polarity reversals between the Chrons had to be interpolated. This was done using the chronogram method (Cox and Dalrymple, 1967) to minimize the error function of K-Ar ages near the polarity boundary relative to assumed ages for the boundary. In addition to the polarity Chrons, that are periods on the order of 10<sup>6</sup> year in length, K-Ar ages and magnetic data from widely dispersed locations began to delineate several  $10^4 - 10^5$  year long subchrons including the Jaramillo, Olduvai, and Reunion subchrons (Opdyke and Channell, 1996).

Still shorter-lived geomagnetic events or Cryptochrons, that include excursions, aborted reversal attempts, or rapid back-to-back reversals, were also detected magnetically in sediments and volcanic rocks. K-Ar dating of normally magnetized basalt flows in Iceland (McDougall and Wensink, 1966) and a transitionally magnetized rhyolite in California (Mankinen et al., 1978) provided the first radioisotopic ages for events within the Matuvama reversed Chron, named the Gilsa and Cobb Mountain events. In the Brunhes normal chron, several transitionally magnetized lavas in the Massif central, France that recorded the Laschamp event have been K-Ar dated, but these ages are imprecise and scatter between 60 and 15 ka (Guillou et al., 2004). In a remarkable study, Hall and York (1978) obtained both K-Ar and <sup>40</sup>Ar/<sup>39</sup>Ar ages from these lavas and concluded that the Laschamp event occurred about 47 ka; it marked the first use of the <sup>40</sup>Ar/<sup>39</sup>Ar method to date lavas this young. The K-Ar age of  $565 \pm 28$  ka (uncertainties herein are  $\pm 2\sigma$  analytical errors) determined from two of four transitionally magnetized lava flows found in Idaho by Champion et al. (1988) provided a precise radioisotopic date for an event during the Brunhes normal chron which was named the Big Lost event for a nearby river. Notably, Champion et al. (1988) discussed the evidence from sediments and volcanic rocks globally that at least 10 geomagnetic events of short duration had occurred during the last 1 Ma.

More recently, as directional excursions associated with brief periods of low relative paleointensity were revealed in sediments worldwide, many of these geomagnetic events have been verified, and new ones proposed (Langereis et al., 1997; Guyodo and Valet, 1999; Channell, 1999; Channell et al., 2002). It is the promise of an accurate, high resolution correlation of these events globally that sparked considerable interest and debate concerning their number and precise timing. There are at least two reasons for this: First, marine and terrestrial sediments contain a rich, quasi continuous, archive of major climate changes that have shaped the Earth's surface over the past several Ma. An accurate calendar of changes in climate is crucial to determining the underlying driving mechanisms in the oceans and atmosphere. Second, theoretical arguments and numerical models have used the frequency and duration of reversals and excursions to infer magnetic or thermal interactions between the liquid outer core and either the solid inner core, or the lowermost mantle, that act to control the stability of the geodynamo (e.g., Gubbins, 1999; see Geodynamo, numerical simulations;

*Core-mantle coupling, thermal*). Thus, an accurate accounting of spatial temporal instabilities of the magnetic field, from excursions to reversals, is critical in advancing the next generation of geodynamo models (Singer *et al.*, 2002, 2005).

In sediments, the timing of an event may be estimated by astronomical tuning of oxygen isotope, or other variations that proxy for orbitallydriven changes in climate (e.g., Langereis *et al.*, 1997; Channell *et al.*, 2002). However, not all marine core is amenable to oxygen isotope measurements, few geomagnetic records have been astronomically tuned, and even the sediment that accumulates at the highest rates may contain hiatuses leading to underestimates of the amount of time actually recorded. In detail, magnetic recordings in sediment are further complicated by postdepositional processes, including lock-in of the magnetic remanence, such that an accurate chronology may be elusive (Merrill and McFadden, 1999). Alternatively,  ${}^{40}$ Ar/ ${}^{39}$ Ar dating of lava flows or tuffs that rapidly lock in a thermal magnetic remanence during cooling has recently made it possible to obtain precise radioisotopic ages for at least 14 reversals and excursions, including previously unrecognized events that occurred during the past 2.2 Ma (Singer *et al.*, 2002, 2004).

## <sup>40</sup>Ar/<sup>39</sup>Ar variant of K-Ar dating

Until the early 1990's K-Ar dating was the preferred method for determining ages of volcanic rocks. The <sup>40</sup>Ar/<sup>39</sup>Ar variant offers many advantages over K-Ar dating and coupled with more sensitive measurement capabilities in such a way it has eclipsed K-Ar dating as the method of choice. The history, theory, and application of these techniques are summarized by McDougall and Harrison (1999), Renne (2000), and Kelley (2002); hence only a brief outline, drawn from these sources, is presented here. Both methods rely on the radioactive decay of naturally occurring <sup>40</sup>K to <sup>40</sup>Ar, which is proportional at any time *t* to the *N* number of <sup>40</sup>K atoms present:

$$\frac{\mathrm{d}N}{\mathrm{d}t} = -\lambda N \tag{Eq. 1}$$

where  $\lambda$  is the total decay of <sup>40</sup>K. A large fraction, 89.52%, of <sup>40</sup>K decays to <sup>40</sup>Ca via beta emission ( $\lambda_{\beta} = 4.962 \times 10^{-10}$  year), whereas 10.48% decays to <sup>40</sup>Ar via electron capture ( $\lambda_{\epsilon} = 5.808 \times 10^{-11}$  year) so that the total decay constant ( $\lambda = 5.543 \times 10^{-10}$  year) corresponds to a half-life of  $1.25 \times 10^9$  year, Solving the differential equation (1) yields the age equation for the K-Ar isotope system:

$$t = \left(\frac{1}{\lambda}\right) \cdot \ln\left[1 + \left(\frac{\lambda}{\lambda_{\epsilon}}\right) \cdot \left(\frac{^{40}\text{Ar}^*}{^{40}\text{K}}\right)\right]$$
(Eq. 2)

where <sup>40</sup>Ar<sup>\*</sup> is radiogenic argon, distinguished from other sources such as the atmosphere. The ratio of modern <sup>40</sup>K/K is constant, hence measurement of K and Ar concentrations (in mol/g), and isotope ratios of Ar, allow the age to be calculated. In practice, the sample is completely fused, the gas released is purified and spiked with a known amount of <sup>38</sup>Ar tracer, then its isotopic composition is measured in a mass spectrometer. K is a salt and must be measured independently on a separate aliquot of the same sample. Alternatively, <sup>40</sup>Ar<sup>\*</sup> may be measured directly by using a unique mass spectrometer which functions as a sensitive manometer able to distinguish minute quantities of radiogenic argon from the large atmospheric component found in most lavas (e.g., Guillou *et al.*, 2004).

One of the more important assumptions of any radioisotopic dating system, including the K-Ar and  ${}^{40}\text{Ar}/{}^{39}\text{Ar}$  methods, is that the rock or mineral has remained closed to loss or gain of parent and daughter nuclides. For example, loss of Ar or gain of K can yield spuriously young dates, whereas gain of Ar or loss of K may give spuriously old dates. From a K-Ar age determination alone, it is impossible to assess the validity of this assumption. Another limitation of K-Ar dates is their precision, which includes the compound uncertainty of two different analytical procedures used to measure separately the absolute contents in mol/g of Ar and K.

The  ${}^{40}$ Ar/ ${}^{39}$ Ar method is based on the same radioisotopic decay system as the K-Ar method, but instead of measuring K in a separate aliquot of the sample, it is measured by creating  ${}^{39}$ Ar from  ${}^{39}$ K via neutron activation. The  ${}^{39}$ Ar is produced by fast neutron bombardment in a nuclear reactor, and because the ratio of  ${}^{39}$ K to  ${}^{40}$ K is constant, it becomes a proxy for  ${}^{40}$ K that allows the  ${}^{40}$ Ar  ${}^{*/40}$ K ratio to be calculated simply from the measurement of the ratio of two Ar isotopes  ${}^{40}$ Ar/ ${}^{39}$ Ar.

Production of <sup>39</sup>Ar atoms is given by

$${}^{39}\text{Ar} = {}^{39}\text{K}\Delta \int \phi(\text{E})\sigma(\text{E})dE \qquad (\text{Eq. 3})$$

where <sup>39</sup>K is the number of atoms originally present,  $\Delta$  the duration of irradiation,  $\phi(E)$  the neutron flux density at energy, E, and  $\sigma(E)$  the neutron capture cross section of <sup>39</sup>K for neutrons of energy E in the <sup>39</sup>K(n,p)<sup>39</sup>Ar reaction. Solving Eq. (2) for <sup>40</sup>Ar<sup>\*</sup> and combining with Eq. (3) yields:

$$\binom{^{40}\text{Ar}^*}{^{39}\text{K}} = \frac{\binom{^{40}\text{K}}{^{39}\text{K}} \left(\frac{\lambda_{\epsilon}}{\lambda}\right) \left(\frac{1}{\Delta}\right) (e^{\lambda t} - 1)}{\Delta \int \phi(E)\sigma(E)dE}$$
(Eq. 4)

This can be simplified by defining a dimensionless irradiation parameter J:

$$J = {\binom{39}{K}}{\binom{\lambda}{\lambda_{\ell}}} \Delta \int \phi(\mathbf{E}) \sigma(\mathbf{E}) dE$$
 (Eq. 5)

which allows Eq. (4) to be written as

$$\begin{pmatrix} {}^{40}\text{Ar}^*\\ {}^{39}\text{Ar} \end{pmatrix} = \frac{\left(\mathrm{e}^{\lambda t} - 1\right)}{J} \tag{Eq. 6}$$

and rearranged to yield the age equation for <sup>40</sup>Ar/<sup>39</sup>Ar dating:

$$t = \left(\frac{1}{\lambda}\right) \ln\left[1 + J \cdot \left(\frac{^{40}\text{Ar}^*}{^{39}\text{Ar}}\right)\right]$$
(Eq. 7)

The value for the neutron fluence parameter *J* is determined by irradiating a standard mineral of known age *t* together with the samples, measuring its  ${}^{40}\text{Ar}^*/{}^{39}\text{Ar}$  ratio, and solving Eq. (6) for *J*. In this sense, the  ${}^{40}\text{Ar}/{}^{39}\text{Ar}$  method is a relative dating technique that relies on high-quality, homogenous standards that are available widely. There are many neutron fluence standards in use, however, not all laboratories use the same standards, nor does each use identical ages for some standards. Therefore, it is critical when comparing  ${}^{40}\text{Ar}/{}^{39}\text{Ar}$  ages determined in various laboratories to normalize the ages to a common value, based on intercalibration of several standards (see Renne, 2002). For example, all the  ${}^{40}\text{Ar}/{}^{39}\text{Ar}$  ages discussed below are calculated or normalized relative to an age of 28.02 Ma for the widely used and intercalibrated Fish Canyon Tuff sanidine standard.

The amount of <sup>40</sup>Ar<sup>\*</sup> measured must be corrected for the presence of atmospheric argon which has a <sup>40</sup>Ar<sup>36</sup>Ar ratio of 295.5. This is done using the relationship (<sup>40</sup>Ar<sup>\*</sup>/<sup>39</sup>Ar) = (<sup>40</sup>Ar<sup>\*</sup>/<sup>39</sup>Ar)<sub>m</sub> - 295.5(<sup>36</sup>Ar/<sup>39</sup>Ar)<sub>m</sub>, where the subscript *m* denotes the measured ratio. Other corrections for Ar isotopes produced by undesirable nuclear reactions during irradiation are also important, particularly for Plio-Pleistocene samples (Renne, 2000).

The fundamental difference between the K-Ar and  ${}^{40}\text{Ar}/{}^{39}\text{Ar}$  dating methods is that the latter allows calculation of an age based solely on the isotopic composition of Ar in the sample, rather than absolute abundances of Ar and K, thereby eliminating major sources of potential error. The  ${}^{40}\text{Ar}^*/{}^{39}\text{Ar}$  ratio is determined using highly sensitive mass spectrometry, thus the total fusion age for a Plio-Pleistocene sample of 10 mg of basalt groundmass or a single 1 mg phenocryst

of sanidine can be determined to a precision of ~1–2%. Systematic uncertainties, including a potential uncertainty in the <sup>40</sup>K decay constant currently in use, may be important when comparing <sup>40</sup>Ar/<sup>39</sup>Ar ages with those determined by other methods. This contribution to the total uncertainty associated with a particular age determination may be small, amounting to only a few hundred to a few thousand years for Pleistocene lava flows, but may be important when comparing <sup>40</sup>Ar/<sup>39</sup>Ar ages of geomagnetic excursions or reversals to those obtained astronomically from marine sediment (Guillou *et al.*, 2004).

### Age spectra

Because measurement of the  ${}^{40}\text{Ar}{}^{*}{}^{39}\text{Ar}$  ratio does not require absolute abundances, another powerful aspect of the  ${}^{40}\text{Ar}{}^{39}\text{Ar}$  method is that rather than totally fusing an irradiated sample, it can be incrementally degassed by stepwise heating to higher temperatures using a controllable furance or laser. The apparent ages of each successive gas increment are monitored for consistency by plotting the ages vs. the cumulative release of  ${}^{39}\text{Ar}$ , as a proxy for the parent isotope  ${}^{40}\text{K}$  (see Figure P55). If successive gas increments yield consistent ages, the spectrum is concordant Figure P55a, reflecting an internally homogenous distribution of  ${}^{40}\text{Ar}{}^{*}{}^{39}\text{Ar}$ , thereby providing evidence against mobility of K and Ar. The "plateau" age is commonly defined as the

**Figure P55** Age spectrum diagrams for two basaltic lava flows erupted during the Matuyama-Brunhes transition. Vertical height of each gas step gives the  $2\sigma$  analytical uncertainty. (a) Concordant age spectrum. The ten gas steps were released by successively raising the temperature of a resistance furnace in 50°C increments between 700 and 1200°C. (b) Discordant age spectrum produced by the same procedure used in A. The plateau age is calculated from seven contiguous steps that comprise 72% of the gas released. The gas released at lower temperatures gives ages younger than the plateau, possibly reflecting argon loss during weathering. In both A and B, the isotopic composition of the plateau steps may be used to calculate an isochron (Figure P56).

mean of the concordant step ages, each step being weighted by its inverse variance. Though arbitrary, most definitions of a plateau specify that it must include at least three successive increments that comprise  $\geq 50\%$  of the <sup>39</sup>Ar released that are concordant in age at the 95% confidence level. Weighting each plateau increment (or individual total fusion age) by its inverse variance  $(1/\sigma_i^2)$ , reduces the uncertainty of the mean age *t* according to

$$\sigma_t = \sqrt{\sum \left(\frac{1}{{\sigma_i}^2}\right)} \tag{Eq. 8}$$

In this manner, the plateau age may approach a precision of 0.2%, depending on the number of concordant increments and the  ${}^{40}\text{Ar}^*$  content of the material.

It is common, particularly with Plio-Pleistocene lavas, that age spectra are discordant. Notwithstanding, discordant spectra may yield a plateau, and depending on the nature of the disturbance, may provide important evidence for mobility of Ar or K. Figure P55b illustrates an example from a Pleistocene basalt interpreted to have lost a small fraction of  $^{40}$ Ar<sup>\*</sup> due to low temperature weathering of the matrix.

### Isochrons

It is routine in the  ${}^{40}$ Ar/ ${}^{39}$ Ar method to measure five isotopes of Ar including  ${}^{36}$ Ar,  ${}^{39}$ Ar,  ${}^{40}$ Ar,  ${}^{37}$ Ar,  ${}^{38}$ Ar; the latter two are required to correct for undesirable quantities of  ${}^{40}$ Ar and  ${}^{36}$ Ar produced artificially from K and Cl in the sample during irradiation. The other three isotopes facilitate isochron analysis; the most commonly used isochron is the plot of  ${}^{36}$ Ar/ ${}^{40}$ Ar vs.  ${}^{39}$ Ar/ ${}^{40}$ Ar where the intercepts yield reciprocals of  ${}^{40}$ Ar '/ ${}^{39}$ Ar, hence age (from Eq. (7)), and ( ${}^{40}$ Ar/ ${}^{36}$ Ar)<sub>i</sub> which gives the initial or trapped component (see Figure P56). Isochrons are calculated by a least squares method that weights individual measurements by their inverse variance. Incremental heating experiments on Plio-Pleistocene volcanic rocks are particularly amenable to isochron analysis. In some instances isochrons are more

**Figure P56** Isotope correlation or isochron diagram. Intercepts of the isochron in this diagram give the reciprocal of  ${}^{40}$ Ar/ ${}^{36}$ Ar and  ${}^{40}$ Ar/ ${}^{36}$ Ar<sub>i</sub>. Hence the isochron is a mixing line between the radiogenic argon and the initial or trapped component. The data points shown correspond to the ten gas increments in Figure P55a. In this example, the trapped component is indistinguishable from air argon. MSWD is the mean square weighted deviation, which indicates the magnitude of scatter about the isochron. A value of 1.0 means that the analytical uncertainties account for most of the error in the age which is calculated using least squares regression that weights each data point by the inverse of its variance.

powerful than the age spectrum approach, because no *a priori* assumption regarding the  $({}^{40}Ar/{}^{36}Ar)_i$  is made, which can be important for the small number of lavas or tuffs that may contain initially a nonatmospheric (or excess) component of argon (e.g., Singer and Brown, 2002). Indeed, the ability to use incremental heating data to test the assumptions of (1) closed system behavior and (2) an initial  $({}^{40}Ar/{}^{36}Ar)_i$  ratio corresponding to the atmosphere, makes it the preferred method for precisely dating lavas and tuffs thought to record geomagnetic reversals and events.

# Direct <sup>40</sup>Ar/<sup>39</sup>Ar dating of polarity transitions and excursional events

#### Matuyama-Brunhes transition

The first direct radioisotopic date for the Matuyama-Brunhes polarity transition corresponding to the last reversal of Earth's magnetic field is based on <sup>40</sup>Ar/<sup>39</sup>Ar isochrons from four incremental heating experiments by Baksi et al. (1992) on three lavas at Haleakala volcano on the island of Maui that possess transitional directions of magnetic remanence. Baksi et al.'s age of  $795 \pm 16$  ka is ca. It was 65 ka older than the K-Ar based age for this reversal, but within error of the astronomical estimate of 780 ka. Singer and Pringle (1996) incrementally heated groundmass separates from eight basaltic to andesitic lavas that erupted during the M-B transition at volcanoes in Chile, and on the islands of Tahiti, La Palma, and Maui, including several replicate experiments to improve precision of the isochrons. Although Singer and Pringle (1996) determined the weighted mean age of these eight lavas at  $791 \pm 4$  ka, they also emphasized that the 12 ka difference in age between the Chilean lavas and those from Maui may reflect the duration of this reversal. To further investigate the duration and structure of the M-B transition, Singer et al. (2005a) obtained 71 <sup>40</sup>Ar/<sup>39</sup>Ar incremental heating experiments on 23 of the transitionally magnetized lavas from the four volcanoes above. Surprisingly, the mean <sup>40</sup>Ar/<sup>39</sup>Ar ages of the lava sequences on La Palma, Tatara San Pedro, and Tahiti were found to cluster at 793  $\pm$  3 ka, whereas the age of the lavas at Haleakala, 776  $\pm$  2 ka, is about 18 ka younger. Singer *et al.* (2005a) propose that the older lavas record the onset of geodynamo instability and nondipolar field behavior, which persisted for a long enough period of time that magnetic flux diffused out of the solid inner core, thereby weakening its stabilizing effect and allowing the field to reverse itself at 776  $\pm$  2 ka. This interpretation is bolstered, in part, by the paleointensity records from marine sediments, in which are observed a pronounced drop in intensity about 15 ka prior to the intensity low associated with the field reversal itself. Singer et al. (2005a) argue that these lava flows provide the first observational evidence in support of Gubbins' (1999) hypothesis that the solid inner core may control the frequency of excursions and probability of full field reversals.

## Dating other reversals and events toward a geomagnetic instability timescale (GITS)

The K-Ar age of the Cobb Mountain event,  $1120 \pm 40$  ka (Mankinen *et al.*, 1978), was revised to  $1194 \pm 12$  ka on the basis of  ${}^{40}\text{Ar}/{}^{39}\text{Ar}$  laser fusion and furnace incremental heating experiments on sanidine by Turrin *et al.* (1994). The 6% to 7% increase in age was attributed to incomplete degassing of sanidine during the K-Ar experiments, a problem that may have biased many K-Ar dates used to develop the original GPTS, including those used in the chronogram estimate of 730 ka for the M-B transition.

Isochron ages for 18 lavas within long basalt flow sequences at Punaruu Valley, Tahiti, and Haleakala volcano, Maui, known to record several polarity transitions and events were determined using the  ${}^{40}\text{Ar}{}^{39}\text{Ar}$  incremental heating method on groundmass separated by Singer *et al.* (1999). The results indicate that an event recorded 1122  $\pm$  10 ka at Tahiti, which was originally correlated with the Cobb Mountain event on the basis of K-Ar dating, is actually a previously

**Figure P57** A Geomagnetic Instability Time Scale (GITS) for the Matuyama reversed and Brunhes normal Chrons. The  ${}^{40}$ Ar/ ${}^{39}$ Ar ages of transitionally magnetized lava flows or tuffs recording reversals or excursional events are from Singer *et al.* (1999, 2002, 2004, 2005a,b), Singer and Brown (2002), and references therein. Postulated events in grey are undated, imprecisely dated, or less well documented magnetically (Singer *et al.*, 2002). The astronomically-dated record of reversals and excursions includes SINT-800, a global compilation of geomagnetic field intensity from 33 marine sediment records over the last 800 ka (Guyodo and Valet, 1999), and the composite record from sediment cored at Ocean Drilling Program sites 983 and 984 (Channell *et al.*, 2002). In the latter, paleointensity lows that correspond with

unrecognized event, now named the Punaruu event. The results of Singer *et al.* (1999) also provided for the first time, the direct radioisotopic ages for the onset and termination of the Jaramillo normal subchron at 1069  $\pm$  12 and 1001  $\pm$  10 ka, respectively, which are in agreement with astronomical estimates (see Figure P57). Between the Jaramillo subchron and the M-B boundary, eight transitionally magnetized lavas from Tahiti and Halekala yielded a common weighted mean <sup>40</sup>Ar/<sup>39</sup>Ar age of 900  $\pm$  6 ka, corresponding to Champion *et al.*'s (1988) Kamikatsura event (Singer *et al.*, 1999; Figure P57).

Singer et al. (1999) suggested that the Kamikatsura event shortly postdated another previously unrecognized event recorded by the Santa Rosa I rhyolite dome in the Valles Caldera, New Mexico. To verify this, Singer and Brown (2002) undertook <sup>40</sup>Ar/<sup>39</sup>Ar laser fusion and incremental heating experiments on sanidine from the transitionally magnetized Santa Rosa I rhyolite dome and determined its age to be  $936 \pm 8$  ka; that is, the Santa Rosa event is 37 ka older than the Kamikatsura event and 65 ka younger than the reversal that terminated the Jaramillo Subchron Figure P57. At Cerro del Fraile in southern Argentina, Singer et al. (2004) have <sup>40</sup>Ar/<sup>39</sup>Ar dated a sequence of 10 basaltic lavas that, in concert with dates from lavas elsewhere, provide precise radioisotopic ages for geomagnetic events marking termination of the Reunion Subchron at  $2137 \pm 16$  ka, plus the onset and termination of the Olduvai Subchron at  $1922 \pm 66$  and  $1175 \pm 15$  ka. A single transitionally magnetized lava gave a discordant age spectrum that, together with a K-Ar age determination, indicate an age between about 1610 and 1430 ka (Figure P57). The termination of the Reunion Subchron is temporally distinguished by about 50 ka from the Huckleberry Ridge event recorded in tuff at Yellowstone national park, Wyoming (Singer *et al.*, 2004). The paleomagnetic and <sup>40</sup>Ar/<sup>39</sup>Ar data of Singer *et al.* (2002)

revealed that two geomagnetic events, including the one that preceded the M-B reversal by 18 ka, and a younger event dated at  $580 \pm 8$  ka are recorded in lavas on the northeast flank of La Palma island. The latter correspond to the Big Lost event that was K-Ar dated in Idaho at 565  $\pm$  28 ka by Champion *et al.* (1988). Moreover, Hoffman and Singer (2004) discovered a third recording of the Big Lost event in lavas at Tahiti, clearly demonstrating the global nature of this excursion at  $579 \pm 6$  ka (Figure P57). Lava flows of the Albuquerque Volcanoes, New Mexico along with a sequence of lacustrine sediments and volcanic ash at Pringle Falls, Oregon, that both record excursional field behavior have been  ${}^{40}\text{Ar}/{}^{39}\text{Ar}$  dated at 217  $\pm$  17 and 211  $\pm$  13 ka, respectively (Singer et al., 2005b). The common age from the two sites suggests that they record the same period of geomagnetic instability with a weighted mean age of  $213 \pm 10$  ka. Using both  $^{40}$ Ar/ $^{39}$ Ar and unspiked K-Ar methods, two lava flows in the Massif Central, France that record the Laschamp excursion have recently been dated to  $40.4 \pm 1.1$  ka, which is about 10% younger than previous estimates discussed earlier (Guillou et al., 2004). This new age is indistinguishable from that of a prominent paleointensity low at 40.9 ka found in marine sediments of the North Atlantic Ocean whose history has been calibrated using an age model based on oxygen isotopes and annual varve counting in the Greenland Ice Sheet Project II (GISP2) ice core. Thus, despite uncertainties in the decay constant for <sup>40</sup>K, which may be as large as 2.4%, the <sup>40</sup>Ar/<sup>39</sup>Ar method is capable of determining ages with

equator crossing shifts in the direction of the virtual geomagnetic pole are dated using an astronomical age model of oxygen isotope variations in the cores. Note that several paleointensity lows in SINT-800 do not readily correlate to events that have been radioisotopically dated or assigned astronomical ages elsewhere. Similarly, although many radioisotopically dated events match those found in the ODP 983 and 984 cores, several paleointensity lows, including some not shown here, have yet to be found in lavas that have been  $^{40}$ Ar/ $^{39}$ Ar dated. Note that all  $^{40}$ Ar/ $^{39}$ Ar ages are calculated relative to an age of 28.02 Ma for the Fish Canyon tuff sanidine standard.

an accuracy and precision of between 1% and 2% for virtually the entire Pleistocene (Guillou *et al.*, 2004).

Comparison of these radioisotopically dated events with more continuous records of paleointensity and paleodirection recovered from marine sediments has helped to (1) verify that excursions mark frequent instability of the geodynamo, (2) test the astronomical age estimates of many events, and (3) better interpret long-term temporal changes in the field. Perhaps the highest resolution recording of the field during the Matuyama reversed Chron comes from drift sediment deposited at high rates at Ocean Drilling Program (ODP) sites 983 and 984 in the Iceland basin (Channell et al., 2002). Hydraulic piston cores from these sites revealed changes in the direction of the magnetic field corresponding to at least seven excursional events and six reversals bounding subchrons (Figure P57). Each of these directional shifts is associated with a low in the relative intensity of the magnetic field, but there are also other paleointensity lows not associated with prominent directional excursions (Channell et al., 2002). ODP 983 and 984 cores record paleointensity lows corresponding to the Santa Rosa and Punaruu events, and to reversals bounding the Jaramillo, Cobb Mountain, Olduvai, and Reunion subchrons, each with an astronomical age that is within an error of the radioisotopic ages (Figure P57). Alternatively, a few events found in the ODP 983 and 984 cores, for example the Bjorn, Gardar, and Gilsa events, have yet to be  ${}^{40}\text{Ar}/{}^{39}\text{Ar}$  dated in lavas, although the transitionally magnetized lava from Cerro del Fraile that is poorly dated between 1610 and 1430 ka may correspond to one of the latter two events (Figure P57). In the site 983 core, a paleointensity low accompanying an equator crossing of the virtual geomagnetic pole direction was not highlighted by Channell et al. (2002), but the astronomically estimated age of 2055 ka is close to the <sup>40</sup>Ar/<sup>39</sup>Ar age of the Huckleberry Ridge event (Figure P57).

For the Brunhes normal Chron we have the global compilation of paleointensity data known as SINT-800 that indicates at least eight periods when the virtual axial dipole moment (VADM) is dropped below about  $4 \times 10^{22}$  Am<sup>2</sup> (Guyodo and Valet, 1999). Three of these events, astronomically dated at ca. 590, 190, and 40 ka, broadly correspond to the Big Lost, Jamaica, and Laschamp excursions. However, closer inspection reveals that the 40 Ar/39 Ar ages for the Big Lost and Albuquerque Volcanoes/Pringle Falls excursions are several ka older than first-order intensity lows recorded in the sediment (Figure P57). The SINT-800 paleointensity record is based on 33 sediment cores, no two of which preserve identical patterns of paleointensity (Guyodo and Valet, 1999). Given uncertainties associated with generating astrochronologic age models, and a limited understanding of how magnetic remanence acquisition may be delayed or distorted in marine sediments, these temporal mismatches suggest that caution be used when attempting to correlate the major paleointensity lows across the globe. Alternatively, dating of transitionally magnetized lava flows relies upon well understood process of radioisotopic decay and thermal magnetic remanence.

<sup>40</sup>Ar/<sup>39</sup>Ar dating of lava flows which directly record brief periods of geomagnetic field instability, coupled with recognition of these events in marine sediment, indicate that both excursions and reversals reflect intrinsic behavior of the geodynamo. Singer *et al.* (2002) proposed that when the stability of the geodynamo is considered, rather than the lengths of polarity chrons, an alternative approach to the GPTS is needed. Hence, a new <sup>40</sup>Ar/<sup>39</sup>Ar-based Geomagnetic Instability Time-Scale (GITS) for the last 2.2 Ma is under construction (Figure P57). Experience suggests that many geomagnetic events remain to be discovered or verified as more lava flow sequences are studied in detail.

## POLE, KEY PALEOMAGNETIC

### Introduction

Using paleomagnetism to reconstruct continents in the Precambrian has proven to be exceedingly difficult despite a database of many hundreds of paleomagnetic poles from around the world. The most serious problem involves the large age uncertainties associated with most Precambrian paleopoles. This is due to a number of factors, most notably the poor age constraints on the rock-units from which the paleopoles are derived and magnetic overprinting during metamorphic events.

Roy (1983) first pointed out that most Precambrian paleopoles were too poorly dated, with uncertainties of tens or even hundreds of millions of years, to be of use in defining apparent polar wander paths (APWPs). Buchan and Halls (1990) suggested rigorous criteria to identify individual paleopoles that are sufficiently well defined and well dated that they are useful for defining apparent polar wander paths or reconstructing paleocontinents. Such paleopoles were termed "key paleopoles" by Buchan *et al.* (1994).

### Criteria of a key paleomagnetic pole

The following basic criteria for a key paleomagnetic pole are adapted from Buchan and Halls (1990) and Buchan *et al.* (2001).

- (a) *Age of the paleopole*: The paleopole should be demonstrated to be primary and the rock-unit precisely and accurately dated.
- (b) *Quality of the paleopole*: The primary paleomagnetic remanence should be properly isolated, secular variation averaged out, and, where necessary, correction made for crustal tilting.

The critical importance of the age criterion cannot be overemphasized; *only* well dated paleopoles should be considered as key paleopoles. Field tests are required to demonstrate that the remanence is primary. For example, igneous rocks can be shown to carry a primary remanent magnetization using the baked contact test (see *Baked contact test*). A Precambrian rock-unit must have a radiometric age with an uncertainty of  $< \pm 20$  Ma (Buchan *et al.*, 2001). At present, only U-Pb and Ar-Ar dating meet this requirement. In the future, with improved analytical techniques it should be possible to strengthen this criterion and require age uncertainties  $< \pm 5$  Ma.

It is important to ensure that the age and the paleomagnetic remanence are actually derived from the same geological unit. Thus, the geochronological and paleomagnetic studies should be integrated and carried out at the same sampling localities wherever possible (e.g., Buchan *et al.*, 1994).

The direction of the paleomagnetic remanence used to calculate the paleomagnetic pole must accurately represent the direction of the Earth's magnetic field. In particular, the paleopole itself must be properly isolated to ensure that secondary magnetizations have been eliminated. This requires the use of stepwise alternating field and thermal demagnetization techniques. Secular variation must be averaged out. For example, in the case of rapidly cooling igneous units such as volcanic flows, several different units must be sampled. The paleopole must be corrected if crustal tilting has occurred since remanence acquisition.

## Apparent polar wander path method vs. comparison of key paleomagnetic poles

The standard practice of comparing APWPs for different continental blocks in order to determine their relative movements often breaks down in the Precambrian. At present, there are simply too few key paleopoles from most continental blocks to allow meaningful APWPs to be constructed. In an attempt to circumvent this problem, it has been standard practice to make use of large numbers of poorly dated paleopoles. In some cases, the large uncertainties in the age of most of the paleopoles are disregarded. In other cases, "grand mean" paleopoles are calculated from the poorly constrained data and used as tie-points along the APWP. In still other cases, the APWP is simply interpolated over relatively long time intervals between existing individual paleopoles or grand mean paleopoles.

However, as noted above, most Precambrian paleopoles are too poorly dated to allow them to be properly sequenced along APWPs. Long time gaps in the paleopole record from a given continental block make it difficult to interpolate between them. In addition, interpolation between widely separated paleopoles is hindered by an ambiguity in magnetic polarity that results from the lack of continuous APWPs from the Precambrian to the Present. The unreliability of Precambrian APWPs based on poorly dated paleopoles was illustrated by Buchan *et al.* (1994), who used key paleopoles to demonstrate that the widely used Paleoproterozoic APWP for the Superior Province of the Canadian Shield was invalid.

The extent of the dating problem has been described in recent reviews by Buchan *et al.* (2000) and Buchan *et al.* (2001), who examined the Baltica-Laurentia database for the Proterozoic and the global database for the period 1700-500 Ma, respectively. They concluded that only a very few Proterozoic paleopoles are sufficiently well dated to pass the age criterion for a key paleopole. Although many paleopoles in the database are well defined, their ages are uncertain. Either they do not have a rigorous field test to determine that the remanence is primary, or the rock-unit from which they have been derived is undated or poorly dated. Most of the key paleopoles that were identified come from a single continental block, Laurentia. A few are available from Baltica. More recent work has yielded key paleopoles for Australia (e.g., Wingate and Giddings, 2000; Pisarevsky *et al.*, 2003). Unfortunately, there are as yet no key Proterozoic paleopoles that can be used for reliable APWP construction from most other continental blocks.

The comparison of APWPs derived from different continental blocks is the ideal method of determining if continental blocks were drifting as a unit or separately. However, Buchan and Halls (1990) and Buchan *et al.* (1994) suggested that key paleopoles only be connected to form a segment of an APWP if their ages are within 30 Ma.
Instead, Buchan *et al.* (2000) proposed that, until enough key paleopoles are available to construct reliable APWPs, individual key paleopoles of the same age from different continental blocks should be directly compared in order to determine the relative position of the blocks. Of course, comparing key paleopoles of a single age would not yield a unique reconstruction, because of the longitudinal uncertainty inherent in the paleomagnetic method. However, as noted by Buchan *et al.* (2000, p. 185–186), a unique reconstruction may be possible if two (or more) ages of key paleopoles are compared and if the continental blocks in question moved as a unit and rotated through a significant angle during the period under study.

# Conclusion

Reliable APWPs and continental reconstructions cannot be obtained from poorly dated paleomagnetic poles, no matter how many are used or how well defined are the paleopole themselves. Key paleopoles that are both well dated and well defined are a prerequisite for establishing reliable APWPs and producing robust paleocontinental reconstructions.

# POTENTIAL VORTICITY AND POTENTIAL MAGNETIC FIELD THEOREMS

Theoretical studies of motions in the Earth's fluid (liquid) metallic outer core, where the main geomagnetic field is produced by self-exciting *dynamo* (q.v.) action, are based on the nonlinear partial differential equations (PDEs) of *magnetohydrodynamics* (*MHD*) (q.v.) that govern the flow of electrically conducting fluids. The equations are mathematical expressions of the laws of *mechanics*, *thermodynamics* and *electrodynamics* applied to a continuous medium.

The equations of electrodynamics are not needed when dealing with fluids of low electrical conductivity, for effects due to Lorentz forces associated with the flow of electric currents are then negligible, as in dynamical meteorology and oceanography. In these highly developed areas of geophysical fluid dynamics a key role is played by the concept of *potential vorticity* (PV). This pseudoscalar quantity— defined as the reciprocal of the density of the fluid multiplied by the scalar product of the vorticity vector and the gradient of any differentiable scalar quantity, such as the potential temperature or specific entropy of the fluid (see Eqs. (2), (17) below)—satisfies an elegant theorem (see Eq. (3)) due to Ertel (1942; see also Gill, 1982; Pedlosky, 1987).

In the words of Pedlosky (1987, p. 38) extolling the virtues of Ertel's theorem: "although the vorticity equation [which expresses the effects of torques associated with forces acting on a moving fluid element] is illuminating because it deals directly with the vector character of vorticity, it is more descriptive of how vorticity is changed than a useful constraint on that change. Kelvin's (circulation) theorem is more powerful, but (it) is an integral theorem dealing with a scalar and requires knowledge of the detailed evolution of material surfaces in the fluid. ... (The) beautiful and unusually useful theorem due to Ertel (governing the behavior of potential vorticity) ... provides a constraint on vorticity which is free from many of (these) difficulties..."

An analogous constraint (Hide, 1983) on the behavior of the magnetic field (rather than vorticity) in a moving electrically conducting medium follows directly from the equations of electrodynamics (see Eqs. (6), (7) below). The constraint involves the concept of potential magnetic field (PMF) (defined by Eq. (6)), the behavior of which is governed by the general expression given by Eq. (7), the electrodynamic analogue of the Ertel PV theorem (for recent references see Hide, 2002, 2004). The full set of mathematical equations obtained by incorporating into extended versions of these PV and PMF theorems (see Eqs. (8) and (9) below) the constraints that arise from thermodynamic considerations on potential temperature or specific entropy should facilitate future theoretical and numerical investigations of the geodynamo (q.v.) and other MHD phenomena encountered in theoretical geophysics and astrophysics; see Hide (1996). The rest of present article closely follows Hide (1996), material from which is reproduced here by kind permission of the Royal Astronomical Society and Blackwell Publishers.

# **Potential vorticity**

Consider a continuous medium in which the mass density is  $\rho(\mathbf{r},t)$  and Eulerian velocity relative to an inertial frame is  $u(\mathbf{r},t)$  at a general point P with position vector **r** at time *t*. Conservation of mass requires that

$$\frac{\mathsf{D}\rho}{\mathsf{D}t} + \rho\nabla \cdot \boldsymbol{u} = 0 \tag{Eq. 1}$$

(where  $D/Dt \equiv \partial/\partial t + \boldsymbol{u} \cdot \nabla$ ), which reduces to  $\nabla \cdot \boldsymbol{u} = 0$  when the medium is incompressible.

If by  $\xi \equiv \nabla \times \boldsymbol{u}$  we denote the (absolute) vorticity and by

$$\rho^{-1}\xi\cdot\nabla H^* \tag{Eq. 2}$$

the so-called "potential vorticity", where  $H^* = H^*(\mathbf{r},t)$  is any continuous and differentiable function, then by a very slight extension of Ertel's theorem (see Gill, 1982; Pedlosky, 1987), we have

$$\frac{\mathrm{D}}{\mathrm{D}t}\left(\frac{\boldsymbol{\xi}\cdot\nabla H^*}{\rho}\right) = \frac{\boldsymbol{\xi}}{\rho}\cdot\nabla\frac{\mathrm{D}H^*}{\mathrm{D}t} + \nabla H^*\cdot\Psi \qquad (\mathrm{Eq.}\ 3)$$

where

$$\Psi \equiv \rho^{-2} [\mathbf{g} \times \nabla \rho + \nabla \times (\mathbf{j} \times \mathbf{B}) + \nabla \times \mathbf{F}].$$
 (Eq. 4)

Here  $-\mathbf{g}$  is the acceleration due to gravity and  $\mathbf{j} \times \mathbf{B}$  the, Lorentz ponderomotive force, if  $\mathbf{j}(\mathbf{r},t)$  is the electric current density at P and  $\mathbf{B}(\mathbf{r},t)$  is the magnetic field, which satisfies

$$\nabla \cdot \boldsymbol{B} = 0. \tag{Eq. 5}$$

The term F in Eq. (4) represents the visco-elastic force acting on an element of material of unit volume which at time t is situated at P, reducing in the case of a fluid to the usual term representing the viscous force.

# Potential magnetic field

Analogous to the derivation of Eq. (3) from the equations of dynamics, is the derivation from the equations of electrodynamics of an expression governing the behavior of the "potential magnetic field", defined as

$$\rho^{-1}\boldsymbol{B}\cdot\nabla G^* \tag{Eq. 6}$$

(where  $G^*$ , like  $H^*$ , is any continuous and differentiable function of r and t), namely

$$\frac{\mathrm{D}}{\mathrm{D}t}\left(\frac{\boldsymbol{B}\cdot\nabla G^*}{\rho}\right) = \frac{\boldsymbol{B}}{\rho}\cdot\nabla\frac{\mathrm{D}G^*}{\mathrm{D}t} + \nabla G^*\cdot\Phi \qquad (\text{Eq. 7})$$

(Hide, 1983). Here  $\Phi$  comprises several terms, all of which vanish when the medium is a perfect conductor of electricity and thermoelectric, Hall, Nernst-Ettinghausen and other "nonohmic" effects are negligible. (Consistent with the neglect of relativistic effects, no account is taken of Maxwell displacement currents and electrostatic forces can be ignored in *F*, see Eq. (4).)

Now make the successive substitutions  $H^* = H$  and then  $H^* = q'H$ in the potential vorticity Eq. (3) and combine the resulting two equations to obtain

$$\frac{\mathrm{D}}{\mathrm{D}t} \left[ \frac{H}{\rho} \boldsymbol{\xi} \cdot \nabla \boldsymbol{q}' \right] = \left( \frac{\boldsymbol{\xi} \cdot \nabla \boldsymbol{q}'}{\rho} \right) \frac{\mathrm{D}H}{\mathrm{D}t} + \frac{H}{\rho} \left( \boldsymbol{\xi} \cdot \nabla \frac{\mathrm{D}\boldsymbol{q}'}{\mathrm{D}t} \right) + H \boldsymbol{\Psi} \cdot \nabla \boldsymbol{q}'$$
(Eq. 8)

In the same way, substitute  $G^* = G$  and then  $G^* = qG$  in the potential magnetic field equation (7); hence

$$\frac{\mathrm{D}}{\mathrm{D}t} \left[ \frac{G}{\rho} \mathbf{B} \cdot \nabla q \right] = \left( \frac{\mathbf{B} \cdot \nabla q}{\rho} \right) \frac{\mathrm{D}G}{\mathrm{D}t} + \frac{G}{\rho} \left( \mathbf{B} \cdot \nabla \frac{\mathrm{D}q}{\mathrm{D}t} \right) + G \Phi \cdot \nabla q$$
(Eq. 9)

(The functions H, G, q, and q' are also arbitrary. see Hide, 1996.)

Equations (8) and (9) are useful extensions of the general results expressed by Eqs. (3) and (7) respectively, for each equation contains two arbitrary scalars, rather than just one. Suitable choices of these scalars lead directly to other general results, such as a relationship between forms of potential vorticity, helicity and superhelicity in hydrodynamics and its counterpart in electrodynamics (see Hide, 1989, 2002).

# Some geophysical applications

As an application of these equations we set  $G = \xi \cdot \nabla q'$  in Eq. (9) and H as a comparable function of **B** and q in Eq. (8) and subtract the resulting equations. Thus:

$$\frac{\mathbf{D}}{\mathbf{D}t} \left[ \log \frac{\mathbf{B} \cdot \nabla q}{\xi \cdot \nabla q'} \right] = (\mathbf{B} \cdot \nabla q)^{-1} \left[ \mathbf{B} \cdot \nabla \frac{\mathbf{D}q}{\mathbf{D}t} + \rho \Phi \cdot \nabla q \right] 
- (\xi \cdot \nabla q')^{-1} \left[ \xi \cdot \nabla \frac{\mathbf{D}q'}{\mathbf{D}t} + \rho \Psi \cdot \nabla q' \right]$$
(Eq. 10)

Equation (10) is particularly useful when q and q' are simply related to the coordinates of the general point P. Consider for example the case when spherical polar coordinates  $(r, \theta, \phi)$  are used and q = q' = r. Equation (10) then reduces to

$$\frac{\mathrm{D}}{\mathrm{D}t} \left[ \log \left( \frac{\mathbf{B}_r}{\xi_r} \right) \right] = \frac{1}{B_r} (\hat{\mathbf{B}} \cdot \hat{\nabla} u_r + \rho \Phi_r) - \frac{1}{\xi_r} \left[ \hat{\xi} \cdot \hat{\nabla} u_r + \rho \Psi_r \right]$$
(Eq. 11)

where the subscript r denotes the r-component of the corresponding vector and the operators

$$\hat{\mathbf{B}} \cdot \hat{\nabla} \equiv \mathbf{B} \cdot \nabla - B_r \partial / \partial r \quad \text{and} \quad \hat{\xi} \cdot \hat{\nabla} \equiv \xi \cdot \nabla - \xi_r \partial / \partial r$$
(Eq. 12)

Comparable relationships can be found by setting q and q' equal to  $\theta$  and  $\phi$ .

In geophysical and astrophysical fluid dynamics we are often interested in fluids for which the electrical conductivity is very high and "non-ohmic" effects (see Eq. (7)) are negligible, so that Alfvén's "frozen magnetic flux" (q.v) theorem holds. Then the vector  $\Phi = 0$ in Eq. (7) (see also Eqs. (9), (10) (11)) which when  $G^* = r$  and the fluid is incompressible (so that Dp/Dt, see Eq. (1)) gives

$$\frac{\mathrm{D}}{\mathrm{D}t}B_r = \mathbf{B} \cdot \nabla u_r \tag{Eq. 13}$$

This equation has been put to good use by geophysicists in work on the determination of the flow just below the Earth's core-mantle interface from observations of the *geomagnetic secular variation* (q.v.); see Eq. (16) below.

Also of interest are studies of flows in rapidly rotating systems, where it is convenient to work in a frame of reference that rotates relative to an inertial frame with angular velocity  $\Omega = (\Omega \cos \theta, -\Omega \sin \theta, 0)$  about the polar axis. Equations (1)–(11) hold in the new frame if we re-define  $\xi$  as being equal to  $\nabla \times \boldsymbol{u} + 2\Omega$ , include centripetal effects in **g** and add the term  $\rho \boldsymbol{r} \times d\Omega/dt$  to  $\boldsymbol{F}$  (see Eq. (4)). Such flows include those where to a first approximation buoyancy forces act in the radial direction and other forces and torques acting on individual fluid elements are in magnetostrophic balance which, when Lorentz forces are also negligible, reduces to geostrophic balance. Magnetostrophic balance is characterized here by setting

$$(\xi_r, \xi_\theta) = 2\Omega(\cos\theta, -\sin\theta)$$
 and  $\Psi = \rho^{-2} \boldsymbol{j} \times \boldsymbol{B}$ , (Eq. 14)

with  $\Psi = 0$  in the geostrophic case. When combined with Eq. (14), Eq. (11) gives

$$\frac{\mathrm{D}}{\mathrm{D}t} \log \left(\frac{B_r}{\cos \theta_r}\right) = \left(\frac{\hat{\boldsymbol{B}} \cdot \hat{\nabla}}{B_r} - \frac{\hat{\boldsymbol{\xi}} \cdot \hat{\nabla}}{2\Omega \cos \theta}\right) u_r - \frac{\left[\nabla \times (\boldsymbol{j} \times \boldsymbol{B})\right]_r}{2\rho \ \Omega \cos \theta}$$
(Eq. 15)

In the case of geostrophic flow over a spherical surface where  $u_r$  is negligibly small in magnitude in comparison with  $u_{\theta}$  and  $u_{\phi}$ , it follows immediately from Eq. (15) that

$$\frac{\mathrm{D}}{\mathrm{D}t}(B_r \sec \theta) = 0 \tag{Eq. 16}$$

implying the conservation of the quantity  $B_r \sec \theta$  on moving fluid elements. This result is a familiar one in work on the determination of motions just below the Earth's core-mantle boundary from *geomagnetic secular variation* data (*q.v.*), where near-uniqueness can be secured by combining the assumption of geostrophy with Alfvén's

842

frozen magnetic flux theorem (see Eq. (13)). Conditions under which the result can be expected to apply are clearly exposed by its novel derivation here from the powerful general theorems governing the behavior of potential vorticity and potential magnetic field in magnetohydrodynamic flows.

The full equations of magnetohydrodynamics express not only the laws of mechanics (the basis of Eq. (3)) and of electrodynamics (the basis of Eq. (7)) but also the laws of thermodynamics governing, inter alia, the behavior of specific entropy  $\Theta = \Theta(\mathbf{r},t)$ . This quantity satisfies

$$\frac{D\Theta}{Dt} = Q \tag{Eq. 17}$$

where  $Q = Q(\mathbf{r},t)$  represents thermal conduction, radiation and other diabatic effects, including ohmic heating. We conclude this short note by observing that Eq. (10) with  $q = q' = \Theta$  shows that isentropic flows, for which Q = 0 by definition, satisfy

$$\frac{\mathrm{D}}{\mathrm{D}t} \left( \frac{\mathbf{B} \cdot \nabla \Theta}{\xi \cdot \nabla \Theta} \right) = 0 \tag{Eq. 18}$$

in regions where  $\Psi^*$  and  $\Phi$  are also negligibly small. According to Eq. (18), within such flows the ratio of the components of **B** and  $\xi$  in the direction of  $\nabla \Theta$ , the gradient of specific entropy, is (like  $\Theta$  itself) conserved on moving fluid elements. A further result of geophysical and astrophysical interest is that Eq. (18) reduces to Eq. (16) in cases when approximate geostrophic balance obtains and the nonradial components of  $\nabla \Theta$  are much weaker than its radial component.

# PRECESSION AND CORE DYNAMICS

The Earth is forced to precess by the gravitational action of the Sun, the Moon and the other planets of the solar system on its equatorial budge. Like a spinning top, the axis of rotation of the planet moves on a cone of semiangle 23.27° with a period of 26000 years, which is known from early astronomy as the precession of the Earth. The motions of the axis on smaller cones with shorter periods are known as nutations. The amplitudes and periods of the precession nutations are directly connected to the shape (ellipticity) and structure of the Earth. The presence of a liquid layer (the core) at the center of the planet introduces a differential precession between liquid and solid parts and their coupling sets the amplitude of this difference. After a first attempt by Kelvin, Hough (1895) and Poincaré (1910) were the first to model this problem in order to determine whether the interior of the Earth is liquid or solid. Considering an inviscid fluid, Poincaré suggested that the response of the fluid is rather simple as it is a solid body rotation and a gradient flow associated with the ellipticity of the solid boundary. More generally, Busse (1968) revealed an analogy between the core flow induced by precession and the one due to tidal bulge. Malkus (1968) envisioned the core motion associated with precession as a possible source for the geodynamo.

# Position of the axis of rotation of the Core

The axis of rotation of the liquid core differs from the axis of rotation of the mantle and the torque balance on the fluid core gives the relative position of the two axes (Poincaré (1910) for the inviscid problem and Busse (1968) for the viscous correction). In Figure P58, the photograph illustrates this situation as the rotation axis of fluid is clearly off the axis of the container. It is worth noting that there is no differential rotation along the axis of rotation of the fluid while the flow

**Figure P58** Precessional flow in a laboratory spheroid. Kalliroscope flakes dispersed in the fluid are illuminated by a beam of light in a plan containing both the rotation axis of the container and of the fluid. Any shear in the flow aligns the flakes. The obliquity angle is 20°. Experimental details can be found in Noir *et al.* (2003). Meridional cross sections of geostrophic cylinders aligned with the axis of the Poincaré mode are clearly seen. Oscillations (or instabilities?) of the axis are also visible.

induced by precession is not associated with a spin-up process, which would not preserve the geometry of the Poincaré mode (Greenspan, 1968). As the Earth's rotation decreases, the precessional and nutational forcings vary and the fluid response may match an eigenmode flow in the rotating core known as the "tilt-over mode" (Greenspan, 1968), generating a resonance in the core which may be related to the reversals frequency of the geomagnetic field or major geologic events (Greff and Legros, 1999). Noir *et al.* (2003) have observed this resonance in their experiment and showed its nonlinear implications from the torque balance; very large excursions of the axis of rotation of the fluid are predicted. It remains unclear how the presence of an inner core (with a different ellipticity) would influence these results.

#### **Boundary layer singularities**

A thin boundary layer develops at the core-mantle boundary to ensure continuity of the velocity field. Both magnetic (electromagnetic skin layer) and viscous (Ekman layer) effects form a layer a few hundreds meter in depth at the liquid core boundaries (see Core, boundary layers, Loper, 1975; Deleplace and Cardin, 2005). Because of their diurnal oscillations, the viscous boundary layer is singular at the critical latitudes ( $\pm 30^{\circ}$ ) and diurnal jets or shear layers erupt in the bulk fluid along characteristic cones associated with inertial waves in the fluid core (Hollerbach and Kerswell, 1995; Noir *et al.*, 2001). Asymptotic scaling (with no magnetic field) lead to diurnal motions in the core of amplitude  $\approx 10^{-5}$  m/s, depending on the effective viscosity of the fluid outer core.

# **Geostrophic motions**

Cylindrical motions have been observed in precession experiments (Malkus, 1968; Vanyo *et al.*, 1995). In Figure P58, we clearly see axisymmetric geostrophic shear flows (Black and white lines parallel to the axis of rotation). Their source is associated with a nonlinear effect in the boundary layer at the critical latitude. These geostrophic motions have been retrieved in nonlinear calculations of precessing flows (Noir *et al.*, 2001). Malkus (1968) determined the amplitude of the velocities of the geostrophic cylinders and the recent numerical results agree qualitatively with his experimental findings. In the absence of magnetic field, an amplitude of  $10^{-5}$  m/s of the geostrophic cylinders is predicted in the Earth's core.

# Instabilities

In Figure P58 the central axis of rotation of the fluid shows a variation of the brightness. This modulation may be the signature of an elliptical or shear instability, which would result from the nonlinear interaction of two inertial waves and the Poincaré flow according to symmetry rules (Kerswell, 2002). Such an instability may lead to intermittency of small-scale turbulence (Malkus, 1989; Lorenzani and Tilgner, 2003; Lacaze *et al.*, 2004). It is difficult to apply these results to planetary interiors as they are only partially understood in simple systems.

#### Dynamo action

In the past, energetic arguments based on the Poincaré mode alone, have been used to rule out precession as a source for the geodynamo (Loper, 1975). This result is invalid if we consider that the Poincaré mode transfers energy from the kinetic energy stored in the Earth's equatorial rotation (Malkus, 1968) to secondary motions within the core (geostrophic cylinders, instabilities) through nonlinear effects which have not been taken into account in Loper's approach.

The Poincaré flow cannot produce any dynamo action as it is mainly a solid body rotation. The erupted layers and connected inertial waves are diurnal and confined to very small regions; they may participate to a permanent dynamo only through a nonlinear and alpha-effect but no results have been reported according to our knowledge. Geostrophic motions and associated instabilities can produce a kinematic dynamo as Tilgner (2005) just proved, at least for a very viscous fluid. The importance of elliptical instabilities for the dynamo remains an open question even though Aldridge and Baker (2003) used them as a basis of an interpretation of the paleomagnetic reversals frequency.

# PRICE, ALBERT THOMAS (1903–1978)

An applied mathematician, born in Nantwich, Cheshire, Price is regarded as one of the founding figures in the development of geomagnetism, and was particularly concerned with the determination of the electrical properties of the Earth's interior. He pioneered methods for analyzing magnetic variations and for separating them into parts arising externally and internally to the Earth's surface. Treating the external part as an inducing field, he sought to explain the internal induced part by establishing theory for electromagnetic induction in spheres, in thin sheets and shells and in half-spaces. These had direct relevance to global problems of induction in the Earth, the oceans and the ionosphere, and to local problems of electromagnetic exploration. He sought mathematical theories to explain existing data and drove data acquisition programs to test mathematical theories.

A fundamental paper by Price and Chapman (1928) (see Chapman, Sydney) established that diurnal variations in the Earth's magnetic field are derivable from a scalar potential. In the 1930s, Price derived formal solutions to induction in uniformly conducting spheres by aperiodic inducing fields (Price, 1930) and included permeability (Price, 1931), complementing solutions of Lamb for periodic fields. This made him possible to investigate the conductivity of the Earth using both the periodic daily variation of the magnetic field on quiet days  $(S_q)$  and the aperiodic storm time variations  $(D_{st})$  (see Storms and substorms, magnetic (q.v.)). He applied these theories, again with Chapman, establishing the validity of global electromagnetic induction and determining conductivity models for  $D_{st}$  (Chapman and Price, 1930) (see Mantle, electrical conductivity, mineralogy). The deeper penetrating storm time fields required a higher conductivity than was the case for  $S_q$  and this was early evidence that the Earth's electrical conductivity increases with depth. In a classic paper (Lahiri and Price, 1939), spheres in which the conductivity varied as a function of radius were considered. Analytic solutions were obtained for the special case of conductivity varying as a power of the normalized radius. These remain the only analytic solutions determined to date. Application of the theory jointly to both  $S_q$  and  $D_{st}$  revealed a rapid increase in conductivity around 600-700 km depth, a result of major importance in the study of the Earth. An additional requirement was the inclusion of a thin conducting shell at the Earth's surface, which was assumed to represent an effect of the conducting oceans.

Price provided theory for induction in nonuniform thin sheets and shells electrically insulated from their surroundings (Price, 1949), establishing what became known as Price's Equation (Parkinson, 1983). He provided analytic solutions for specific conductivity distributions and iterative schemes for obtaining numerical approximations for the general case. Through this he initiated two lines of researchinduction in the ionosphere and induction in the oceans. Price's reappraisal of ionospheric current flow with Cocks (Cocks and Price, 1969) concluded that the prevalent theory of two-dimensional current flow was inadequate and that the external part of the  $S_q$  variations required a component of vertical current flow, now a well-established premiss in ionospheric studies (see Ionosphere). With Hobbs (Hobbs and Price, 1970) he derived a suite of surface integral formulae which found direct application in his iterative schemes for solving problems of induction in the nonuniformly distributed oceans. An intense period of thin-sheet oceanic induction studies followed until computing power in the 1980s was able to cope with a thin surface sheet electrically coupled to the underlying mantle (see Ocean, electromagnetic effects).

Price's continuing interest in  $S_q$  led to a new method of separating parts arising externally to the Earth from those arising from within the earth due to induction. The two-step method, proposed with Wilkins (Price and Wilkins, 1963), involved first determining values of a potential function on the Earth's surface representing the total magnetic variation field and then separating this total field into its external and internal parts using surface integrals. The potential function was determined by iteration, minimizing residuals of line integrals of the magnetic field around closed contours on the Earth's surface. Application of the surface integrals required establishing tables of values of integrands over worldwide tesseral elements. The new method was applied, using banks of mechanical calculators, to observations made during the International Polar Year (Price and Wilkins, 1963) and to the International Geophysical Year (1964). Price was instrumental, again with Chapman, in proposing and establishing  $S_q$  as a subject of study during the International Quiet Sun Year.

Price also provided theory for so-called local induction problems, whereby the Earth is represented as a half-space. In 1950 he gave complete solutions for induced and freely decaying modes and showed that induction in a half-space by a uniform field is an indeterminate problem (Price, 1950). In 1962 he presented formal theory for the magnetotelluric method including consideration of the dimensions of the source field (Price, 1962) (see *Magnetotellurics*). Work with Jones (Jones and Price, 1970) involved a detailed analysis of boundary conditions applicable to two-dimensional induction problems and showed how numerical solutions could be obtained for models that included inhomogeneous conducting regions. This paved the way for the interpretation of anomalies found in the rapidly expanding field of magnetotelluric surveys.

Summaries of much of his work, and that of others, are given in two valuable reviews (Price, 1967a,b). These reviews include observational material, theory, and applications together with physical and mathematical insights into geomagnetic phenomena. They are still useful works of reference.

In an academic career spanning of 43 years, Price held appointments at Queen's University, Belfast (1925); Imperial College, London (1926–1951); Royal Technical College, Glasgow (1951–1952) and University of Exeter (1952–1968). He was an IGY Research Associate at the National Academy of Sciences, Washington (1961–1962) and Chairman of Commission IV of IAGA on Magnetic Activity and Disturbances (1964–1968). The Gold Medal of the Royal Astronomical Society was awarded to Price in 1969 for his work on geomagnetism and especially for his studies of the electrical conductivity in the interior of the Earth. The Royal Astronomical Society awards the Price Medal for geomagnetism and aeronomy, in his honor.

# PRINCIPAL COMPONENT ANALYSIS IN PALEOMAGNETISM

When studying the mean and variance of paleomagnetic data it is a common practice to employ principal component analysis (Jolliffe, 2002). The theory of this method is related to the mathematics quantifying the moment of inertia of a set of particles of mass about some reference point of interest. For the purposes of data analysis, principal component analysis was first promoted by Pearson (1901) and Hotelling (1933), and it also often associated with Karhunen (1947) and Loéve (1977). Principal component analysis is widely applied in crystallography (e.g., Schomaker *et al.*, 1959). In paleomagnetism (e.g., Mardia, 1972; Kirschvink, 1980), it finds application in studies of the average paleofield, paleosecular variation, demagnetization, and magnetic susceptibility. Here we discuss and demonstrate principal component analysis in application to full paleomagnetic vectorial data and, separately, to paleomagnetic directional data.

# Vectorial analysis

Consider a set of paleomagnetic vectors, with the *i*th vector  $\mathbf{x}(i)$  having intensity, inclination, and declination values (F(i), I(i), D(i)). Their equivalent Cartesian expression is just

$$\begin{aligned} x_1(i) &= F(i) \cos I(i) \cos D(i), \\ x_2(i) &= F(i) \cos I(i) \sin D(i), \\ x_3(i) &= F(i) \sin I(i), \end{aligned}$$
 (Eq. 1)

where  $\mathbf{x} = (x_1, x_2, x_3)$  represents the usual geographic components of (north, east, down). With *N* such vectorial data we can calculate their values relative to some fixed reference point  $\mathbf{r} = (r_1, r_2, r_3)$ 

$$\delta \mathbf{x}(i) = \mathbf{x}(i) - \mathbf{r} \tag{Eq. 2}$$

and with which we can calculate their covariance matrix,

$$C = \frac{1}{N} \begin{pmatrix} \sum \delta x_1(i)^2 & \sum \delta x_1(i)\delta x_2(i) & \sum \delta x_1(i)\delta x_3(i) \\ \sum \delta x_2(i)\delta x_1(i) & \sum \delta x_2(i)^2 & \sum \delta x_2(i)\delta x_3(i) \\ \sum \delta x_3(i)\delta x_1(i) & \sum \delta x_3(i)\delta x_2(i) & \sum \delta x_3(i)^2 \end{pmatrix}.$$
(Eq. 3)

This matrix can be reduced to diagonal form by an appropriate choice of axes, obtained by solving the eigenvalue problem

$$\mathbf{C}\mathbf{e}^m = \lambda_m \mathbf{e}^m,\tag{Eq. 4}$$

where  $\mathbf{e}^m$  is an eigenvector and  $\lambda_m$  is an eigenvalue (e.g., Strang, 1980). Three eigenvectors  $\mathbf{e}^m$ , for m = 1, 2, 3, and their corresponding eigenvalues  $\lambda_m$  can be found using standard numerical packages, such as LAPACK. The eigenvectors are orthogonal, and therefore

$$\mathbf{e}^m \cdot \mathbf{e}^n = 0, \quad \text{for} \quad m \neq n.$$
 (Eq. 5)

The eigenvectors only define directions; they are of arbitrary length. Here we choose to normalize the eigenvectors, so that

$$\mathbf{e}^m \cdot \mathbf{e}^m = 1. \tag{Eq. 6}$$

The eigenvalues  $\lambda_m$  are real, but they have no particular ordering; we choose an ascending order here  $\lambda_1 \leq \lambda_2 \leq \lambda_3$  for specificity.

Let us now examine transformations between geographic space  $\mathbf{x}$  and eigen space, which we designate  $\mathbf{z}$ . A transformation matrix  $\mathbf{E}$  can be constructed from a columnar arrangement of the eigenvectors  $\mathbf{e}^m$ . We choose to arrange the eigenvector columns in the order of their ascending eigenvalues,

$$\mathbf{E} = \begin{pmatrix} e_1^1 & e_1^2 & e_1^3 \\ e_2^1 & e_2^2 & e_2^3 \\ e_3^1 & e_3^2 & e_3^3 \end{pmatrix}.$$
 (Eq. 7)

The matrix  $\mathbf{E}$  is orthonormal, and therefore its inverse is equal to its transpose,

$$\mathbf{E}^{-1} = \mathbf{E}^{\mathrm{T}}.\tag{Eq. 8}$$

The matrix **E** rotates data from the eigenspace  $\mathbf{z} = (z_1, z_2, z_3)$  into the original geographic space  $\mathbf{x} = (x_1, x_2, x_3)$  through the transformation

$$\mathbf{x}(i) = \mathbf{E}\mathbf{z}(i). \tag{Eq. 9}$$

The inverse transformation is given by

$$\mathbf{z}(i) = \mathbf{E}^{\mathrm{T}} \mathbf{x}(i). \tag{Eq. 10}$$

The matrix E also diagonalizes the covariance matrix, so that

$$\mathbf{E}^{\mathrm{T}}\mathrm{C}\mathrm{E} = \Lambda, \tag{Eq. 11}$$

where

$$\Lambda = \begin{pmatrix} \lambda_1 & 0 & 0\\ 0 & \lambda_2 & 0\\ 0 & 0 & \lambda_3 \end{pmatrix}.$$
 (Eq. 12)

All of these transformations are orthonormal, they are special cases of a more general similarity transformation, for which the trace is invariant, and so

$$\operatorname{tr}(\mathbf{C}) = \operatorname{tr}(\Lambda) = \sum_{m} \lambda_{m}.$$
 (Eq. 13)

The eigenvectors and values have an important geometric interpretation. The variance of the data about the reference point  $\mathbf{r}$  is an ellipsoid, which has the following simple expression in eigenspace

$$\frac{z_1^2}{\lambda_1} + \frac{z_2^2}{\lambda_2} + \frac{z_3^2}{\lambda_3} = 1.$$
 (Eq. 14)

Depending on the relative sizes of the eigenvalues, different symmetries of the data distribution are revealed; a summary is given in Table P2. Note that each eigenvalue  $\lambda_m$  is the variance of the data along the direction defined by its corresponding eigenvector  $\mathbf{e}^m$ . If  $\lambda_3$  is the largest eigenvalue, then the major axis is defined as the line segment joining the two points  $\pm \sqrt{\lambda_3} \mathbf{e}^3$ ; the two other shorter minor axes are defined similarly. The eccentricity of each ellipsoidal equator is measured by

$$\epsilon_{mn} = \sqrt{1 - \frac{\lambda_m}{\lambda_n}}, \quad \text{for} \quad m < n.$$
 (Eq. 15)

The overall anisotropy of the variance can be roughly quantified by the most eccentric ellipsoidal equator  $\epsilon_{13}$ . Finally, it is important to recognize the fact that the line parallel to  $e^3(\mathbf{r})$  is, in a least-squares sense, the best fitting line to the data that passes through the reference point  $\mathbf{r}$ , with  $\lambda_3(\mathbf{r})$  being a measure of the misfit to this line. Moreover, the plane normal to  $e^1(\mathbf{r})$ , and which contains  $e^2(\mathbf{r})$  and  $e^3(\mathbf{r})$ , is the least-squares, best fitting plane to the data that contains the reference point  $\mathbf{r}$ , with  $\lambda_2(\mathbf{r}) + \lambda_3(\mathbf{r})$  functioning as a measure of misfit.

It is of interest to translate the eigenvalues into more conventionally interpretable quantities. For a prolate variance ellipsoid, Kirschvink (1980) has defined an approximate maximum angular deviation (MAD<sub>p</sub>) from the major axis  $e^{3}(0)$  by the conic angle determined by a projection of the minor ellipse onto the unit sphere

$$MAD_{p} = \tan^{-1}\left[\sqrt{\frac{\lambda_{1}(0) + \lambda_{2}(0)}{\lambda_{3}(0)}}\right], \text{ for } \lambda_{1} \simeq \lambda_{2} \ll \lambda_{3}. \quad (Eq. 16)$$

For an oblate variance ellipsoid, we can also define a corresponding maximum angular deviation (MAD<sub>o</sub>) from the plane normal to the most minor axis along  $e^{1}(0)$ ,

$$MAD_{o} = \tan^{-1} \left[ \sqrt{\frac{\lambda_{1}(0)}{\lambda_{2}(0) + \lambda_{3}(0)}} \right], \text{ for } \lambda_{1} \ll \lambda_{2} \simeq \lambda_{3},$$
(Eq. 17)

which is somewhat different from the definition offered by Kirschvink. With respect to the maximum intensity deviation, if the variance ellipsoid about  $\mathbf{r} = \overline{\mathbf{x}}$  is more or less spherical, then the maximum intensity deviation (MID) can be estimated as

Table P2 Eigenvalue classifications

Eigenvalues	Eigenvectors	Variance ellipsoid
$\lambda_1 = \lambda_2 = \lambda_3$	No preferred oriention	Spherical
$\lambda_1 = \lambda_2 < \lambda_3$	$e^1$ and $e^2$ have no preferred orientation	Prolate ellipsoid with rotational symmetry about $e^3$
$\lambda_1 < \lambda_2 = \lambda_3$	$e^2$ and $e^3$ have no preferred orientation	Oblate ellipsoid with rotational symmetry about $e^1$
$\lambda_1 \neq \lambda_2 \neq \lambda_3$	All eigenvectors have definite orientation	Scalene ellipsoid, with no axis of symmetry

	0.9088	31.1	-1.5					

*Note:* Results are shown for data recording a mixture of normal and reverse polarities over the past 5 Ma, as well as for normal Brunhes data only. Covariance is measured relative to the origin  $\mathbf{r} = (0, 0, 0)$  and, for Brunhes data, relative to the vectorial mean  $\overline{\mathbf{x}} = (31.3, 15.4, 19.7)\mu$ T. The direction-only analysis utilizes unit vectors of the 5 Ma data set.

846

**Figure P59** Projection of Hawaiian paleovector data onto the three geographic planes defined by  $(x_1, x_2, x_3)$  and onto the eigenplane  $z_1 - z_2$  normal to the direction of the major axis defined by  $e^3$ . (a-d) show data covering the past 5 Ma. (e-f) show data covering the normal Brunhes. In (a-c) and (e-f) we plot the major axis, and in (d) and (h) we plot the projection of the variance ellipse. Solid circles (disks) represent normal data, open circles represent reversed data.

$$MID = \sqrt{\frac{\lambda_1(\overline{\mathbf{x}}) + \lambda_2(\overline{\mathbf{x}}) + \lambda_3(\overline{\mathbf{x}})}{3}}, \quad \text{for} \quad \lambda_1 \simeq \lambda_2 \simeq \lambda_3.$$
(Eq. 18)

Otherwise, for aspherical dispersion, we need to consider the projection of the variance onto  $e^{3}(0)$ ,

$$MID = \sqrt{\sum_{m} \lambda_m(\overline{\mathbf{x}}) [\mathbf{e}^m(\overline{\mathbf{x}}) \cdot \mathbf{e}^3(0)]^2}.$$
 (Eq. 19)

# Hawaiian bimodal vectors

Let us now illustrate the utility of principal component analysis with paleomagnetic data. For this example, we consider Hawaiian paleomagnetic vector data coming from lava flows emplaced over the past 5 Ma (Love and Constable, 2003), a period of time that encompasses several periods of normal and reverse field polarity. We consider only those flows that, upon sampling and subsequent measurement, have yielded complete triplets of intensity, inclination, and declination (F(i), I(i), D(i)), and which, therefore, represent the full ambient magnetic vector at the time of deposition. Calculating the covariance matrix about the origin, using  $\mathbf{r} = 0$  in Eq. (3), we perform a principal component analysis to obtain the eigenvalues and corresponding eigenvectors; see Table P3. The major axis along  $e^3$  is orientated almost parallel to the mean direction found by others using other methodologies. This axis is shown in Figure P59a-P59c, where we see that it passes through both the zero point origin and the cloud of points defining the paleosecular variation. As a physical interpretation, it is this axis about which the geomagnetic field varies over time and, even, occasionally reverses its polarity. In Figure P59d we show the projection of the data onto the eigenplane  $z_1 - z_2$ , where we also plot the variance ellipse defined by the projection of the variance ellipsoid.

**Figure P60** Projection of Brunhes Hawaiian paleovector secular-variation data (with mean vector having been subtracted) onto (a-c) the three geographic planes defined by  $(x_1, x_2, x_3)$  and onto (d-f) the three eigenplanes defined by  $(z_1, z_2, z_3)$ . Also shown are the projections of the three equators of the variance ellipsoid in each coordinate system.

The slightly asymmetric form of the paleosecular variation about the major axis is to be noted.

# Hawaiian unimodal vectors

Next, let us consider Brunhes normal data from Hawaii. Results of a principal component analysis of these data for reference point r = 0are given in Table P3. In Figure P59e-P59g we plot the major axis defined by  $e^3$ , and in Figure P59h we show the projection of the data onto the eigenplane  $z_1 - z_2$ , along with the corresponding variance ellipse. The results here are not dramatically different from the previous result, where we used data of mixed polarities, although some slight differences in the orientation of the major axis and variance size are noted. In order to better inspect the nature of the paleosecular variation at Hawaii during the Brunhes, we perform a principal component analysis of the covariance about the mean vector  $\mathbf{r} = \overline{\mathbf{x}}$ . In Table P3 we see that much of the secular variation is roughly parallel with the mean vector; the angular difference between the orientation of the two vectors is only  $14.9^{\circ}$ . The geometric form of the variance of the secular variation is shown in Figure P60, where we plot both the data and the variance ellipse in geographic and eigencoordinates. The utility of measuring the variance about the vectorial mean  $\mathbf{r} = \overline{\mathbf{x}}$ and in the eigenspace z should now be obvious.

#### **Directional analysis**

Usually, paleomagnetists do not have complete vectorial data. Instead, directional data, consisting of inclination and declination values (I(i), D(i)), are most commonly available. Therefore, let us consider a principal component analysis for directional-only data. The equivalent Cartesian expression of the data is

$$\hat{x}_1(i) = \cos I(i) \cos D(i),$$
  
 $\hat{x}_2(i) = \cos I(i) \sin D(i),$   
 $\hat{x}_3(i) = \sin I(i).$  (Eq. 20)

With N such directional data we can calculate their covariance about the defined origin  $\mathbf{r} = (0, 0, 0)$ 

$$\hat{\mathbf{C}} = \frac{1}{N} \begin{pmatrix} \sum \hat{x}_1(i)^2 & \sum \hat{x}_1(i)\hat{x}_2(i) & \sum \hat{x}_1(i)\hat{x}_3(i) \\ \sum \hat{x}_2(i)\hat{x}_1(i) & \sum \hat{x}_2(i)^2 & \sum \hat{x}_2(i)\hat{x}_3(i) \\ \sum \hat{x}_3(i)\hat{x}_1(i) & \sum \hat{x}_3(i)\hat{x}_2(i) & \sum \hat{x}_3(i)^2 \end{pmatrix}.$$
(Eq. 21)

As before, eigenvalues  $\lambda_m$  and eigenvectors  $\mathbf{e}^m$  can be obtained for this matrix. Because all the data are unit vectors, the total variance measured relative to the origin is one and the trace of  $\hat{\mathbf{C}}$  is unity:

$$tr(\hat{\mathbf{C}}) = 1, \tag{Eq. 22}$$

and so the sum of the three eigenvalues is determined,

$$\lambda_1 + \lambda_2 + \lambda_3 = 1. \tag{Eq. 23}$$

This means that the eigenvalues have only two degrees of freedom. For a prolate variance ellipsoid, the approximate maximum angular deviation from the major axis along  $e^3$  is

$$MAD_{p} = \tan^{-1} \left[ \sqrt{\frac{1 - \lambda_{3}}{\lambda_{3}}} \right],$$
 (Eq. 24)

and for an oblate variance ellipsoid, the corresponding angular deviation from the plane normal to  $e^1$  is

**Figure P61** Equal-area projection of Hawaiian directional data, defined in (a) geographic coordinates and (b) eigen coordinates. Also shown are the projections of the variance minor ellipse, defined by  $\lambda_1$  and  $\lambda_2$ . As is conventional, the azimuthal coordinate is declination (clockwise positive, 0°–360°), and the radial coordinate is inclination (from 90° in the center to 0° on the circular edge).

$$MAD_{o} = \tan^{-1} \left[ \sqrt{\frac{\lambda_{1}}{1 - \lambda_{1}}} \right].$$
 (Eq. 25)

# Hawaiian bimodal directions

As a final example, we return to the mixed polarity Hawaiian data covering the past 5 Ma, but this time we only consider the paleodirections (I(i), D(i)). Results of a principal component analysis of the corresponding unit vectors for reference point r = 0 are given in Table P3. In Figure P61a we plot the data, and the minor ellipse defined by  $\lambda_1$  and  $\lambda_2$ , in an equal-area projection of geographic coordinates. After rotation into eigenspace (Figure P61b), we see, quite clearly, the asymmetric variance of paleodirections, thus, demonstrating the utility of inspecting directional data in the eigenspace z.

# PROJECT MAGNET

Project Magnet is a comprehensive vector aeromagnetic surveying enterprise that spanned much of the last five decades. Under the direction of the United States Navy and management by the Naval Oceanographic Office, test flights began in 1951 and full operational capabilities were established in 1953. The project ran through 1994, ultimately contributing many thousands of track miles (see Figure P62) of geomagnetic data (Coleman, 1992). The data are available on CD-ROM through the National Geophysical Data Center (Hittelman *et al.*, 1996).

The primary purpose of Project Magnet was to supply data in support of the World Magnetic Modeling (WMM) and charting program, which in turn supported civilian and military navigation requirements. The WMM has been incorporated into many global positioning system (GPS) receivers manufactured in the United States and has been used to control drift rates in inertial navigation systems. As a geophysical tool, the WMM has been useful as a reference measurement for Earth's coremantle boundary field and as an aid in geophysical prospecting and resource evaluation.

Over the years, Project Magnet surveys have been performed using five different aircrafts, with each successive one improving in range, speed or altitude, navigational capabilities, and geophysical instrumentation. From 1953 to 1970 survey aircraft flew at 4615 m and most surveys were confined to remote ocean areas. Navigation methods in use at the time were periodic celestial fixes, LORAN, and dead reckoning. As a result, navigational accuracy was rather poor and was limited to about 5 nautical miles. Altitudes were determined using a baroclinic altimeter, with an uncertainty of  $\pm 30$  m. Observations of declination, inclination, and intensity (to an accuracy of  $\pm 15$  nT) were made using a self-orienting fluxgate magnetometer, while a towed, optically pumped metastable helium magnetometer measured field intensity to  $\pm 4$  nT. Until 1970, data acquisition systems consisted primarily of strip chart recorders and navigation logs. The majority of this data has been manually digitized.

The introduction of a new aircraft in 1970 permitted high level (over 4615 m) vector aeromagnetic surveying, usually conducted at altitudes between 6200 and 7700 m. During this era, the use of inertial navigation systems improved navigational accuracy to about 1 nautical mile, and in 1987, after the appearance of GPS, accuracies were further increased to several tens of meters, but only when a reliable signal was available. A baroclinic altimeter similar to the previous one was again the only source of altitude data. Improved magnetic measurements were facilitated by a fluxgate magnetometer, providing three vector components *X*, *Y*, and *Z* in the local reference frame to accuracies of  $\pm 40$  nT. An optically pumped metastable helium magnetometer mounted on a stinger extending from the rear of the aircraft measured intensity to  $\pm 1$  nT.

Major technological improvements arrived with the 1990s and by 1992 the Project Magnet aircraft had been fitted with an ASG-81 scalar magnetometer, a NAROD ring-core fluxgate vector magnetometer, and a ring-laser gyro (RLG) inertial system. The latter two instruments were mounted on a rigid beam in a magnetically clean area at the rear of the aircraft. The RLG was used primarily for attitude determination, while GPS, a radar system and a precision barometer were employed for altitude measurements, which were determined to a precision of less than 2 m. The GPS system was the primary navigational tool, with a circular error probability of 15 m. However, the accuracy of the magnetic measurements remained the same. Technological advancements also led to the incorporation of a number of other surveying capabilities, including gravity, ocean acoustics, and ocean temperature.

Survey data were calibrated by several low level "airswings" prior to and during the high level surveying. The airswings included straight and level passes as well as roll, pitch and yaw maneuvers in each cardinal direction at 1000 feet over a ground based observatory. The calibration data were used to model aircraft intrinsic magnetic fields that perturb the magnetometer data. The contaminating fields are due to: the permanently magnetized part of the aircraft; magnetization induced by the core field; and eddy currents driven by changes in the crustal and core fields as the aircraft passed through them. A compensation model, based on developments by Leliak (1961), involves a two-step iterative least squares solution for 21 coefficients, which characterize the contaminating fields, and three bias angles, which account for differences in the orientations of the vector magnetometer and the inertial navigation system. Measurements taken over all airswing maneuvers are then included in a least squares minimization of the difference between the magnitudes of the decontaminated aeromagnetic observations and the transformed ground based observations. This transformation involves upward continuation to aircraft altitude and rotation into the aircraft reference frame using roll, pitch and heading data.

The compensation model is imprecise in that it is based on the assumption that the coefficients are constant with respect to latitude and frequency of the airswing maneuvers. There have been attempts to account for these variations and the Project Magnet database includes compensation coefficients from repeated calibration flights at observatories over the globe. More importantly, Project Magnet orientation accuracy is insufficient to prevent contamination of the magnetic field vector components due to misalignment of the aircraft coordinate system (Parker and O'Brien, 1997). Because field intensity is immune from orientation errors, Parker and O'Brien (1997) show that simple spectral analysis of intensity and the three vector magnetic components as functions of along track distance may be used as a diagnostic for this contamination.

Although one of the primary goals of Project Magnet was to characterize the magnetic field generated in Earth's core, the majority of published studies exploiting Project Magnet data have been focused on the crustal part of the field, including numerous regional magnetic

Figure P62 Coverage of Project Magnet aeromagnetic surveys, 1953–1994 (cylindrical equidistant projection). Reproduced by permission of the National Geophysical Data Center.

mapping efforts spread across the globe. These include sub-Saharan Africa (Green, 1976), South Georgia Island (Simpson and Griffiths, 1982), Iceland (Jonsson et al., 1991), and New Zealand (McKnight, 1996). A detailed study by Horner-Johnson and Gordon (2003) of short wavelength features (20-150 km) over the equatorial Pacific, suggests that magnetic anomalies associated with seafloor spreading are more clearly delineated by vector aeromagnetic data than by the traditional shipboard total field observations. O'Brien et al. (1999) developed a method, based on spectral analysis of Project Magnet data along great circle paths, to estimate the geomagnetic spatial spectrum of the oceanic crust for spherical harmonic degrees from  $l \approx 60$  to 1200. Observational models based on satellite data had previously been limited to  $l \approx 100$ . Korte et al. (2002) observed that the agreement of the new model with satellite based observations was unsatisfactory for degrees l < 100, and found that O'Brien et al. had overcompensated for external magnetic field variations in their analysis. The improved model of Korte et al. (2002) achieves better agreement with theoretical and satellite based models of the spatial spectrum.

The advent of satellite based magnetic observations, in particular Magsat in the 1980s raised the question of agreement between aeromagnetic and spaced based geomagnetic observations. An early study by Won and Son (1982), using Project Magnet data spanning the continental US and upward continued to Magsat altitude, revealed agreement in gross features of the crustal field. Using an improved method for removing the core field (spherical harmonic degrees  $l \leq 13$ ) and long wavelength external contributions, Wang *et al.* (2000) demonstrated excellent agreement between aeromagnetic and satellite data over the continental US, and suggest that an anomaly field derived from a combined dataset provides accurate estimates of the long wavelength crustal field.

# PROUDMAN-TAYLOR THEOREM

Geophysicists accept a suggestion traceable back to a paper by Elsasser (1939) that the near-alignment of the main geomagnetic field (see *Main field*) with the Earth's geographic polar axis is a manifestation of the influence on convective motions in the liquid, metallic outer *core* (q.v.) that is exerted by gyroscopic (Coriolis) forces associated with the Earth's diurnal rotation. Such forces render core motions anisotropic and highly sensitive to the mechanical and other (thermal and electromagnetic) boundary conditions imposed on the motions by the underlying solid inner *core* (q.v.) and the overlying *mantle* (q.v.) (for further references see Hide, 2000).

The influence of Coriolis forces on motions in spinning fluids is most pronounced in mechanically-driven flows satisfying the so-called Proudman-Taylor (PT) theorem. Stated in words, the theorem (see Eq. (5)) shows that "slow and steady hydrodynamical motion of an inviscid (and electrically insulating) fluid of constant density that is otherwise in steady "rigid-body" rotation will be the same in all planes perpendicular to the axis of rotation". Given in a paper by J. Proudman in 1916, the PT theorem was successfully tested by means of a laboratory experiment in which G.I. Taylor investigated the relative flow produced in a tank of water in rapid rotation about a vertical axis by the slow and steady horizontal motion of a solid body through the water (see Greenspan, 1968). In accordance with the theorem, the flow was highly two-dimensional nearly everywhere and the moving solid object carried with it a "Taylor column" of water extending axially throughout the whole depth of the tank.

We note here in passing (a) that the theorem had appeared much earlier in the literature, in a paper on tidal theory by S.S. Hough (Gill, 1982), and (b) that some writers find it convenient to refer to it as the "Proudman theorem" (Hide, 1977), to avoid confusion with another theorem, due to G.I. Taylor, concerning effects of Coriolis forces on fluid motions (see Greenspan, 1968; Hide, 1997).

Convective motions in the *core* (q.v.) cannot satisfy the PT theorem exactly because they are driven by buoyancy forces due to the action of gravity on density inhomogeneities, which give rise to axial variations of the horizontal components of the relative flow velocity (see Eq. (6)). Core motions are also influenced by Lorentz forces associated with electric currents and magnetic fields in the core, which in regions well below the *core-mantle boundary* (q.v.) may be comparable in strength with Coriolis forces (see Eqs. (1) and (2)). But—as in theoretical work in dynamical meteorology and oceanography, see e.g., Gill, 1982; Pedlosky, 1987—certain basic dynamical processes and phenomena can be elucidated by means of simplified theoretical models in which axial variations of the nonaxial components of the relative flow velocity are neglected in the first instance.

Characteristic shear waves that occur in fluids subject to Coriolis and/or Lorentz forces—such as Rossby waves, Alfvén (*magnetohydrodynamic waves* (q.v.)) and related hybrid waves (one important type of which may underlie the *geomagnetic secular variation* (q.v.))—have been investigated in this way. And so have other phenomena, such as torsional oscillations of the core-mantle system associated with angular momentum transfer within the Earth's core (Hide *et al.*, 2000) and differential rotation produced in a rapidly rotating spherical fluid annulus by *potential vorticity* (q.v.) mixing (Hide and James, 1983).

### Geostrophic and magnetostrophic flows

Flows satisfying the PT theorem belong to a wider class of "geostrophic" flows (see Gill, 1982; Pedlosky, 1987), for which the horizontal component of the local pressure gradient, **grad** p, is closely balanced by the horizontal component of the Coriolis force (per unit volume),  $2\rho \Omega x u$  (see Eq. (1)), but torques produced by buoyancy forces associated with horizontal density gradients give rise to systematic axial variations in the horizontal components of u (see Eqs. (5) and (6)). Consider a moving element of fluid of density  $\rho$  which at time t is located at a general point P with vector position r in a frame of reference that rotates with angular velocity  $\Omega$  relative to an inertial frame. Newton's second law is conveniently expressed as follows (see Hide, 1971):

$$2\rho \boldsymbol{\Omega} \mathbf{x} \boldsymbol{u} + \operatorname{grad} \boldsymbol{p} + \rho \operatorname{grad} \boldsymbol{V} + \boldsymbol{A} = 0 \tag{Eq. 1}$$

where the Eulerian flow velocity at P and the corresponding pressure and the potential due to gravitational plus centripetal effects are denoted by u, p, and V respectively. The "ageostrophic" term, A, in Eq. (1) is defined as follows:

$$A = \rho[\partial u/\partial t + (u.grad)u - rxd\Omega/dt] + curl(v\rho\omega) - jxB$$
(Eq. 2)

if  $\boldsymbol{\omega} = \operatorname{curl} \boldsymbol{u}$ , the relative vorticity vector at P, and v denotes the coefficient of kinematic viscosity. The term  $j \mathbf{x} \boldsymbol{B}$  in Eq. (2) is needed when dealing with electrically conducting fluids; it represents the Lorentz force per unit volume acting on the fluid element if  $\boldsymbol{j}$  is the electric current density and  $\boldsymbol{B}$  the magnetic field at P.

The flow is said to be *geostrophic* in regions where A is negligible in comparison with other terms in Eq. (1). Within the Earth's *core* (q.v.), such regions probably arise in its upper reaches (LeMouël, 1984; Hide, 1995) where the toroidal part of the *geomagnetic field* (q.v.) is no stronger than the poloidal part and the corresponding Lorentz term is typically no more than a few parts percent of the Coriolis term in magnitude. On the other hand, the flow is said to be in "*magnetostrophic*" (rather than geostrophic) balance in any regions where the Lorentz force provides the main contribution to A and is comparable in magnitude with  $2\rho \Omega xu$ . Such regions probably arise at depth within the core, where the toroidal part of the magnetic field may be an order of magnitude stronger than the poloidal part.

Following Hide, 1971, now consider the balance of torques acting on the moving fluid element by taking the **curl** of Eq. (1), thereby obtaining the so-called "vorticity" equation in the useful form

$$2\boldsymbol{\Omega}.\operatorname{\mathbf{grad}}(\rho\boldsymbol{u}) + \operatorname{\mathbf{grad}}\boldsymbol{V} \operatorname{\mathbf{x}}\operatorname{\mathbf{grad}}\rho + \operatorname{\mathbf{curl}}\boldsymbol{A} + 2\boldsymbol{\Omega}\boldsymbol{C} = 0.$$
(Eq. 3)

Here  $C = \partial \rho / \partial t$  which, by the mass continuity equation, satisfies

$$\operatorname{liv}\left(\rho\boldsymbol{u}\right) + C = 0. \tag{Eq. 4}$$

The PT theorem follows immediately from Eq. (3), for when the conditions A = 0, grad  $\rho = 0$  and C = 0 are satisfied, the equation reduces to

$$(2\boldsymbol{\Omega}.\mathbf{grad}) \ \boldsymbol{u} = 0. \tag{Eq. 5}$$

The above equation implies that all three components of u are independent of the axial coordinate. When the restriction to cases of fluids of constant density is relaxed we have

$$2\boldsymbol{\Omega}.\operatorname{\mathbf{grad}}(\rho \boldsymbol{u}) + \operatorname{\mathbf{grad}} V \operatorname{\mathbf{x}} \operatorname{\mathbf{grad}} \rho = 0, \qquad (\text{Eq. 6})$$

in place of Eq. (5).

Flow patterns satisfying Eqs. (5) or (6) are constrained by Coriolis forces to have no circulation in (meridian) planes containing the axis of rotation. But by Eq. (6) the horizontal component of  $\boldsymbol{u}$  is not independent of the axial direction, except in regions where **grad**  $\rho$  has no horizontal component. We note here in passing (a) that the *specific helicity*,  $\boldsymbol{u}.\boldsymbol{\omega}$ ,—a quantity of importance in *dynamo theory* (q.v.)—of flows satisfying Eq. (6) is generally nonzero (Hide, 1976), and (b) that with certain geometrical simplifications Eq. (6) leads to the meteorologist's "*thermal wind*" equation (q.v.) relating the rate of increase of the speed and direction of the geostrophic wind with height in the atmosphere to the horizontal gradient of temperature.

# Ageostrophic effects and detached shear layers

The full expression of the laws of mechanics given by Eq. (1) is, of course, *prognostic*, in the sense that when solved simultaneously with the full equations of thermodynamics and electrodynamics under all the relevant boundary conditions the equation gives the fields of all the dependent variables, p, u,  $\rho$ , j, B etc. But the expression for geostrophic flow to which Eq. (1) reduces in regions where the ageostrophic term, A, is negligible is *diagnostic* (rather than prognostic), in the sense that it provides useful relationships between u, p and  $\rho$ , but it cannot give full solutions satisfying all the relevant boundary conditions.

It follows that flows in real systems cannot be geostrophic everywhere. Regions of ageostrophic flow involving length scales so short that A is comparable in magnitude with  $2\rho \Omega xu$  must be present not only on bounding surfaces (in Ekman-Hartmann and Stewartson boundary layers (see core, boundary layers)) but also within the main body of the fluid, in "detached shear layers". It is within such regions, where effects due to Coriolis forces are countered by strong ageostrophic effects, that meridional circulation can occur. Detached shear layers formed the "walls" of the so-called "Taylor column" of fluid that remained attached to the moving solid body in G. I. Taylor's experiment. Geophysical examples of ageostrophic detached shear layers embedded in geostrophic flows are the jet streams and their associated frontal systems seen in the Earth's atmosphere and "western boundary" currents such as the Gulf Stream in the Atlantic Ocean and the Kuroshio Current in the Pacific Ocean (see Gill, 1982; Pedlosky, 1987).

Amongst the various laboratory investigations that were stimulated directly by the original "Taylor column" experiment were several studies of the effect of the inner spherical boundary on patterns of mechanically-driven (Greenspan, 1968; Hide, 1977) and buoyancy-driven flows in a rotating spherical annulus of fluid. These studies clearly demonstrated what general arguments based on Eq. (5) or (6) predict, namely that near the imaginary "tangent cylindrical surface" (see Inner core tangent cylinder) in contact with the equator of the inner spherical surface and extending axially throughout the fluid, a detached shear layer would form inhibiting mixing of fluid in the "polar" regions inside the cylinder with fluid in the "equatorial" region outside the cylinder. Such behaviour is thought to bear on core dynamics and the influence of the solid inner core on structure of the geomagnetic field (for further references see Hide, 2000 and Hide, 1966a,b).

# RADIOACTIVE ISOTOPES, THEIR DECAY IN MANTLE AND CORE

#### Introduction

The Earth is a thermal engine driven largely by heat produced from the decay of naturally occurring radioactive isotopes in its interior. At present, the main radioactive isotopes are <sup>40</sup>K, <sup>235</sup>U, <sup>238</sup>U, and <sup>232</sup>Th, whose atomic percentages, radioactive decay constants, half-life, and the heat production characteristics are given in Table R1. <sup>26</sup>Al, an extinct radioactive isotope may have been an important heat source in the early history of the Earth. Many other radioactive isotopes are also present in the Earth but they play a negligible role in heat production, either because of their low abundance or their low heat producing capacity.

The abundances of K, U, and Th in common rocks from the crust and some upper mantle materials are available from direct measurements. The compilation by Van Schmus (1995) lists their abundances and also shows some primitive mantle (present mantle+crust) estimates. Since then, new estimates of these elements in the primitive mantle (bulk silicate Earth—BSE) and the Earth have appeared, as also new experimental and theoretical studies bearing on radioactivity in the core.

# Radioactivity of the mantle

Direct measurements of the radioactivity of rocks from the mantle are limited to its outermost layers just a few hundred kilometers deep in the upper mantle. Much of the lower mantle is not accessible for direct measurements and geophysical parameters such as seismic velocities and mineral physics data cannot provide strong constraints to its composition (Mattern *et al.*, 2005). Current estimates of the abundances of K, U, and Th in BSE, and the Earth as a whole, are derived from

several geochemical models. These combine cosmochemical considerations and composition of meteorites with some coherent trace element ratios observed in upper mantle samples and meteorites. The composition of volatile-rich C1 carbonaceous chondrites (a primitive class of meteorites with elemental abundances that closely match the composition of the solar photosphere) is used as a reference to compare the terrestrial abundances and deduce chemical fractionation patterns in the Earth (C1 models). The most comprehensive modeling of this type by McDonough and Sun (1995) provides a complete description of the methods and references to prior work. The abundance data of K, U, and Th in the primitive mantle from some of these studies (Table R2) are now included in the GERM database (GERM-A Geochemical Earth Reference Model at http://earthref.org/GERM/index.html). Implicit in these models is the assumption that the lower mantle is compositionally similar to the upper mantle and that the Fe-metallic core of the Earth has no radioactivity. Whether or not the mantle is compositionally layered is still unresolved (see for example, Anderson, 1989a,b). The K/U ratio in rocks from the crust and upper mantle is  $\sim 1 \times 10^4$  but in chondrite meteorites is  $\sim 8 \times 10^4$  (see Lassiter, 2004 for an up-to-date discussion of K/U ratios in terrestrial materials and meteorites). In the geochemical models, the low K/U ratio in the Earth, and the estimated low K abundance in the Earth relative to meteorites is attributed to the loss of moderately volatile K from the Earth.

Some recent experiments have raised questions about the C1-chondrite comparisons and the postulated loss due to volatility. Oxygen, the most abundant major element in the Earth (>30% by mass) has a different isotopic composition from that in carbonaceous and ordinary chondrites (Clayton, 1993) casting doubt on their suitability for the precursor Earth material. The identical K isotopic composition of terrestrial and meteoritic material indicates that the loss of K could not be due to partial vaporization from the Earth but must have preceded the process of planetary formation (Humayun and Clayton, 1995). Furthermore, C1 meteorites cannot provide for the  $\sim$ 30% Fe abundance in the Earth (Javoy, 1995).

<sup>a</sup>Suggested average values.

Drake and Righter (2002) have discussed the general difficulty of using chondritic meteorites for the initial starting composition of the Earth. Given these considerations, and the debate about whether the mantle is compositionally layered, the geochemical estimates of K, U, and Th in Table R2 seem not well constrained.

Geophysical models use terrestrial heat-flow data or other aspects of geodynamics and plate tectonics to constrain the radioactivity of the mantle. Global average heat-flow estimates range from 30 to 44TW (TW =  $10^{12}$ W). The higher value (Pollack *et al.*, 1993; Stein, 1995) is greater than twice the radiogenic heat production of various C1 models (see compilation by Lodders and Fegley, 1998). Even at the recently suggested heat flux of  $31 \pm 1$ TW (Hofmeister and Criss, 2005), the C1 models fall short by about 10-12TW. This short-fall may be satisfied by considering a significant secular cooling delay of >1-2Ga (Ga =  $10^9$  years) where the surface heat flux represents radiogenic heat produced in the past, or by including residual primordial heat from the time of accretion. Definitive conclusions about either of these possibilities cannot be reached at present. Alternatively, additional radioactive heat sources in the interior can also meet the global surface heat flux requirement.

The only meteorite materials with O-isotopic composition similar to the Earth (and the Moon) are the enstatite chondrites (EH, EL) and the enstatite achondrites (aubrites). Models of the Earth with EH chondrites as precursor materials have been considered in some recent studies (Javoy, 1995; Lodders, 1995, 2000; Hofmeister and Criss, 2005). These models have the advantage of simultaneously satisfying the stringent requirement of the O-isotopic composition, the high iron content of the Earth, and the global heat-flow data. Models of this type result in a BSE with higher radioactive contents than those listed in Table R2. For example, Hofmeister and Criss (2005) find that suitable BSE compositions that satisfy the surface heat flux of 31 TW can be represented by compositions or mixtures with EH meteorites as one end member. If the terrestrial K/U of  $10^4$  is a constraint, for no secular cooling delay or delay of <1Ga, a BSE composition with 300–350ppmK, about 30–35ppbU, and 110–130ppbTh is required. Higher heat fluxes lead to even higher K, U, and Th contents. Using essentially EH chondrites as precursor materials, Lodders (1995) estimated the model BSE to contain over 1000ppmK. It thus appears that estimates of the radioactivity of the silicate portion on the Earth (~68% by mass of the planet) cannot be uniquely constrained at present; rather, we have some model-dependent estimates that need further evaluation.

# Radioactivity of the core

Radioactivity in the core has been a controversial topic for a long time. The traditional view is that there is no radioactivity in the core (see for example, McDonough, 1999). In contrast, some recent developments in experiments and theory suggest the possible presence of radioactivity in the core. Of the radioactive elements discussed here, K is the only element for which there is some basis both in theory and experiment (Murthy *et al.*, 2003; Lee *et al.*, 2004 and the references cited in the papers). Table R3 summarizes the theoretical and experimental estimates of K from these studies and the corresponding radiogenic heat production in the core. U and Th have been hypothesized to be in the core (Herndon, 1980), but the experimental investigations so far are inconclusive or contradictory.

The estimated core-mantle boundary (CMB) heat flux ranges from 2 to 12TW (Labrosse and Macouin, 2003 and references cited therein). The CMB heat flux controls the rate of core cooling. Nimmo *et al.* (2004) have studied the question of how best to reconcile the CMB heat flux with the small size of inner core together and the >3.5Ga age of the magnetic field. These authors note that the presence of K in the core at about 400ppm is in best accord with the present size of the inner core and the power needs of a geomagnetic dynamo for the past 3.5Ga. Using somewhat different parameters, similar conclusions have been reached by others (Labrosse, 2003 and the references cited therein). Purely thermal models of the core call for an additional heat source in the core and in view of the recent experimental data, it is reasonable to attribute this to the radioactivity of K in the core.

The GERM database values are shown for comparison.

<sup>a</sup>With chondritic U and Th.

<sup>b</sup>As quoted in Labrosse and Macouin (2003).

<sup>c</sup>See discussion in Lee and Jeanloz (2003). This is an upper limit; for realistic conditions of core formation in the Earth, the authors note that the value is likely to be much less.

We have made major strides in deciphering the chemistry and physics of the Earth's interior in the past few decades but the specific radioactive content of the mantle is not well constrained yet. The new evidence for radioactivity and radiogenic heat in the core is receiving much increased attention from geophysical and geochemical theorists and experimentalists because of its impact on the thermal and chemical evolution of the core, the planet, and the geomagnetic field.

# **REDUCTION TO POLE**

Introduced by Baranov (1957) (see also, Baranov and Naudy, 1964), the reduction-to-pole transformation of total field magnetic anomalies (see crustal magnetic field) is intended to remove the skewness of the anomalies (see Figure R1). The transformation makes the anomalies overlie the sources, makes it possible to correlate the magnetic anomalies with other types of geophysical anomalies (e.g., gravity) and geological information, and aids their interpretation. In reality, even the amplitude of the anomaly is affected (increased) when sources of induced magnetization are observed at poles in comparison to lower magnetic latitudes because the Earth's field intensity increases from equator to poles; some of the reduction-to-pole methods can take this change in amplitude into account (e.g., equivalent source method) while the others typically do not (e.g., rectangular coordinate wavenumber domain methods). The expression of a magnetic anomaly,  $\Delta T$ , due to a localized spherical source of uniform magnetization is helpful in understanding the transformation

**Figure R1** Skewness of a magnetic anomaly due to a uniform arbitrarily magnetized source below Earth's surface in an obliquely oriented Earth's magnetic field (left) and its reduced-to-pole expression in the vertical magnetization and vertical field conditions (right).

$$\Delta T(r) = -\frac{\partial}{\partial \beta} \Delta V_{\alpha}(r) = \Delta J \frac{\partial^2}{\partial \beta \partial \alpha} \frac{1}{r},$$

where *r* is source to observation distance,  $\Delta V_{\alpha}$  is anomalous potential due to the uniform anomalous magnetization direction  $\alpha$ ,  $\Delta J$  is the intensity of anomalous magnetization (q,v), and  $\beta$  is the direction of the Earth's main field (assumed uniform). To derive the anomalous source function  $(\Delta J/r)$ , one integrates the equation twice, once with respect to  $\beta$  (to find the anomalous potential), and once with respect to  $\alpha$ . The magnetization direction of the source is usually not known and, therefore, induced magnetization is assumed, leading to  $\alpha = \beta$ . The reduced-to-pole magnetic anomaly (vertical intensity anomaly due to vertical magnetization) can then be computed by twice differentiating this source function in the vertical direction (to find first the potential due to the vertically magnetized source, and then its anomaly in the vertical direction) as

$$\Delta T_z(r) = \Delta Z(r) = \frac{\partial^2}{\partial z^2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \Delta T(r) \partial \alpha \partial \beta,$$

where both  $\Delta Z$  and  $\Delta T_z$  represent the vertical intensity magnetic anomaly.

In practice, these computations are significantly easier to perform in the wavenumber domain, where the process of integration involves division by a factor and differentiation involves multiplication by a factor. Under induced magnetization conditions (i.e.,  $\alpha = \beta$ ), the reduced-to-pole anomaly in the wavenumber domain is given by

$$\Delta T_z(k)^* = |k|^2 \frac{\Delta T(k)^*}{B^2},$$

where asterisks denote wavenumber domain representation of the respective anomalies, k is the radial wavenumber; in Cartesian coordinates,  $k = (k_x^2 + k_y^2)^{1/2}$ , where  $k_x$  and  $k_y$  are the wavenumbers in x and y directions; and  $B = 1/[ik_x \cos I \cos D + ik_y \cos I \sin D + k \sin I]$ , where I and D are the main field inclination and declination, respectively, and the trigonometric quantities represent direction cosines in the north, east, and down directions, respectively. An iterative wavenumber domain method for variable directions of magnetization and Earth's field intensity appropriate for a large region is described by Arkani-Hamed (1988).

Another customary approach of achieving reduction to pole is through the equivalent source technique (Dampney, 1969; Emilia, 1973; von Frese *et al.*, 1981, 1988; Silva, 1986), where a configuration of equivalent sources is first assumed. Magnetization is generally assumed in the direction of the inducing field, but it can also be different if known for particular sources. Using inverse methods, and taking advantage of Green's principle of the equivalent layer (see Blakely, 1995), one can map magnetization variation for the region where anomalies are available. Using the derived magnetization distribution, it is possible to compute the reduced-to-pole anomaly under vertical magnetization and vertical Earth's field conditions.

The equivalent source method is subject to instabilities due to a variety of reasons (e.g., spacing of sources, altitude difference between observations and the sources, low magnetic inclinations, etc.), but most of the instabilities can be reduced or eliminated using damped least-squares or ridge regression approach (Silva, 1986; von Frese *et al.*, 1988). The wavenumber domain reduction-to-pole operations also encounter instabilities in low magnetic latitudes ( $<30^{\circ}$  inclination, i.e., when the terms involving vertical component of direction cosines are close to zero). Under these circumstances, when the other two direction cosines nearly negate one another, which happens along a line in a  $k_x - k_y$  plane due to the shape of the reduction-to-pole filter (see, e.g., Blakely, 1995), the quantity  $B^2$  is nearly zero and small errors in the anomaly field are significantly enlarged in the reduction-to-pole process. Hansen and Pawlowski (1989) describe methods to overcome these artifacts by designing a Wiener filter for this purpose.

REPEAT STATIONS

# **REPEAT STATIONS**

# Definition

Repeat stations are permanently marked sites where it is possible to make accurate observations of the Earth's magnetic field vector for a period of a few hours (sometimes a few days) every few years. Their main purpose is to track secular variation (see *Geomagnetic secular variation* and *Time-dependent models of the geomagnetic field*) and, if accurate observational techniques and careful reduction procedures are followed, they can be a cost-effective way of supplementing observatory data for secular-variation modeling. Figure R2 shows a plot of repeat station locations. The distribution is somewhat uneven, being determined more by local need and resources rather than requirements to achieve global coverage.

#### History

One of the earliest repeat station networks was in the UK where 190 stations were established and measurements were made at each by Sabine and colleagues in the 1830s (see Sabine, Edward). Many of these sites were reoccupied between 1857 and 1861. However, as the distribution of these stations was somewhat uneven and records enabling their further reoccupation do not seem to have survived, Rücker and Thorpe established a new network between 1884 and 1888 comprising some 200 stations (Barraclough, 1995 and references therein). Some of these stations are still in use today although probably none are exact reoccupations. Elsewhere in the world, the Carnegie Institution of Washington, Department of Terrestrial Magnetism (see Carnegie Institution of Washington, Department of Terrestrial Magnetism) permanently marked sites to enable reoccupation during their excursions around the world starting in the early 20th century (see Bauer, Louis Agricola) and many countries began to establish repeat station networks at around about this time.

#### Equipment

The instruments are usually the same as those used at magnetic observatories; a fluxgate theodolite to measure declination and inclination and a proton precession magnetometer (PPM) to measure field strength (see *Observatories, instrumentation*). At observatories fixed marks are usually already surveyed in but this is not always the case at repeat stations. Therefore additional instrumentation may be necessary for the determination of true north. This may be a gyro-attachment for the theodolite, eyepieces or sun filters and accurate timing equipment for sun or star observations, or separate geodetic-quality Global Positioning System (GPS) units. Also often necessary is a tent to provide shelter for the equipment and observer from the weather.

# Procedures

Great care is taken to ensure that exact reoccupation of the site is made at each visit because, if there is an appreciable local gradient in the crustal field, any error in positioning the instruments will contaminate the resulting secular-variation data. At each visit a site survey with a PPM is usually done to check for magnetic contamination of the repeat station. An auxiliary station is established a few meters from the marked site and the difference in the total intensity of the field between these two sites is established using two PPMs running simultaneously. Depending on the method being used to determine true north the fluxgate theodolite or GPS unit may then be set up over the marked site. The fluxgate theodolite for observing declination and inclination is then set up over the marked site. The PPM at the auxiliary station logs data for the duration of the declination and inclination observations. Several rounds of observations are made over a number of hours, each round involving four circle readings to eliminate collimation errors between the theodolite telescope and the fluxgate sensor and within the theodolite itself.

An important aspect of the data reduction procedures is correction for the regular daily variation (see *Periodic external fields*) and magnetic storms (see *Storms and substorms, magnetic*). When repeat stations are close to observatories, these variations are observed and corrected for using continuous observatory data. Elsewhere, especially for repeat stations in areas of complex external fields such as the auroral zones or remote from geomagnetic observatories, on-site variometers are sometimes run to monitor these variations.

A useful publication for guidance on repeat station survey procedures is that published under the auspices of IAGA (Newitt *et al.*, 1996, see *IAGA*).

Figure R2 Locations of all known repeat stations visited more than once since 1975.

# Use in modeling

Efforts to model the field over restricted regions of the Earth for the purposes of mapping rely on good local coverage of vector data such as that provided by repeat stations. Different approaches are used around the world depending on the extent of the area and coverage of data, but the most common is some form of spherical cap harmonic analysis (SCHA) (see *Harmonics, spherical cap*). As well as being applied in many individual countries to map the magnetic field, for example Canada, Spain, South Africa, SCHA has also been applied to European repeat station data to search for secular-variation anomalies. However, the degree of success has been limited partly because of the high uncertainties associated with the data (Korte and Haak, 2000). Repeat station data have also been used in global modeling and help fill in some gaps in the observatory distribution.

# **REVERSALS, THEORY**

Once it was appreciated that reversals of the geomagnetic field occurred (see Geomagnetic polarity reversals), it was natural to seek a theoretical understanding of these events. The dominant, dynamo theory for the generation of the Earth's field has no difficulty accounting for configurations in which the field is reversed from the present "normal" polarity; but detailed mechanisms, explaining how and why the field comes to reverse, remain the topics of active research, with many fundamental questions still to be definitively answered. Are reversals isolated phenomena, triggered by exceptional events within the core, or are they simply part of the normal range of the dynamical variations of the geodynamo? Does a reversal transition involve a fundamentally different regime of dynamo action (e.g., a period of field decay), or is it a relatively minor variation in the normal behavior? How does the transition field compare with the normal field? Despite the current lack of final answers, dynamo theory has been used to address all of these questions. (Reversal mechanisms have also been proposed for some of the alternative theories of geomagnetism; see Nondynamo theories.)

#### Equivalence of normal and reverse polarity states

Within the general theory of *Magnetohydrodynamics* (q.v.), the overall sign of the magnetic field is not dynamically important; the governing

equations remain unchanged, if a field in the opposite direction is substituted (see *Geodynamo, symmetry properties*). There is therefore no problem in accounting for fields of both "normal" and "reverse" polarities (with dipoles oriented parallel and antiparallel to the present-day field, respectively). Indeed, if a state such as the present-day field exists, then the reverse state must be equally possible, theoretically; it is therefore gratifying that observations suggest that both polarities have occurred equally frequently, over the lifetime of the geomagnetic field.

The dynamo can therefore be viewed as a "bistable" system, which may reside in one of two equivalent states of opposite polarity; it is relatively stable within either of these states (or else reversals would be more common than they are), and yet is prone to occasionally flipping from one state to the other. The theoretical problem is to explain how, and why, the field moves between these two states in the irregular manner which it does. This remains a rather broad question, which may be addressed in many different ways. Some authors have focused on the study of individual reversals, considering in more detail how one particular reversal is "triggered", and exactly what happens to the field as it undergoes the process; others have considered the problem over longer timescales, developing models which seek to explain the statistical properties of sequences of reversals.

# **Kinematic mechanisms**

The first successful models of dynamo action were kinematic models (see *Dynamos, kinematic*), which prescribed a flow, and investigated the magnetic field generated by this flow. It is therefore natural that some of the first attempts to explain reversals related to such models; these were typically formulated in terms of the *mean field* or *Braginsky dynamos* (*q.v.*) which were being developed at about the same time.

Within the kinematic problem, a stationary flow can generate fields of either stationary or oscillatory character (which may both ultimately grow or decay, depending on the overall strength of the flow). If the flow is made up of a number of components whose relative magnitude may be varied (e.g., differential rotation, "cyclonic" convection, and meridional circulation; the most common ingredients of mean field dynamo models), then solutions of different character are typically preferred for different forms of the velocity. Changes in the underlying flow can therefore result in changes in the nature of the field being excited (or decaying); and if the velocity moves through a suitable sequence of states, then a field reversals may be effected. The various kinematic mechanisms all propose some such sequence of velocity variations.

It is worth explicitly noting that some variation in the velocity is required, to obtain an irregularly reversing field; a stationary flow can only produce stationary or periodically reversing fields, as described above. The types of velocity variations envisaged in kinematic mechanisms are therefore entirely plausible; it is only the arbitrary manner in which the variations are assumed, without reference to the coupled dynamics of the full dynamo problem, that makes kinematic mechanisms somewhat unsatisfactory. Nevertheless, these mechanisms may still effectively isolate the important physics of reversal transitions, and thus provide insights often lost in more complex dynamical simulations.

One such mechanism was suggested by Braginsky (1964), when he first considered the consequences of dynamo action in his "nearly axisymmetric" system (see *Dynamo, Braginsky*). He found that, in the absence of a component of meridional circulation (i.e., an axisymmetric flow whose streamlines lie on planes of constant azimuth), his flows preferred to excite oscillatory fields; with some meridional circulation present, however, stationary fields were preferred. (The same situation often pertains to solutions of the closely related mean field dynamo systems.) He therefore argued that the geodynamo may normally function in the latter regime, with some meridional circulation stabilizing the solution, to give the predominantly steady geomagnetic field. If a fluctuation takes the velocity into a state with weaker meridional circulation, however, it is easy to see how an oscillation might commence, from the initially steady field. (And if the original flow was near the boundary in preferences, then only an infinitesimal change of velocity might be needed.) Indeed, such an oscillation might be expected to take the form of a simple *dynamo wave* (q,v). If the flow has returned to its original state after a single change of sign of the field (i.e., about half a period of the oscillating solution), then a stationary solution will again be preferred; but now, the stationary solution will be based on the post-oscillation field, in its new, reversed state. The same mechanism was later highlighted by Gubbins and Sarson (1994), who carried out three-dimensional kinematic calculations; and Sarson and Jones (1999) later found the effect to be important within a dynamical calculation, described below.

An alternative series of kinematic mechanisms was developed from original papers by Parker (1969) and Levy (1972). All of these are based on some form of *mean field dynamo* (q.v.), and rely on fluctuations in the strength or location of the eddy flows, or "cyclones", responsible for producing dipolar field from azimuthal field via the so-called "alpha"-effect. Parker (1969) noted that an occasional excess of cyclones at high latitudes (or a relative dearth at low latitudes) led to the fields generated at low latitudes being of opposite sign to the original, stable configuration. The new state therefore acts "degeneratively", with respect to the original field; if this situation persists for long enough for the low-latitude field to reverse sign, before the normal flow regime is restored, then the subsequent generation will be based on the new field sign, and a reversal will have been achieved. In a similar scheme, applied to a related mean field model, Levy (1972) showed that an occasional period of high-latitude cyclone activity, in a dynamo which normally generates field via low-latitude activity (or vice versa), would likewise lead to the field in some regions being "flooded" with fields of the "reverse" sign: this again can lead to a reversal, if the episodes are suitably timed. In contrast with the meridional circulation mechanism, these schemes are based entirely on stationary kinematic solutions, and rely upon the different morphologies of field excited before and after the change in velocity, to effect the reversal.

In all such kinematic mechanisms, the change in velocity responsible for triggering the reversal—and the change responsible for subsequently stabilizing the system in the new polarity—is simply imposed, and is not subject to self-consistent dynamical forces (including the feedback of the field on the flow). It may also seem rather convenient that the change of flow persists for just long enough to undergo a single transition, leading to a reversal. But in defense of the mechanism, shorter deviations in flow would plausibly give rise to excursions, which may occur more frequently than full reversals. Such fluctuations in the flow may be happening all the time, with only the more extreme cases leading to reversals (e.g., Gubbins, 1999). Additionally, there are some dynamical reasons to accept that the flow might plausibly be restored on the timescale of the field oscillation itself.

Other kinematic mechanisms are also possible, of course. It has been suggested by more than one author, for example, that reversals may begin when the field and flow have evolved to a state too close to being axisymmetric. Then, since *Cowling's theorem* (q.v.) states that such an axisymmetric state cannot be maintained, a period of field decay must commence; and depending upon the subsequent development of field and flow, a reversal may occur before the normal generation process is resumed. (A number of similar "free decay" models have been proposed, where interruptions to the normal state of convection result in flows unable to sustain dynamo action, and thus also leading to periods of field decay, and the possibility of reversals.)

# Dynamic mechanisms

The obvious limitation in the kinematic mechanisms outlined above as with kinematic theories in general—is the lack of a self-consistent treatment of the varying velocity responsible for the reversal; the equations of motion are not explicitly addressed. This is particularly unsatisfactory given that the magnetic field is thought to play a dynamically important role in the dynamo process; so that a reversal is rather likely to influence the velocity.

A strong case can be made for the geodynamo being in a so-called "strong field" state, with the magnetic Lorentz force being a dominant force. Since the magnetic field often acts to make convection easier (see, e.g., Magnetoconvection), then such a state may be dynamically distinct from nonmagnetic or weakly magnetic states, in the sense that it requires some "boot-strapping" to attain: the dynamo is stable, as long as the field is present; but if the field is lost, e.g., as a result of natural fluctuations, then the entire convective state may decay. In such a scenario, a reversal may occur as a catastrophic event, with the dynamo losing the strong field solution branch, and both field and flow initially decaying. Subsequently, convection must reestablish itself, and the strong field state may ultimately be reattained. Given the drastic nature of this field collapse, however, it is quite reasonable to allow that fluctuations might result in the new field having been seeded with either polarity, so that a reversal may have occurred. Such a scenario was envisaged by Zhang and Gubbins (2000), who noticed the extreme sensitivity of magnetoconvection calculations to the strength of the dipolar magnetic field, in particular.

Such dynamic mechanisms differ from kinematic mechanisms through their consideration of the evolving equations of motion (particularly with respect to the Lorentz force) during the reversal process. This makes such scenarios formidably complex, however, and detailed reversal mechanisms along these lines remain relatively uncommon. In terms of appreciating the dynamics of reversals, more work has perhaps been invested in studying the reversals observed in numerical geodynamo simulations. Dynamic mechanisms are also inherent in the dynamical systems models discussed further below.

# **Reversals in numerical simulations**

Another approach to understanding reversals theoretically—possible since the advent of detailed numerical simulations (see *Geodynamo*, *numerical simulations*)—is to study the reversals produced by such simulations phenomenologically, to try to understand why these particular systems, at least, undergo reversals. Given the inability of these simulations to attain the regime of the geodynamo, reversal mechanisms deduced in this way may or may not ultimately prove relevant to geomagnetic reversals; yet such studies remain clearly of interest. The output of such simulations is highly complex, however, with field and flow fluctuating together in ways that can be difficult to track, so that clear-cut mechanisms for reversals remain difficult to isolate.

Glatzmaier and Roberts (1995) noted that their reversal was accompanied by oscillations in the quadrupole component of the field, and also noted that the reversal proceeded through a relatively complex sequence of events, with the azimuthal field, and then the dipole field in the interior, reversing before the dipole field visible at the surface. They also identified an effect earlier noted by Hollerbach and Jones (1993), that the solid inner core can act to stabilize the system, providing a "reservoir" of field that cannot easily be overturned by short-term oscillations (and thus stabilizing the field to the sort of fluctuations envisaged by Gubbins, 1999). Nevertheless the overall picture remains extremely complicated, and a clear causal process is not obvious.

In a calculation with highly truncated azimuthal resolution, Sarson and Jones (1999) observed a reversal to occur shortly after a fluctuation in the meridional circulation of their solution. They could therefore relate their reversal to one of kinematic mechanisms outlined above, an interpretation that was endorsed by subsequent kinematic calculations. In this case, however, the fluctuation in meridional circulation occurred as a natural part of the full dynamic system. (It appeared to be related to a surge in the buoyancy driving.)

In perhaps the most detailed study of simulated reversals to date, Wicht and Olson (2004) analyzed a sequence of reversals obtained from a single calculation, highlighting a relatively clear sequence of effects. They also found meridional circulation to play an important role in this reversal process (and also verified this role via related kinematic calculations). Unfortunately, these reversals did not occur in a very Earth-like solution; e.g., the flow contained a significant component of transequatorial flow, which is not expected to be significant within *rotating convection* (q,v). Furthermore, as the authors themselves point out, the solution behaves almost kinematically, with the magnetic field playing no important dynamical role; again, rather far from the case expected for the Earth. (It is arguably true that all of the current numerical dynamo models behave rather too kinematically, with the magnetic field never yet playing as strong a dynamical role as it should in the geodynamo.)

Li *et al.* (2002) obtain irregular reversals in a weakly compressible, ideal gas, dynamo system. Interestingly, they find their system to possess more than one steady state (in either polarity), differentiated by different relative signs of the dipole and octupole terms. In the "high energy" state, characterized by antialigned dipole and octupole moments, the system is susceptible to reversals. This state is also associated with more vigorously fluctuating convection, and by significant transequatorial flows (as in Wicht and Olson, 2004). As in the reversal of Glatzmaier and Roberts (1995), a significant component of axial quadrupole field is observed during the transitions.

It is somewhat encouraging that the current set of numerical simulations seem to share at least some aspects of their reversal behavior. On the other hand, the detailed mechanisms occurring within any of the simulations remain imperfectly understood; and the ultimate relevance of these simulations to the geodynamo remains unproven. While promising, therefore, the analysis of reversals from numerical simulations remains at rather an early stage, in terms of deriving new models for geomagnetic reversals.

# Dynamical systems approaches

The preceding sections discussed attempts to analyze individual reversals in terms of detailed deterministic processes. Another, parallel line of enquiry, however, is concerned with the analysis of sequences of reversals. Sufficiently many reversals have been observed that reasonable sequence statistics are available (e.g., describing the statistical distribution of the durations of the stable polarity intervals). By taking sequences of "synthetic" reversals from numerical models, and calculating comparable statistics for these, theoreticians can check the long-term time-behavior of their dynamo models.

Unfortunately, obtaining reversal sequences of the length required, from the detailed numerical simulations described above, is computationally prohibitive. For this approach, a rather simplified model is required instead; various authors have chosen a variety of ways to isolate simple sets of equations which allow reversals, while, hopefully, retaining much of the essential physics of the dynamo process. In studying these systems, the dynamics omitted from the earlier kinematic mechanisms is restored to central place Yet within this approach, the question "why does the field reverse?" is not often addressed. It is accepted that such dynamical systems are subject to occasional reversals (and the systems studied are, essentially, constructed to exhibit such behavior); reversals are just one part of the normal range of behavior, together with secular variation or excursions.

This approach has a long history, going back to the coupled disk dynamos of Rikitake (1958), based on the homopolar disk dynamo (q.v.) earlier studied by Bullard. The original disk dynamo had been proposed as a heuristic model of dynamo action; by coupling two such disks together, and obtaining a system of equations exhibiting irregular reversals, Rikitake derived a heuristic model for dynamical systems reversals. This model, notably, predates the 1963 Lorenz equationsderived in a similar spirit to model atmospheric convection-which have become something of a paradigm for deterministic chaos. Although the coupled disk dynamos do not model the geodynamo more than schematically-the disk dynamo is perhaps best viewed simply as an analogue of the true geodynamo system, rather than being essentially related to it-they have retained interest as a simple dynamical model of reversals, and been subject to many studies and refinements; some early work on these systems is summarized in Moffatt (1978). While the coupled disk dynamos exhibit behavior suggestive

of reversals and excursions, however, the statistics of such behavior is not particularly "Earth-like", and alternative models have been proposed, following a variety of approaches.

Melbourne *et al.* (2001) constructed a model based on the interaction of various symmetries of magnetic field—axial dipole, equatorial dipole, and axial quadrupole—that separate in the kinematic problem, for geophysically plausible symmetries of the velocity (see *Geodynamo, symmetry properties*). For certain specializations from the generic form for the dynamical interaction of such symmetries, this system has structurally stable "heteroclinic cycles," which allow intermittent excursions and reversals between dominantly axial dipole states; and for some choices of parameters, the sequences of reversals display relatively realistic properties. While somewhat abstract in construction, the explicit use of symmetry interactions in this model is an attractive feature, potentially allowing more detailed comparisons with the paleomagnetic record, or with the output of detailed numerical simulations.

Although most models studied in this vein have been of "low order"—evolving typically just a few scalar variables, as proxies for the whole complex process of dynamo action—models of increasing complexity can now also be studied in this way. Hoyng *et al.* (2001) considered a nonlinear, axisymmetric *mean field dynamo* (*q.v.*), with the addition of random fluctuations to the "alpha"-effect term responsible for the generation of dipole field. The fluctuations model the variations in this flow on rapid timescales (cf. the magnetic timescales explicitly modeled here); in a sense they implement, in a random way, the type of fluctuations envisaged in the kinematic mechanisms of Parker and Levy. The resulting system exhibits plausible reversal behavior, with a Poissonian distribution of inter-reversal intervals, as is often claimed for the paleomagnetic data.

A complementary approach is taken by Narteau *et al.* (2000), who couple a simple mean field model for the magnetic field to a rather complex "multiscale" model for the evolution of the flow producing the "alpha"-effect. This model tries to simulate the evolution of eddy flows over a variety of length scales, albeit in a rather phenomenological way (with the cascades of energy both up and down the range of length scales being controlled in a rather arbitrary manner). The result, however, is a system containing some memory of past behavior, allowing for a wide variety of reversal behavior.

All of the above models show how the intermittent behavior observed of reversals can arise, from relatively simple dynamical systems modeling the nonlinear interactions of interest in the full geodynamo system. The challenges for future work in this direction are to identify which interactions appear most important, in modeling the true reversal behavior, and to develop this type of analysis towards more realistic simulations.

# Long-term changes in reversal behavior

The preceding analyses have assumed the problem of reversal behavior to be a static problem; they have assumed that the Earth's core is in some stationary base state, and that the observed reversal behavior reflects this underlying state (with a single statistical distribution, for example, being applicable across the whole span). Given the timescales for the evolution of the Earth's core (see, e.g., Core origin), this is a reasonable approximation for the analysis of individual transitions, or of reversal sequences of even moderate length. Yet considered over the full history of the geomagnetic field, it need not obviously remain valid. Another approach, also amenable to theoretical enquiry, considers mechanisms whereby variations in the mean state of the core over such timescales can affect the reversal behavior. Note that this approach assumes that there truly are significant variations in reversal behavior which can be investigated, and this is not vet definitively resolved. Even relatively "obvious" changes in long-term reversal behavior, such as superchrons (see Superchrons, changes in reversal frequency), might alternatively arise from "intermittency" in the dynamical system responsible for the reversals. Yet there remain some clear theoretical reasons why the long-term reversal behavior might vary.

862

Receiving most attention to date has been the thermal influence of the overlying mantle, which evolves on a much slower timescale than the core, effectively applying very slowly varying boundary conditions to the latter system (see *Core-mantle boundary coupling, thermal*). Different regimes of reversal behavior can then be anticipated for different states of this boundary; one configuration might produce flows conducive to reversals, while another may produce very stable flows. This possible effect has already been illustrated via a suite of dynamo simulations by Glatzmaier *et al.* (1999), incorporating a series of different thermal boundary conditions, and indeed obtaining different patterns of reversal behavior. While the exact relation between the simulations and the true Earth remains open to debate (as with all current simulations), the potential importance of such coupling on reversals remains clear.

Another long-term effect of potential importance is the slow growth of the Earth's inner core, which has solidified within the fluid outer core since the original differentiation of the Earth's interior (see, e.g., *Core origin.* For a number of reasons—including the important role of the inner core in permitting *chemical convection* (q.v.) in addition to thermal convection; the nonnegligible geometrical effect of a moderately sized inner core; the importance of the *Inner core tangent cylinder* (q.v.) on outer core fluid dynamics; and the magnetically stabilizing role of the inner core noted by Hollerbach and Jones (1993)—it is very likely that different regimes of dynamo behavior existed during different stages of inner core growth. Although some simulations have begun to address this topic (e.g., Roberts and Glatzmaier, 2001), the net effect of all these factors remains far from clear. Nevertheless, the potential importance to long-term reversal behavior is apparent.

Both of the above mechanisms are discussed in more detail under *Superchrons: changes in reversal frequency (q.v.)*.

# RIKITAKE, TSUNEJI (1921–2004)

The late Tsuneji Rikitake (1921–2004), professor emeritus of the University of Tokyo and the Tokyo Institute of Technology, contributed greatly to the advancement of the following areas in geomagnetism through his extensive research activity, mostly at the Earthquake Research Institute, University of Tokyo, Japan.

- 1. Electromagnetic induction by geomagnetic variations and the electrical state of the Earth's interior
- 2. Short-period geomagnetic variations and electrical conductivity anomalies in the upper *mantle* (q.v.)
- 3. Dynamo theory as a mechanism of Earth's magnetic field generation
- 4. Fluid motion in the Earth's *core* (q.v.)
- 5. A model of polarity reversal of the magnetic field (q.v.)
- 6. Magnetohydrodynamic waves (q.v.) in the Earth's core
- 7. Geomagnetic and geoelectric changes associated with earthquakes
- 8. Electrical resistivity changes of rocks associated with strain and their application to earthquake prediction
- Magnetic anomalies of volcanoes and their changes before and after volcanic eruptions (see *Volcano-electromagnetic effects*)

Figure R3 Professor Tsuneji Rikitake (1921–2004).

Rikitake (Figure R3) proposed a global model of electrical conductivity distribution in the Earth's interior by his own analyses of various types of geomagnetic variations since the latter half of the 1940s and a theory of electromagnetic response of a spherical conductor. He then found an anomaly in the vertical component of short-period geomagnetic variations in central Japan in the early 1950s. Subsequent intensive observations revealed a systematic short-period geomagnetic variation anomaly, called the Central Japan Anomaly, which was one of the earliest findings of a series of similar anomalies over the globe. He interpreted such an anomaly in terms of a conductivity anomaly, possibly undulation of the surface of the conducting mantle (q.v.). Conductors under oceanic areas seemed to be depressed under the Japanese island arc; this was understood as representing subduction of the oceanic plate beneath the island arc. Such pioneer work stimulated, in 1972, an IAGA (q.v.) workshop on electromagnetic induction; these workshops have been continued every two years, the latest (18th) having been held in Spain. Rikitake is also well known as one of the pioneers in Magnetotellurics (q.v.) for investigating the crust and upper mantle.

Rikitake was also one of the pioneers in the so-called dynamo problem in the 1950s, but without the use of high-speed electronic computers. The epoch-making work of Sir E.C. Bullard (q.v.), widely known for the Bullard-Gellman dynamo model (q.v.), showed how the magnetic field might be generated in the Earth. However, no kinematic dynamo model can give rise to polarity reversal. One day an idea suddenly came to the mind of Rikitake when he was in the train in Tokyo. He must have been thinking about the *disk dynamo* (q.v.), for which a nonreversing analytical solution had been found by Sir Edward Bullard. In an analogy to possible turbulence in the Earth's core, he considered two disks coupled together electrically. This coupled-disk model cannot be solved analytically because of nonlinearity, so Rikitake solved the nonlinear equations numerically using a mechanical calculator. He found a spontaneous polarity reversal (q.v.). This result was published by Rikitake (1958), 5 years before the finding of a famous example of chaos by a meteorologist, E.N. Lorentz. It should be remembered that recent numerical results for MHD dynamo models, derived from high-speed supercomputers, have shown the occurrence of such a spontaneous reversal. This coupled-disk model has been called the Rikitake model.

Rikitake was a professor at the Earthquake Research Institute and hence was naturally involved in earthquake and volcano studies. In the 1960s an earthquake swarm hit a small town in central Japan. Rikitake undertook electric and magnetic measurements in an attempt to find anomalous phenomena associated with earthquakes. He became one of the most distinguished experts in this research field. In particular, he found from *in situ* observations that the electrical resistivity of rock changes in response to small strains. He then devised and installed a very sensitive field instrument and discovered many examples of resistivity steps associated with earthquakes that obviously corresponded to strain steps. His interest expanded further to include various kinds of phenomena precursory to earthquakes and to systematic understanding of precursory phenomena—for example, he established empirical relations for precursory times and earthquake magnitudes.

Rikitake's research achievements were published in more than 200 original papers and more than 50 books. Although most of the books were written in Japanese, some books are written in English, such as "Electromagnetism and the Earth's Interior" (1966), or "Earthquake Prediction" (1976) which have proved invaluable to graduate students and researchers over the world.

# **RING CURRENT**

The Earth's ring current consists of millions of Amperes of electrical current, encircling the Earth in space near and within the geosynchronous orbit (6.6 Earth radii). It is a feature of the interaction between the magnetized conducting solar wind and the Earth, with its geomagnetic field and conducting ionosphere.

The geomagnetic field is a peculiar feature of Earth when compared to our planetary neighbors in the inner solar system. Mercury has a weak dipolar magnetic field, but Mars' field consists of scattered patches of remnant crustal magnetization, and Venus has no sensible planetary field. It seems plausible that the geomagnetic field has played an important role in the habitability of Earth, but this is so far unproven. We do know that the geomagnetic field creates a well-defined bubble in space, called a *magnetosphere* (q.v.). The Earth's ionosphere expands into and fills the magnetosphere with a low density conducting plasma (the fourth state of matter, consisting of free electrons and their parent ions) that is to some degree confined within it but eventually escapes.

The solar atmosphere, also in the plasma state, similarly expands into a well-defined bubble called the *heliosphere*, consisting of the solar wind plasma and magnetic field and their extension to the limits of the solar system. Just as the Earth's magnetospheric bubble is embedded in the solar wind, the heliospheric bubble is embedded within the interstellar medium, a partially ionized plasma having its own magnetic field, flowing generally away from the galactic center, but otherwise of so far indeterminate characteristics. Our galaxy has a bubble of its own, with a boundary at the edge of intergalactic space. Owing to solar variations and activity, the solar wind inside the heliosphere is highly variable in intensity and magnetic structure, on timescales much shorter than the time required for a particular parcel of the solar wind to expand to the boundary of the heliosphere.

Many types of motion of conducting gases or fluids generate electrical currents that in turn produce magnetic fields. Much as surface tension acts to confine water in droplets or air in bubbles, magnetic fields act to confine plasmas in magnetic cells. When two cells of plasma collide, or when a single magnetic cell of plasma divides into two smaller cells that go separate ways, their magnetic field lines are reconfigured accordingly by a process called *reconnection*, which links or unlinks magnetic field lines between the two cells at their boundaries. The behavior of magnetic cells is loosely analogous to the behavior of surface tension bubbles, but the magnetic field and its cohesive influence are distributed throughout a plasma cell and are not concentrated at the boundaries, as surface tension is for water droplets or air bubbles. Magnetic field lines act more like a connective tissue of fibers that thread the entire cell of plasma, rather than as a membrane at the outer boundary.

When two magnetic cells collide, magnetic field lines that were initially limited to the respective cells become linked from one cell to the other. Cohesive electromagnetic forces are created that act to accelerate each of the cells toward the velocity of the other, tending toward a merger and the formation of a single unified plasma cell with properties weighted by the relative contributions of the two merged cells.

Conversely, if any section of a magnetic plasma cell should acquire a large velocity relative to the overall cell of which it is a part, the magnetic field may not be strong enough to maintain the integrity of the initial cell. In such a case, the cell will stretch out as the errant plasma attempts to escape from the cell proper. Depending upon the amount of momentum acquired by the plasma and the strength of the magnetic field, the cell magnetic field may become so highly distorted by the stretching motion that a separate blob of plasma is formed and the overstretched field is pinched off between the two. Field lines connecting the cell with the errant subcell are then reconnected so that they no longer link the two and are confined to their respective cells. Readers may recognize this behavior as being analogous to the behavior of fluid cells confined by surface tension, a familiar example being found in the "lava lamp" that became popular in the 1960s.

We have been discussing discrete cells of plasma and their magnetic fields. But what if one cell is much larger than another and the smaller is embedded within the larger, as the larger one streams by at high velocity. This is the situation of Earth's magnetosphere, embedded within the solar wind. The large bubble will tend to engulf and acquire the smaller cell; to pick it up and carry it off downstream, and assimilate it. The solar wind and geomagnetic fields reconnect so that they are interlinked, and the magnetic forces that are created seek to accelerate Earth's ionospheric plasma up to solar wind speed while simultaneously exerting drag on the solar wind plasma. The electrical currents that form link the solar wind to the roots of the interlinked field lines, in the auroral zone around each magnetic pole.

The larger cell (solar wind flow in the heliosphere) seeks continuously to link to and entrain the small cell into itself. Conversely, the smaller cell seeks to slow down the solar wind and entrain it into itself, but can succeed only to a limited degree. The outermost contents of the smaller cell are accelerated downstream, driving a return flow through the interior of the small cell. When this circulation is sufficiently strong, the slowed solar wind and accelerated ionospheric plasmas form an errant plasma cell in the tail of the magnetosphere, which episodically pinches off and escapes from the main cell, forming new cells of mixed plasma called "plasmoids." These are carried off downstream in the solar wind. The result is a continual ablation of the plasma in the smaller cell, which is fed by the sunlit atmosphere and auroral zones. A substantial amount of solar wind is slowed down and incorporated into the magnetosphere, with excess energy being either thermalized or transferred to the ionospheric plasmas. This increases the ionospheric plasma contribution to the cell and the rate of loss downstream.

So finally, we come to the formation of the ring current (Figure R4). As the solar wind seeks to erode away the plasma and fields of the Earth and carry them off downstream, the magnetosphere responds by forming a ring of current around the Earth that increases the total dipole moment of the Earth and inflates the magnetic field lines. This is a result of the energy dissipation associated with the work or effort on the part of the solar wind to accelerate and assimilate the magnetosphere. The situation is analogous to a water droplet suspended in a supersonic gas flow, for which the frictional interaction is so intense that it heats the droplet contents, turns them to vapor, and only then carries them off downstream.

In the magnetosphere, solar wind energy dissipation goes partly into the ionosphere and partly into the plasma clouds of the magnetosphere. Energy going into the ionosphere and atmosphere causes them to expand and inflate upward against gravity into the magnetosphere. The energy that goes into the magnetospheric plasma clouds (which

**Figure R4** The Earth's ring current is depicted as a red toroidal or donut-shaped region encircling the Earth near the equator inside geosynchronous orbit (6.6 Earth radii). Also shown are the cold extended ionospheric region known as the *plasmasphere*; the ionospheric outflow regions at latitudes higher than the plasmaspheric boundary, and ionospheric features such as the subauroral red (SAR) arcs and polarization streams. Coulomb collisions and wave particle interactions are indicated as loss mechanisms operating on the ring current particles.

then contain more material from the ionosphere) raises the pressure of those plasmas to the point that they inflate the magnetic field that confines them. This is just another way of saying that the plasmas carry currents in the same sense as the Earth's core, adding to the total dipole moment of the planet and inflating the geomagnetic field. Since the pressure and current exists in space around the Earth, it reduces the magnetic field intensity near Earth's surface, while increasing it outside the ring of current.

This can also be viewed as a Faraday's law response: any action that changes a magnetic field induces a current with a sense to oppose that change. The harder the solar wind blows and the more it tries to erode the magnetosphere, the more current is generated in magnetospheric plasmas in such a sense as to oppose that erosion and inflate the magnetosphere. In fact, the solar wind is a tempestuous medium, and the magnetosphere is buffeted by its variations. A side effect of this buffeting is the acceleration of a fraction of the charged particles to very high energies, creating large variations of the Van Allen radiation belts around the Earth.

The ring current was originally discovered by 1917 as the reduction of the magnetic field near the equator of the Earth, by as much as 1-2%. It was inferred by Chapman and Ferraro that this was consistent with a large scale current flowing around the Earth in space (see Bibliography), adding to the dipole moment of the Earth. Theoretical work refined this inference quantitatively, and the advent of spacecraft measurements led to direct observations of the responsible particles, which are mainly ions in the energy range of 50-500keV. Energetic electrons carry at most 20% of the current. Beginning in the 1970s, ion composition observations showed that the ring current acquires a substantial component of oxygen ions when it becomes strong. These  $O^+$  ions have certainly come from the ionosphere, illustrating the point made above that solar and terrestrial plasmas mix when the solar wind interaction is very strong. The largest ring currents consist almost entirely of ionospheric O<sup>+</sup> plasmas, making it clear that the ring current results in large part from the ablation of the ionosphere into space by solar wind energy deposition.

In recent years, the IMAGE mission has enabled us to globally image and visualize the dynamics of both the outflow of ionospheric plasmas into the magnetosphere, and the creation of high pressure clouds of ionospheric and solar plasmas that produce the ring current. Imaging of plasmas is made possible by a fundamental interaction between atoms and ions in which an electron is exchanged between a fast ion and a slow atom; leading to a fast atom and a slow ion. The fast atom, no longer bound by electromagnetic forces, flies off in a straight line. Suitable cameras record the "glow" of fast atoms coming from any hot plasma that coexists within a neutral gas. For Earth, the hot ring current plasmas coexist with the so-called "geocorona" of the Earth, a spherical region of declining hydrogen density that extends well beyond geosynchronous orbit and a fraction of the way to the moon. Global imaging has revealed some surprises about the ring current, including the fact that it is stronger on the night side than on the day side when it intensifies, and only relaxes into a symmetric ring shape as it fades. This and other more subtle aspects of the ring current can be understood through study of the motions of individual charged particles in the disturbed electromagnetic fields of the storm time magnetosphere.

Other planets that have substantial internal magnetic fields also have ring currents. These include Mercury, Jupiter, Saturn, Neptune, and Uranus in our own planetary system. Presumably other magnetized planets would share this feature, provided that a mechanical energy source dissipates energy in the plasma confined with each magnetosphere. Mercury has a magnetosphere so small that there is not much room for a ring current, and it has very little sensible atmosphere, so the internal source of plasma is weak. Mariner 10 observations of Mercury will soon be complemented by new observations by the Messenger spacecraft, which will greatly increase our understanding of this case. Jupiter is a special case in that it is so large and rotates so rapidly (every 10h) that more energy comes from braking the rapid rotation

than from braking the solar wind flow. Nevertheless, a strong ring current results as plasma from the atmospheres of both the planet and its moons (especially Io) fill the magnetosphere and are spun up by the planetary rotation. Saturn rotates less rapidly and has a solar wind interaction more like that of Earth. It also has a strong ring current inflation of its magnetic field. The magnetosphere of Neptune is also more like that of Earth in terms of ring current, but that of Uranus is peculiar in that the spin and dipole axes are tilted to a large angle from the ecliptic plane normal, so that the magnetosphere lies nearly "poleon" to the solar wind for half of the Uranian "year." The Earth may resemble Uranus in this respect during a geomagnetic field reversal. This leads to a magnetosphere whose tail is nearly aligned with its magnetic poles, yielding significant differences in the shape of many magnetospheric features. Nevertheless, Uranus has a substantial ring current, and for the same reasons: internal plasmas from the planet, its moons, and the solar wind are heated by energy dissipation, building up pressure and inflating the dipolar magnetic field region.

Ring currents are thus a common feature of magnetospheres filled with hot plasma. That includes in some sense the magnetized astrospheres of the sun and other stars, whose stellar plasma winds inflate their magnetic fields enormously, distending them throughout their astrospheres and generating extended ring currents. In these cases the energy to create and inflate the plasma currents comes from the object itself, rather than being derived from an enveloping medium, as is the case for the Earth's magnetosphere. On the other hand, a rotationdominated magnetosphere like Jupiter's may be understood as an intermediate case in which energy to create and heat the plasma originates both internally and externally. In summary, ring currents should be thought of as natural extensions of the intrinsic magnetic fields of astrophysical objects, which are sustained when the supply of energy is sufficient to create and maintain a plasma atmosphere of sufficient pressure.

Magnetosphere of the Earth

# ROBUST ELECTROMAGNETIC TRANSFER FUNCTIONS ESTIMATES

Deep probing electromagnetic (EM) induction methods use naturally occurring temporal variations of EM fields observed at the surface of the earth to map variations in electrical conductivity within the Earth's crust and mantle. In the magnetotelluric (MT) method, which is most commonly used for studies of crustal and upper mantle conductivity structure, both electric and magnetic fields are measured at a series of sites. Under the generally reasonable assumption that external sources are spatially uniform, the two horizontal components of the electric field variations can be linearly related to the two horizontal magnetic field components through a  $2 \times 2$  frequency-dependent impedance tensor. Estimation of these impedances from the raw electromagnetic time series (Figures R5 and R6) is the first step in the interpretation of MT data, followed by inversion of the estimated impedances for Earth's conductivity, and then mapping of electrical conductivity to parameters more directly related to geological processes. The MT impedance tensor is a particular case of a more general electromagnetic response or transfer function (TF). This article focuses primarily on MT impedances and their estimation, but other closely related examples of TFs are also discussed briefly.

The earliest approaches to MT TF estimation were based on classical time series methods (e.g., Bendat and Piersol, 1971), applying a simple linear least squares (LS) fitting procedure to a series of Fourier transformed data segments (Figure R5). However, MT data quality can be highly variable, with both signal and noise amplitudes varying by orders of magnitude over the data record. Furthermore, contrary to the standard LS assumption, there is typically noise in both the "output" or predicted electric field channels, and the "input" or independent magnetic channels, leading to biases in TF estimates. As a consequence the simplest LS approach often fails to yield physically reasonable or reproducible results. Two developments have improved the situation considerably: remote reference, in which data from a simultaneously operating second MT site is used for noise cancellation (Gamble et al., 1979), and data adaptive robust TF estimation schemes which automatically downweight or eliminate poor quality data (Egbert and Booker, 1986; Chave et al., 1987).

# Electromagnetic induction transfer functions

The basic assumption underlying the EM TF approach is that the external source variations which induce currents in the earth can be approximated well as random linear combinations of a small number of modes of fixed known geometry. In the most important case, relevant to MT, the external sources are assumed to be spatially uniform and hence linear combinations of two simple modes: unit magnitude sources linearly polarized North-South and East-West, respectively. Physically this assumption is justified if the spatial scale of external magnetic fields at the Earth's surface is large compared to the depth of penetration of the EM fields in the conducting Earth. Except at long periods (>10<sup>4</sup> s), for which penetration depths in the Earth exceed several hundred kilometers, and in the auroral zone where ionospheric current systems vary over short-length scales, this assumption generally holds quite well. For very long-period global studies other sorts of simplifying source assumptions are used to justify TFs.

#### Uniform source transfer functions

For periodic sources at a fixed frequency the uniform source assumption implies that the horizontal electric and magnetic field vectors measured at a single site are linearly related in the frequency domain as

$$\begin{pmatrix} E_x \\ E_y \end{pmatrix} = \begin{pmatrix} Z_{xx}(\omega) & Z_{xy}(\omega) \\ Z_{yx}(\omega) & Z_{yy}(\omega) \end{pmatrix} \begin{pmatrix} H_x \\ H_y \end{pmatrix}.$$
 (Eq. 1)

The 2×2 TF **Z**, which depends on frequency  $\omega$ , is referred to as the impedance tensor; see Figure R6 for an example. Equation(1) can be justified by the linearity of Maxwell's equations, and the assumption that all sources can be expressed as linear combinations of two linearly independent polarizations. Under these circumstances, two independent field components (e.g.,  $H_x$  and  $H_y$  at one location) uniquely determine all other EM field components everywhere in the domain. The uniform source assumption also justifies other sorts of TFs. In particular, vertical magnetic fields can be linearly related to the two horizontal components at the local site

$$H_z = \begin{pmatrix} T_x(\omega) & T_y(\omega) \end{pmatrix} \begin{pmatrix} H_x \\ H_y \end{pmatrix}.$$
 (Eq. 2)

**Figure R5** Example of time series used for estimation of MT TFs, from a site near Parkfield, CA. From top, the three vector components of the magnetic field (measured by an induction coil), two colocated orthogonal horizontal electric field components (measured as the potential difference between pairs of electrodes separated by 100m), and two horizontal components of the magnetic field at a distant remote site. Two short (128 point) overlapping data segments are indicated by the vertical dashed lines. Segments such as these are Fourier transformed to yield a series of complex Fourier coefficients for each data channel, which are then used for the various transfer function estimates discussed in the text.

**Figure R6** Examples of TFs estimated from the time series of Figure R5. (a) Two components of the TF relating  $E_x$  to  $H_x$  and  $H_y$ , the first row of the impedance tensor:  $Z_{xx}$  (circles) and  $Z_{xy}$  (crosses). Upper plots give real parts, lower plots imaginary. (b) TF for  $E_y$ , the second row of the impedance tensor:  $Z_{xy}$  (circles) and  $Z_{yy}$  (crosses). Note that the off-diagonal components of the impedance ( $Z_{xyy}$ ,  $Z_{yx}$ ) are dominant. (c) Vertical field TF  $T_x$  (circles),  $T_y$  (crosses).

Vertical field TFs (Figure R6c), which are commonly estimated along with the impedance in most MT surveys, are referred to variously as the Tipper vector, Parkinson vector, or Wiese vector (see *Induction Arrows*). Vertical field TFs have frequently been used to map lateral conductivity variations in the crust qualitatively, and they provide useful additional constraints (along with the impedance) in quantitative two- and three-dimensional inversions for conductivity.

When two or more sites are run simultaneously, interstation magnetic TFs can also be defined. These relate magnetic fields at a remote site to the horizontal components at a reference site

$$\begin{pmatrix} H_{x2} \\ H_{y2} \end{pmatrix} = \begin{pmatrix} T_{xx}(\omega) & T_{xy}(\omega) \\ T_{yx}(\omega) & T_{yy}(\omega) \end{pmatrix} \begin{pmatrix} H_{x1} \\ H_{y1} \end{pmatrix}.$$
 (Eq. 3)

Interstation TFs are used to map concentrations of electric current in the crust resulting from lateral variations of conductivity, and can in principle also be used as data for inversion.

#### Transfer functions for global induction and large arrays

The TFs of (1)–(3) derived from the assumption that external sources are approximately spatially uniform. For global studies and for large arrays other sorts of source assumptions are appropriate, leading to additional examples of induction TFs. The best known of these is the Z/H TF used for long-period global studies of mantle conductivity. Here the assumption is that external magnetic sources can be approximated as a single zonal dipole ( $P_1^0$ ). With this one-dimensional source space an appropriate TF is

$$H_z = T_{zh}(\omega)H_x,\tag{Eq. 4}$$

i.e., the scalar TF  $T_{zh}(\omega)$  is the ratio of vertical (Z) to meridional (H) geomagnetic variation components. Under the assumption that conductivity in the Earth depends only on depth, and that sources are purely  $P_1^0$ ,  $T_{zh}(\omega)$  can be transformed to an equivalent MT impedance.

Variants on (4) have also been applied to studies at daily variation periods, with a fixed geometry for sources (dominated by the  $P_{m+1}^m$  spherical harmonic for a frequency of *m* cpd) assumed.

With geomagnetic arrays of large enough size spatial gradients of the magnetic fields can be directly computed, and gradient TFs can be estimated. In the standard approach, the TF function relationship takes the form

$$H_z = C(\omega)[\partial_x H_x + \partial_y H_y]. \tag{Eq. 5}$$

Equation (5) strictly applies only to the case where conductivity varies only with depth, and in this case  $C(\omega)$  can be converted into an equivalent one-dimensional impedance  $Z(\omega) = i\omega C(\omega)$ . Extension to the more general case of multidimensional conductivity is possible, as reviewed in Egbert (2002).

# Robust transfer function estimation

#### Least squares estimates

To be explicit consider estimating the MT TF between one component of the electric field (e.g.,  $E_x$ ) and the two horizontal magnetic field components  $H_x$  and  $H_y$  at a single fixed frequency  $\omega$ . This TF corresponds to the first *row* of the usual MT impedance tensor. All of the discussion here and in subsequent sections applies equally to the second row of the impedance, and to the other transfer functions outlined above. Because all the TFs are most succinctly described in the frequency domain as in (1)–(5) the first step in processing is generally to Fourier transform the data. After possibly despiking and/or prewhitening, time series for each component are divided into M short time-windows, tapered, and Fourier transformed (Figure R5). Fourier coefficients for N periods in a band centered around  $\omega$  are used for the TF estimate, for a total of I = MN complex data. Estimates  $\hat{\mathbf{Z}}$  of the TF (i.e., impedance elements) are then obtained for frequency  $\omega$  by LS fitting of the linear model

$$\mathbf{E} = \mathbf{H}\mathbf{Z} + \mathbf{e}.$$
 (Eq. 6)

or in matrix notation

$$\begin{pmatrix} E_1 \\ \vdots \\ E_I \end{pmatrix} = \begin{pmatrix} H_{x1} & H_{y1} \\ \vdots & \vdots \\ H_{xI} & H_{yI} \end{pmatrix} \begin{pmatrix} Z_{xx} \\ Z_{xy} \end{pmatrix} + \begin{pmatrix} \varepsilon_1 \\ \vdots \\ \varepsilon_I \end{pmatrix}, \quad (Eq. 7)$$

With standard LS this is accomplished by minimizing the sum of the squares of the residuals

$$\sum_{i} |E_{xi} - (H_{xi}\hat{Z}_{xx} + H_{yi}\hat{Z}_{xy})|^2 = \sum_{i} |r_i|^2 \to \text{Min},$$
 (Eq. 8)

yielding

$$\hat{\mathbf{Z}} = (\mathbf{H}^{\dagger}\mathbf{H})^{-1}(\mathbf{H}^{\dagger}\mathbf{E}), \qquad (\text{Eq. 9})$$

where the superscript *†* denotes the conjugate transpose of the complex matrix.

#### The regression M-estimate

The simple LS estimator implicitly assumes a Gaussian distribution for the errors  $\epsilon$  in (6). This assumption often fails for MT data due to the nonstationarity of both signal and noise, which can result in a marginal error distribution in the frequency domain which is heavy tailed, or contaminated by outliers. As a result, the simple LS estimate all too frequently leads to biased and noisy TF estimates with large error bars (Figure R7a). A number of MT processing methods have been proposed to overcome these difficulties, generally using some sort of automated screening or weighting of the data. Early efforts in this direction used *ad hoc* schemes, for example weighting data segments based on broadband coherence between input and output channels. A more rigorously justifiable approach is based on the regression M-estimate (RME; Huber, 1981), a variant on LS that is robust to violations of distributional assumptions and resistant to outliers (Egbert and Booker, 1986; Chave *et al.*, 1987).

For the RME minimization of the quadratic loss functional of (8) is replaced by the more general form

$$\sum_{i} \rho \left( |E_{xi} - (H_{xi}\hat{Z}_{xx} + H_{yi}\hat{Z}_{xy})|/\hat{\sigma} \right) = \sum_{i} \rho \left( |r_i|/\hat{\sigma} \right) \to \text{Min},$$
(Eq. 10)

where  $\hat{\sigma}$  is some estimate of the scale of typical residuals. LS is a special case of the general form of (10), with  $\rho(r) = r^2$ . By instead choosing  $\rho$  to penalize large residuals less heavily than with the quadratic used for LS, the influence of outliers on the estimate can be substantially reduced. The Huber (1981) loss function

$$\rho(r) = \begin{cases} r^2/2 & |r| < r_0 \\ r_0|r| - r_0^2/2 & |r| \ge r_0 \end{cases}$$
(Eq. 11)

is commonly used with  $r_0 = 1.5$  for robust estimation of induction TFs. To find the minimizer of (10) an iterative weighted LS procedure can be used. Let  $\psi(r) = \rho'(r)$  be the derivative of the loss function (referred to as the influence function), and set  $w(r) = \psi(r)/r$ . Then it is easily shown that the minimizer of (10) satisfies

$$\hat{\mathbf{Z}} = (\mathbf{H}^{\dagger} \mathbf{W} \mathbf{H})^{-1} (\mathbf{H}^{\dagger} \mathbf{W} \mathbf{E}), \qquad (\text{Eq. 12})$$

where  $\mathbf{W} = \text{diag}(w_1, \ldots, w_I) = \text{diag}(w(|r_1|), \ldots, w(|r_I|))$  is a diagonal matrix of weights. The RME thus corresponds approximately to the weighted LS problem  $\sum_i w(|r_i|)|r_i|^2 \rightarrow \text{Min.}$  However the weights depend on the residuals  $r_i$  (and hence on the TF estimate), so an iterative procedure is required. Given an estimate of the TF (and of the error scale  $\hat{\sigma}$ ) residuals can be used to calculate weights, and the weighted LS problem can be solved for a new TF estimate. This procedure can be started from a standard LS estimate of the TF (and some robust estimate of error scale) and then repeated until convergence.

For convex loss functions (e.g., the Huber function of (11)) convergence of this procedure to the unique minimizer of (10) is guaranteed (Huber, 1981). For the loss function in (11) the weights are

$$w(r) = \begin{cases} 1 & |r| < r_0 \\ r_0/|r| & |r| \ge r_0 \end{cases},$$
 (Eq. 13)

i.e., data corresponding to large residual vectors get smaller weights. To allow for a sharp cutoff, with data completely discarded if residuals

**Figure R7** Comparison of TFs estimated from the same time series with (a) standard unweighted LS and (b) the regression M-estimate (RME) described in the text. Here apparent resistivities  $\rho_a = (\omega \mu_0)^{-1} |Z|^2$  and phases  $\phi = a \tan(Z)$  are plotted, computed from the dominant off-diagonal impedances  $Z_{xy}$  (circles) and  $Z_{yx}$  (crosses). The LS estimates are too noisy to be useful over much of the frequency range, while the robust estimates vary smoothly with frequency and have small error bars.

F

exceed a prescribed threshold, a nonconvex loss function must be used. Convergence of the iterative minimization algorithm cannot be guaranteed in this case, so standard practice is to iterate with a convex loss function such as (11) to convergence, followed by a final step with a hard cutoff to completely discard extreme outliers. This completely automated procedure frequently results in significant improvements in TF estimates, as indicated by improvements in smoothness and physical realizability of apparent resistivity and phase curves (Figure R7b), and reproducibility of results.

More *ad hoc* schemes are also frequently used, sometimes in conjunction with the RME, for down-weighting noisy or inconsistent data. These can be viewed as special cases of the weighted LS estimate of (12), but with weights now determined by some criteria other than residual magnitude. For example, in coherence weighting, broadband coherence of input and output channels is used to downweight time segments with low signal-to-noise ratios.

#### Leverage

The RME can be excessively influenced by a small number of very large amplitude data sections, resulting in breakdown of the estimator. In the terminology of linear statistical models, these large amplitude data are *leverage points*. For the LS estimate the predicted data are

$$\hat{\mathbf{E}} = [\mathbf{H}(\mathbf{H}^{\dagger}\mathbf{H})^{-1}\mathbf{H}]\mathbf{E}, \qquad (\text{Eq. 14})$$

with the matrix expression in brackets (which maps observed data to be predicted) referred to as the "hat matrix." It is readily shown that the sum of the diagonal elements of the hat matrix satisfies,  $\sum_{i=1}^{I} h_{ii} = 2$ , and that the individual diagonal elements  $h_{ii}$  can be interpreted as the fraction of total magnetic field signal power in the *i*th Fourier coefficient. Large values of  $h_{ii}$  indicate data points with inordinate influence on the TF estimates. Furthermore, in extreme cases leverage points are used heavily to predict themselves, making the iterative RME ineffective. To deal with leverage points in routine MT processing, it is thus useful to include an additional weighting term (a function of the magnitude of  $h_{ii}$ ) to reduce the influence of any observations of unusually large amplitude.

# **Remote reference**

The linear statistical model (6) is strictly appropriate to the case where noise is restricted to the output, or predicted electric field channels. Violation of this assumption results in the downward bias of estimated impedance amplitudes. These biases are proportional to the ratio of noise power to signal power, and can be quite severe in the so-called MT "dead band" at periods of around 1–10s (Figure R8). To avoid these bias errors horizontal magnetic fields recorded simultaneously at a remote reference site are correlated with the EM fields at the local site. Letting  $R_{xi}$  and  $R_{yi}$  be the Fourier coefficients for the two remote site components for the *i*th data segment, and **R** the corresponding  $I \times 2$  matrix, then the analogue of the LS estimate is

$$\hat{\mathbf{Z}} = (\mathbf{R}^{\dagger}\mathbf{H})^{-1}(\mathbf{R}^{\dagger}\mathbf{E}).$$
(Eq. 15)

To generalize the RME to remote reference, one can iterate the weighted analogues of (15), i.e.,  $\hat{\mathbf{Z}} = (\mathbf{R}^{\dagger} \mathbf{W} \mathbf{H})^{-1} (\mathbf{R}^{\dagger} \mathbf{W} \mathbf{E})$ , with the weights on the diagonal of  $\mathbf{W}$  determined from the residual magnitudes, exactly as for the single site robust estimator. It is also useful to add some additional weighting to allow for outliers at the remote site, and as with the single site estimates, for leverage.

When arrays of simultaneously operating EM instruments are available more complex procedures, which use data from multiple sites to define the reference fields, are possible (Egbert, 2002).

# **Error estimates**

With a statistical approach to TF estimation, one also obtains estimation error variances which define the precision of the TF estimates. These error bars are ultimately required at the modeling or inversion stage to assess the adequacy of fit of a derived model to the measured data, and thus play an important role in the overall interpretation of EM data. The covariance of the linear LS TF estimate of (9) is readily derived from standard theory, using linear propagation of errors

$$\operatorname{Cov}(\hat{\mathbf{Z}}) = \hat{\sigma}^2 (\mathbf{H}^{\dagger} \mathbf{H})^{-1}, \quad \hat{\sigma} = (I-2)^{-1} \sum_i |r_i|^2, \quad (\text{Eq. 16})$$

**Figure R8** Comparison of TFs (from a different site) estimated with (a) the RME applied to data from a single station and (b) the robust remote reference estimate. As in Figure R7, results are plotted as apparent resistivity and phase. Although both curves are smooth, and have small error bars, a significant (nonphysical) bias is evident in the single site results of (a).

where  $r_i$  are again the residuals. An analogous expression for the error covariance for the remote reference estimate is

$$\operatorname{Cov}(\hat{\mathbf{Z}}) = \hat{\sigma}_{\mathrm{r}}^{2} (\mathbf{R}^{\dagger} \mathbf{H})^{-1} (\mathbf{R}^{\dagger} \mathbf{R}) (\mathbf{H}^{\dagger} \mathbf{R})^{-1}, \quad \hat{\sigma}_{\mathrm{r}} = (I-2)^{-1} \sum_{i} |r_{i}|^{2}.$$
(Eq. 17)

For both (16) and (17) the diagonal components of the  $2 \times 2$  covariance matrices are the estimation error variances for the two impedance elements.

For the RME variances of the estimates are complicated by nonlinearity, but asymptotic expressions (valid in the limit of large sample sizes) can be obtained from standard theory (Huber, 1981)

$$\operatorname{Cov}(\hat{\mathbf{Z}}) = \frac{(I-2)^{-1} \sum_{i} w_{i}^{2} |r_{i}|^{2}}{\left[I^{-1} \sum_{i} \psi'(|r_{i}|/\hat{\sigma})\right]^{2}} (\mathbf{H}^{\dagger} \mathbf{H})^{-1},$$
(Eq. 18)

where  $r_i$ ,  $w_i$ , i=1, I, and  $\hat{\sigma}$  are the residuals, weights, and error scale from the final iteration, and the prime denotes the derivative of the influence function. An analogous asymptotic covariances for the robust remote reference estimates can be given with  $(\mathbf{H}^{\dagger}\mathbf{H})^{-1}$  in (18) replaced by  $(\mathbf{R}^{\dagger}\mathbf{H})^{-1}\mathbf{R}^{\dagger}\mathbf{R}(\mathbf{H}^{\dagger}\mathbf{R})^{-1}$ .

As an alternative to asymptotic error estimates such as (18), the nonparametric jackknife method (Efron, 1982) has also been frequently used for computing TF error estimates (Thomson and Chave, 1991). The jackknife approach can also be applied to compute error bars for complicated nonlinear functions of TFs, as arise for example in some forms of distortion analysis. The jackknife approach significantly increases computational effort required for TF estimation, unless some approximations are used.

# **ROCK MAGNETISM**

#### Introduction

Rock magnetism is the study of the magnetic properties of rocks and it includes the study of magnetic minerals. Rock magnetism is one of the oldest sciences known to man. Historians still debate when the magnetic properties of lodestone (leading stone or compass) were first discovered. Some historians suggest that the Greek philosopher Thales made observations in the 6th century B.C. on lodestone, known today as magnetite. Beginning as early as the 3rd century B.C. the Chinese literature makes reference to the magnetic properties *ci shi*, the loving stone, still another name for magnetite. One early school of thought (the animists), which included Thales, argued that the attraction powers of lodestone occurred because it possessed a soul. Even the commonly referred to father of magnetism, William Gilbert of Colchester (who was born in 1544 and died of the plague in 1603), offered the following explanation for lodestone's magnetic attraction: "the Loadstone hath a soul."

The separation of rock magnetism from the broader subject of magnetism of materials occurred in the first half of the 20th century following particularly influential experimental work of Koenigsberger, Thellier, and Nagata. The theoretical foundations of rock magnetism were later established by Néel. The first book on rock magnetism, written by Nagata in 1953, preceded the first book on paleomagnetism written in 1964 by Irving. Rock magnetism primarily deals with the records of magnetic fields recorded in rocks. The inferences drawn from these records usually fall under the subject of paleomagnetism. An excellent modern comprehensive coverage of rock magnetism has been given by Dunlop and Özdemir (1997). In this brief overview article several topics are introduced that are more fully discussed elsewhere in this volume.

#### Physics of magnetism

Essentially all materials are magnetic because they possess electrons that have a spin (magnetic moments) and because the electron's motion results in currents with their associated magnetic fields. Magnetism is often subdivided into induced magnetization and "permanent" magnetization. Induced magnetization is described by the equation

$$\mathbf{M} = \chi \mathbf{H}$$

where **M** is the magnetization, **H** is the magnetic field, and  $\chi$  is a second order tensor referred to as the susceptibility. If  $\chi$  is negative, the material is diamagnetic (halite, NaCl, is an example) and if  $\chi$  is positive, the material is paramagnetic (for example, iron-rich olivine or fayalite, Fe<sub>2</sub>SiO<sub>4</sub>).

Scientists no longer attribute the cause of permanent magnetism to a soul, but instead attribute it to exchange energy. A permanent magnetic order results from exchange energy, which combines Coulomb interaction energy with the Pauli exclusion principle. Thus, exchange energy can only properly be understood through quantum mechanics. Exchange energy is often calculated by evaluating the nature of overlap of electron orbitals. Depending on the details of the electron overlap, a minimum in exchange energy sometimes requires that adjacent atoms have parallel magnetic moments and the material is referred to as ferromagnetic. With different overlap, the minimum in energy occurs when the adjacent magnetic moments have opposite sign. Then the material is described as antiferromagnetic when the moments are of equal magnitude and ferrimagnetic when the adjacent magnetic moments differ in magnitude. The best-known example of a ferrimagnetic mineral is magnetite (Fe<sub>3</sub>O<sub>4</sub>). Magnetite is said to have an indirect exchange energy because the coupling of adjacent iron atoms occurs through intervening oxygen atoms.

As the temperature of a material is increased the thermal energy (primarily recorded in quantized lattice vibrations referred to as phonons) increases and eventually overwhelms the exchange energy. The Curie temperature is the highest temperature a ferromagnetic material can possess a magnetic structure in the absence of an external magnetic field. The analogous permanent loss of magnetic order in antiferromagnetic and ferrimagnetic structures occurs at the Néel temperature. (Some paleomagnetists also refer to this as the Curie temperature.) The saturation magnetization monotonically increases on cooling from the Curie or Néel temperature to absolute zero providing no phase change occurs on cooling. The Curie temperature at ambient pressure of iron, a ferromagnetic material, is 1043 K and the Néel temperature of ferrimagnetic magnetite is 853 K. Ilmenite (FeTiO<sub>3</sub>) is an example of an antiferromagnetic substance and it has a Néel temperature of 40 K. It is useful to recognize that the melting temperature of a magnetic material always exceeds the Curie or Néel temperature. (So-called magnetic fluids contain suspended solid magnetic material.) Because the electron overlap is a function of pressure, the Néel and Curie temperatures are also functions of pressure. Physics and engineering aspects of magnetism are summarized in books such as Mattis (1988) and Hubert and Schäfer (1998).

#### **Remanent magnetizations**

Remanent magnetization (RM) is what is meant by most people when they refer to "permanent magnetization." An RM is defined as the magnetization that is present in a material in the absence of an external magnetic field. One of the prime goals of rock magnetists is to explain the properties and origins of various forms of RM. Of particular interest is the origin of RM that was acquired under natural conditions, natural RM (NRM).

A particularly useful way to gain insight into RM is through an oversimplified model involving a large ensemble of identical uniformly magnetized particles that are noninteracting. (These particles would correspond to individual magnetic mineral grains in a rock.) We assume there are only two assessable minimum energy states,  $E_{\rm u}$  and  $E_{\rm d}$ , of equal magnitude (in the absence of an external field) in which the magnetization is, respectively, in the up or down direction. There is an energy barrier separating these two states of magnitude  $E_{\rm B}$ . In equilibrium and in the absence of an external field one expects both states to be occupied by the same number of magnetic particles. The material, which we will subsequently refer to as rock, is then said to be demagnetized. Let us apply a very large external magnetic field in the up direction. We take this field to be so large that all the particles become magnetized up. When the external field is removed the majority of the particles will remain in Eu. (All the particles would be in  $E_{\mu}$  if the experiment were carried out at absolute zero temperature where thermal fluctuations could be ignored.) The sample now has an RM referred to as a saturated isothermal RM (SIRM). If we had used a smaller, but still strong, external field so that there were some particles still in  $E_d$  after the external field was applied, then the resulting RM would be referred to as an IRM. Consider yet a different thought experiment in which we start with a demagnetized rock and apply a weak field such that  $\mathbf{m} \cdot \mathbf{H}$  (where  $\mathbf{m}$  is the magnetic moment of a particle) is smaller than  $E_{\rm B}$ . With time thermal fluctuations may displace some of the particles from  $E_d$  to the minimum energy state  $E_u$ . The magnetization of the rock acquired over time in a magnetic field is referred to as a viscous RM (VRM) acquired at temperature T. If T is not explicitly given, the VRM is assumed to have been acquired at ambient temperature.

There are many types of RM, far more numerous that can be reviewed here. However, rock magnetists are often interested in distinguishing between a primary RM, one acquired when the rock formed, from a secondary RM formed later. The most common forms of primary RM of interest to paleomagnetists are TRM, DRM, and postdepositional DRM. Thermal RM (TRM) is the primary RM acquired by an igneous rock when it cools from the Curie or Néel temperature to room temperature in a weak field, such as that of Earth's magnetic field. Detrital RM (DRM) is acquired by sediments as they settle out of a quiet fluid environment, such as a lake. Postdepositional DRM seems to be the predominant mechanism by which a primary RM is acquired by marine sediments. Mixing, often by marine organisms, and compaction typically occurs in the sediments closest to the surface in a marine environment. The primary RM, a postdepositional DRM in this case, is acquired at a depth in the sediments. The depth of acquisition varies depending on the type of sediment and its physical and biological environment. Postdepositional DRM also can, and sometimes does, occur in lakes.

Similarly there are many types of secondary RM such as a VRM or an IRM. One of the most common forms of secondary RM is a chemical RM (CRM) usually defined as any RM acquired during chemical change below the Curie or Néel temperature. Some scientists use a more restricted definition of CRM to mean that RM acquired during the growth of a mineral in a magnetic field (CRM then refers to crystalline RM). Unfortunately, this ambiguity in definition of CRM is not always contextually obvious. There are more than 30 different types of RM that have been introduced into the literature, a dozen or so of which are commonly used.

There are two other terms that are useful to introduce and are common to those scientists who have worked with magnetic hysteresis. The bulk coercive force is the magnitude of a field that is applied in the opposite direction to the magnetization to reduce the magnetization to zero. The remanent coercive force is equal to or larger than the bulk coercive force; it is the magnitude of the field applied to a sample in the opposite direction to its RM that will leave the sample demagnetized after the external field is removed. The bulk coercive force and the remanent coercive force provide somewhat different measures of the stability of the RM with respect to an external magnetic field.

#### Anisotropy

It is important to recognize that the presence of an RM in a sample is a nonequilibrium process that requires magnetic anisotropy. This is manifested in the thought experiment used above. In the absence of an external magnetic field, the particles in the rock example considered possess uniaxial anisotropy: there is an easy axis of magnetization parallel to the magnetization of the grain and a plane of hard directions perpendicular to the easy axis. In the above example discrete energies were used, but in an actual grain it would be possible for the magnetization to be in a direction other than an easy axis in the presence of an external field but not otherwise. (We exclude the possibility of the magnetization residing in the metastable hard direction because thermal fluctuations would quickly lead to the magnetization changing to the easy axis, except close to absolute zero.) Note that the equilibrium state in zero external field is the demagnetized state. If there is no anisotropy, there is no energy barrier separating minimum energy states and thermal fluctuations would quickly reduce the magnetization to zero.

Although magnetic anisotropy at the grain level is a necessary condition to have a remanence, it is also important to recognize that a rock can be magnetically isotropic and carry an RM. For example, if the particles discussed above (each of which is by itself magnetically anisotropic) were randomly orientated, the rock would be isotropic. The most common extrusive rock, basalt, is typically isotropic while other igneous rocks sometimes exhibit magnetic fabrics and thus are anisotropic.

The basic underlying mechanisms that produce magnetic anisotropy in a grain at the microscopic level include dipole-dipole interaction and most importantly the coupling of unquenched orbital moments with spin. However, a continuum approach is applied in rock magnetic calculations that use phenomenological equations to describe anisotropy. Magnetostatic, magnetostriction, shape, and exchange are explicitly described by equations that are not strictly valid at the microscopic level. They probably are valid down to a scale size comparable to that applicable to reconstructed surfaces in solids; i.e., a size of ten to several tens of angstroms. Scientists that claim accuracy below a 100Å or so using a continuum approach might wish to investigate their assumptions closely. The external part of the magnetostatic energy is the energy difference of a material in zero external field and in the presence of an external field. The internal part of the energy is most commonly referred to as the demagnetization energy. It can be derived from the constitutive equation

$$\mathbf{B} = \mu_0 \mathbf{H} + \mathbf{M}_1$$

where **B** is the magnetic induction field and  $\mu_0$  is the free-air permeability. Using the fact that the divergence of **B** and the curl of **H** (in the absence of electric current and electric displacement current) are zero, it is straightforward to use the constitutive equation to derive Poisson's equation for a scalar potential in which the divergence of M acts as a magnetic charge density. This means that wherever the magnetization changes in direction or magnitude there is a bound magnetic charge. In particular, these charges are present on all grain boundaries for which there is some perpendicular component of the magnetization. Then the bound magnetic charges (analogous to electric charges on a capacitor) produce an internal field that has a component opposite to the magnetization. Because of this, the internal field is often referred to as the demagnetization field. The demagnetization field can result in a strong magnetic anisotropy. For example, the presence of a demagnetization field explains why it is typically much easier to magnetize a needle-shaped grain along its long axis than perpendicular to this axis.

The magnetocrystalline anisotropy energy is represented in the uniaxial case by

$$E_K = K \sin^2 \theta,$$

where *K* is the anisotropy constant and  $\theta$  is the angle between the easy anisotropy axis and the magnetization. The larger *K* the more difficult it is to reverse the magnetization. Additional anisotropy constants are used for most materials, such as cubic magnetite for which two anisotropy constants are commonly employed. These constants are usually empirically determined rather than calculated from first principles.

The ordering of magnetic moments in a material results in a stress that produces strain, referred to as magnetostriction. Because stress and strain are second order tensors, the equations for magnetostriction can be complicated. Not only do they depend on crystallography, but they also must be able to accommodate additional sources of stress, such as associated with dislocations. One of the simplest examples is the equation for energy applicable to isotropic magnetostriction in which the magnetization and strain are measured in the same direction

$$E_{\lambda} = (3/2)\lambda\sigma V \sin^2 \alpha$$

where the stress  $\sigma$  is a tension applied in the direction of the magnetization and  $\lambda$  is the magnetostriction constant, *V* is the volume, and  $\alpha$  is the angle between the easy magnetostrictive anisotropy axis and the magnetization. Note that in this case the equation for magnetostriction energy is of the same form as that given for the uniaxial magnetocrystalline anisotropy. Most situations are more complicated and additional magnetostriction constants are introduced to describe experimental results.

Although the exchange energy is purely isotropic, it can result in anisotropy when two or more phases are present. An example is when an antiferromagnetic phase with a relatively high Néel temperature is coupled through exchange to a ferromagnetic phase with a lower Curie temperature. In this case there is a uniaxial anisotropy in the ferromagnetic material that has an easy axis aligned with the directions of the antiferromagnetic moments.

#### Self-reversal

An isotropic rock will usually acquire an RM parallel to the external field. However there are circumstances for which a rock can acquire an RM antiparallel to the field and when such circumstances occur the rock is said to have self-reversed. Néel presented the first mechanisms for self-reversal in the mid-1950s and shortly thereafter Nagata and Uyeda discovered the first reproducible self-reversing rock, the Haruna dacite. Self-reversal always involves two magnetic phases. The first phase acquires an RM parallel to the external field. An antiparallel coupling to a second phase produces an RM opposite to the external field. If the magnetic moment of the second phase exceeds that of the first phase at room temperature, then a self-reversal will have occurred. The negative coupling between the two phases can be cause by exchange interaction (as is the case for the Haruna dacite) or by magnetostatic interaction. Another process that can lead to self-reversal involves an order-disorder transition. For example, suppose the collective magnetic moment of cations at lattice site A is greater than at lattice site B at elevated temperature where a material is disordered. Further suppose that the exchange coupling between the two sites is negative (antiferromagnetic). If on cooling the material becomes an ordered one with the dominant magnetic moment now being that of site B, then a self-reversal will have occurred.

#### Demagnetization

There are several different demagnetization procedures that can be employed to bring a rock to a demagnetized state (defined above in the section entitled remanent magnetizations). An RM has a relaxation time  $\tau$  that is useful to describe the decay of an initial magnetization  $M_0$  with time t:

$$M = M_0 \mathrm{e}^{-t/\tau}.$$

In actual rock samples there typically is a range of relaxation times that correspond to the fact that there are many contributions to anisotropy energy. These relaxation times are functions of many intrinsic variables (associated with the anisotropy energies) and extrinsic variables, such as magnetic field, stress, and temperature. Demagnetization procedures provide information on the sensitivity of magnetic relaxation to these extrinsic factors. A magnetic component is said to be stable or locked in to a sample when it has a long relaxation time with respect to the time of interest to the investigator.

Only the two most commonly employed demagnetization methods will be mentioned here. The first is thermal demagnetization that measures the sensitivity of the sample to temperature. A complete thermal demagnetization of a sample can occur by heating the sample to a temperature exceeding its Curie or Néel temperature and cooling the sample back to room temperature in the absence of an external magnetic field. Partial thermal demagnetization occurs when the sample is heated to some temperature T that is lower than the Curie or Néel temperature and then cooled to room temperature in zero external field. The magnetization that is demagnetized by the last process is referred to as being unblocked at T. In igneous rocks it is often found that a TRM consists of independent components of magnetization that are locked into the rock during cooling at different temperatures. These components can be unlocked by progressively thermally demagnetization of a sample. This is the process by which a sample is partially demagnetized in a series of experiments in which the peak demagnetization temperature is sequentially increased. (This procedure is sometimes referred to as the progressive method and it is the one most commonly employed. There also is a continuous method in which the RM is measured while the sample is still hot.) The unblocking temperature is typically assumed to be the blocking temperature, that temperature at which the component of magnetization was locked into an igneous rock during cooling. Although it is well known by modern rock magnetists that the unblocking and blocking temperatures are not usually identical, the difference is often negligible for practical purposes (especially for single domain grains defined in the next section). Thermal demagnetization is a measure of the instability of the magnetization as a function of temperature and it often provides valuable information of a sample even when the magnetization is not a TRM.

The second method discussed here is alternating field (AF) demagnetization. This method involves the gradual decrease of an alternating (often at 60Hz) magnetic field from some peak value  $H_p$  to zero. The preferred AF demagnetization method also randomly tumbles the sample with respect to the external field. Those components of magnetization with relaxation times that are small with respect to some characteristic time of the experiment (associated with the rate the alternating field is decreased) are thought to be randomized by this process. Usually AF demagnetization employs a sequence of increasing values for  $H_p$ .

Most paleomagnetists use thermal demagnetization, which provides information on the stability of magnetization with respect to temperature, and AF demagnetization, which provides information on the stability of the magnetization with respect to alternating magnetic fields, to infer stability of magnetization in a rock sample with time. The magnetic components that are most stable with respect to temperature or alternating magnetic fields are believed to be the most probable carriers of the primary RM. However, paleomagnetists are well aware that this is not always the case, for example when the sample has acquired a particularly stable CRM. Thus numerous experiments are undertaken to determine the primary RM. There are no hard and fast rules to do this and undoubtedly mistakes are made. For such reasons consistency of a variety of data and interpretations are sought and rock magnetism remains a vibrant field of intellectual endeavor.

#### Magnetic structure

The structure of magnetic grains depends on many factors including mineralogy, grain size, grain shape, and defects. Grains are classified for a fixed mineralogy as superparamagnetic (SP), single domain (SD), pseudo-single domain (PSD), and multidomain (MD). The smallest are the uniformly magnetized SP grains that have short relaxation times (usually less than 10s or so). These grains do not contribute to the remanent magnetization but they do affect the susceptibility. SD grains are also uniformly magnetized and can exhibit relaxation times from the largest SP grains to times that exceed the age of Earth (4.6 billion years). PSD grains have the poorest defined structures that range from slight deviations from a SD structure to small multidomain grains. MD grains are grains that contain uniformly magnetized regions, called domains that are separated from each other by transition regions referred to as domain walls. A domain wall is referred to as an x wall, where x is the number of degrees required by the gradual rotation of magnetic moments in the wall to accommodate the magnetization in the adjacent domains. For example, a 180° domain wall separates domains with opposite magnetizations, while a 70° wall is a transition of magnetic moments between two magnetic domains that have magnetic directions that differ by 70°. MD grains are often classified on the basis of the number of domains they have. For example, a two-domain grain has two oppositely magnetized domains separated by a 180° wall.

Micromagnetic calculations minimize the exchange and anisotropy energies to determine the equilibrium states available to a grain. The structures found this way can be compared to those found by various imaging techniques, such as magnetic force microscopy. One finds that there is often more than one magnetic structure that a grain can have depending on its magnetic history. These different structures reflect different local energy minimum or LEM states. Let us consider what happens to an initial SD grain of magnetite as its size is increased. We will assume the grain is a cube and use one side to indicate its size. The SP-SD threshold at room temperature is near 0.045 µm, the SD-PSD is near 0.05 µm, and there is no agreed upon PSD-MD threshold size. This lack of agreement on the PSD-MD transition probably reflects that the transition is a gradual one, although some investigators using a hysteresis parameter definition put this size around 15 µm. The largest PSD domains have several magnetic domains, but they exhibit different stability properties from large MD grains. A reference to a PSD grain or PSD behavior can be confusing because there are incompatible definitions of them that are still commonly used.

It needs to be pointed out that one might find a SD magnetite with a size of say  $0.06 \,\mu\text{m}$  at room temperature. However, this would presumably not reflect a global minimum energy state. In the case of magnetite the curling, also called vortex, state would have a lower energy at this size. Vortex and flower states, names that reflect the magnetic structure, are the most common states calculated for the smallest PSD grains. A given size grain can exhibit more than one domain structure depending on the circumstances under which the grain became magnetized. Further discussion of this subject can be found in Dunlop and Özdemir (1997).

# Magnetic mineralogy

Although the elements Fe, Co, and Ni are ferromagnetic, only Fe plays a prominent role for magnetic properties in minerals and rocks on Earth. Pure iron is the primary phase responsible for remanence on the moon and Fe-Ni alloys are common in meteorites. However, on Earth the most common forms of remanence are found in compounds of iron such as iron oxides, iron-titanium oxides, iron oxyhydroxides, and iron sulfides. There are also other less common systems, such as the solid solution series Mn<sub>3</sub>O<sub>4</sub>-Fe<sub>3</sub>O<sub>4</sub> (end members hausmannite and magnetite and intermediate members collectively called jacobsite) in which the peak in saturation magnetization occurs when Mn<sub>3</sub>O<sub>4</sub>/ Fe<sub>3</sub>O<sub>4</sub> is around 16.7%. The most commonly studied solid solution series are those of titanomagnetites,  $FeO-Fe_3O_4$  with end members wüstite and magnetite, and titanohematites, FeTiO<sub>3</sub>-Fe<sub>2</sub>O<sub>3</sub>, with end members ilmenite and hematite. Low temperature oxidation of titanomagnetites produce  $\gamma$  phases (titanomaghemites) while high temperature oxidation includes titanohematites as products. For instance,  $Fe_3O_4$  is oxidized to cubic maghemite,  $\gamma Fe_2O_3$ , at room temperature and to rhombohedral hematite, aFe2O3, at say 900 K. The magnetic properties vary significantly with changes in composition. The magnetic properties of hematite will be briefly discussed to illustrate some of the complexities associated with magnetic mineralogy.

Hematite is an antiferromagnetic substance that contains a parasitic ferromagnetism and thus it possesses a different magnetic order than given earlier in the oversimplified description of the origins of magnetic order. It is well known that alternating basal planes in hematite are antiferromagnetically coupled. There is a slight canting of the magnetic moments in these planes such that the moments in alternating planes are not precisely 180° apart. This implies that there is a weak, or parasitic, ferromagnetism that is perpendicular to the ternary axis. In addition, hematite sometimes displays a defect moment in which defects occur more commonly on alternating planes and thereby produces a ferrimagnetic-like moment that is nearly perpendicular to the spin-canted moment. The magnetocrystalline anisotropy of hematite changes sign near 258 K, the Morin transition, and below this temperature the ternary axis (perpendicular to the basal plane) becomes the easy axis. Only the defect moment is present below the Morin temperature. Because of the defect moment the saturation magnetization of hematite is somewhat variable with magnitude around 1/200 of that of magnetite at room temperature (the latter is  $480 \times 10^3 \text{ Am}^{-1}$ ). Interestingly some intermediate values of titanohematites reach saturation magnetization values that are a significant fraction of that for magnetite. Although this brief discussion of hematite is far from exhaustive, it should be sufficient to illustrate the complexity of magnetic mineralogy and the prominent role such mineralogy plays in the understanding of magnetic properties of rocks.

# Some applications

Magnetic minerals are very sensitive to oxidation conditions. Because of this, iron titanium oxide assemblages in igneous rocks are sometimes used to estimate the oxygen fugacity and temperature in Earth's mantle. In partial contrast, it is the pE and pH that is often responsible for the equilibrium assemblages in marine sediments. Because of their sensitivity to climatic conditions, magnetic minerals in sediments are sometimes used as proxies for paleoclimatic variation. For similar reasons magnetic minerals are sensitive to man-induced changes and this has led to the field of environmental magnetism. Such studies are complicated by the fact that microbes can also mobilize some cations, including Fe, in sediments. In addition, some microbes such as magnetotatic bacteria produce chains of SD magnetite within their cells and appear to use this magnetite to determine the vertical direction in mud where they are neutrally buoyant. The microbe examples reflect the use of rock magnetism in the fields of geobiology and biomagnetism. Magnetic properties such as susceptibility, remanence, and magnetic phase transitions are often used to correlate sedimentary layers in magnetostratigraphy. Paleoflow directions of fluids are sometimes estimated from the magnetic fabric of rocks. Finally, the most common uses of rock magnetism are in paleotectonic and paleogeomagnetic studies.

# ROCK MAGNETISM, HYSTERESIS MEASUREMENTS

# Use and scope of hysteresis measurements

The term hysteresis in general describes that an effect is lagging behind its cause (from greek  $v\sigma\tau\epsilon\varrho\epsilon iv$ : to lag behind). More specifically, magnetic hysteresis is a property of all ferromagnetic materials (in sensu lato) causing the magnetization of such a material to be strongly dependent on its magnetic history, i.e., exposure to an external magnetic field.

# Practical description of magnetic hysteresis

In order to obtain a complete hysteresis loop, the magnetization  $\mathbf{M}$  of a sample is measured as a function of an external inducing field  $\mathbf{B}$  which is cycled from zero to the maximum positive value, back to zero, up to the maximum negative value and then back again to the maximum positive value. Magnetization is generally measured only in the direction of the inducing field so that both quantities are treated as scalars.

The most simple hysteresis measurement of a rock is performed with a set of two concentric coils of which one is inducing the external field B (Figure R9). The magnetic moment of the rock is generating a magnetic stray field which, when the sample is pulled out from the set of coils, in turn induces a voltage pulse in the second (measurement) coil. This induction pulse is a direct measure for the magnetization

Figure R9 Schematic drawing of a simple hysteresis measurement.

of the sample for a given external field step. The whole procedure can then be repeated for a sufficient number of field steps to obtain the hysteresis loop.

Rocks generally present a mixture of different minerals. Some of these minerals (in most cases ore minerals containing iron) form a long range ferro-, ferri-, or antiferromagnetic spin order below their critical Curie or Néel temperature. In this ordered state the volume dV at r carries a spontaneous magnetization M(r). In most materials  $M(r)^2 = M_s^2$  is constant. Within a given external field B(r) and stress tensor  $\sigma(r)$  the magnetization structure M(r) adjusts itself into a local minimum of the total magnetic energy  $E(M(r), B(r), \sigma(r))$  which encompasses exchange, anisotropy, demagnetizing, magnetoelastic, magnetostrictive, and external field energy.

During an isothermal external field variation the magnetization change of such a system usually lags behind the field change which is expressed in the term "hysteresis." If the field amplitude  $B_{\text{max}}$  in measuring a hysteresis loop is sufficiently large, this loop defines four basic quantities (Figure R10) (1) the saturation magnetization  $M_s$  is the maximal magnetization of the ordered phase within any external field, (2) the saturation remanence  $M_{\text{rs}}$  is the maximal magnetization of the sample in zero field, (3) the coercive field  $B_c$  is the maximal field where zero magnetization of the ordered phase is possible, and (4) the total hysteresis work  $E_{\text{hys}}$  corresponds to the area inside the hysteresis loop. The coercivity of remanence  $B_{\text{cr}}$  is the counter field necessary to remove the saturation remanence. It cannot be directly read from the hysteresis loop but requires an additional measurement.

Most rocks also contain paramagnetic minerals, i.e., minerals containing ions with permanent magnetic moments which are not forming a long range spin order. As these minerals cannot carry a remanent magnetization, they do not contribute to  $M_{\rm rs}$ ,  $B_{\rm c}$ , or  $E_{\rm hys}$ . However, they do contribute to the induced magnetization  $\mathbf{M}_{\rm i} = \chi_{\rm p}(1/\mu_0)\mathbf{B}$ , where  $\chi_{\rm p}$  is the paramagnetic susceptibility.  $\chi_{\rm p}$  is independent of *B* in the field range typically used for hysteresis measurements. It thus defines the slope of the hysteresis loop above the field where the ordered phase saturates. The paramagnetic contribution has to be subtracted to determine the saturation magnetization of the ordered phase (Figure R10). Another contributor to the field independent susceptibility in rocks are diamagnetic minerals, e.g., quartz.

# Definitions and units for magnetic quantities

Much confusion in rock magnetism arises from the fact that the older system of cgs units is still used in many publications besides the now recommended SI units. Table R4 shows the basic magnetic quantities, their units in the cgs and SI system, and the conversion factors. In the SI system the following applies for the relation between magnetic induction **B** and magnetic field **H** 

874

$$\mathbf{B} = \mu_0 (\mathbf{H} + \mathbf{M}) \tag{Eq. 1}$$

with  $\mu_0 = 4\pi \times 10^{-7} \,\mathrm{V\,s\,A^{-1}\,m^{-1}}$  being the magnetic permeability of vacuum.

Note, that for convenience in the case of M = 0, i.e., outside a sample, the term "magnetic field" is also used for  $\mathbf{B} = \mu_0 \cdot \mathbf{H}$ .

Most measurement techniques for hysteresis curves determine the magnetic moment of a given sample which is then normalized either by sample volume V or sample mass m.  $M = \mu/V$  is called the (volume) magnetization, whereas  $\sigma = \mu/m$  is called the specific magnetization.

#### Use of hysteresis measurements

The shape of hysteresis loops measured on rocks is determined by several properties of the contained minerals: Among these are the type of spin ordering (i.e., ferro-, ferri-, and antiferromagnetic) or the absence of spin order (para- and diamagnetic), the grain size, grain shape, concentration, and also distribution of each contributing mineral. Due to the multitude of influencing factors, generally some additional information about the magnetic mineralogy is needed for the interpretation

Figure R10 Measured hysteresis loops (a) contain para- or diamagnetic susceptibilities  $\chi_{pd}$  from sample holder or admixtures which first must be removed to obtain the ferromagnetic loop (b). The coercive force  $B_c$  is defined by the zero crossing (M = 0) of the lower hysteresis branch, the saturation remanence  $M_{rs}$  is the magnetization of the upper branch at B = 0. The saturation magnetization  $M_s$  is obtained by estimating the limit value of the asymptotic approach to saturation. The coercivity of remanence  $B_{\rm cr}$  is defined to be the field value at which switching off the field in course of the lower hysteresis branch would lead to zero remanence. Note that the susceptibility correction leads to different  $B_c$  values for (a) and (b), whereas  $M_{rs}$ ,  $M_s$ , and  $B_{cr}$  are unchanged. Subtracting the hysteresis branches either in vertical direction or subtracting their average in horizontal direction leads to two representations of the coercivity distribution with respect to B or M. The shaded area in all cases is equal and represents the magnetic energy dissipation  $E_{hys}$  during one hysteresis run.

of hysteresis loops in rock magnetism. If such information is available, hysteresis loops allow a rapid characterization of samples regarding compositional variations, the stability of paleomagnetic information carried by the rocks, change of depositional regime in the case of sediments or alteration processes affecting rocks in general.

# Physical mechanisms of hysteresis

#### Reversible and irreversible magnetization processes

Magnetic hysteresis is a result of irreversible magnetization changes. An abstract physical process between two states  $A \rightarrow B$  is reversible if each intermediate state is arbitrarily close to an equilibrium state. In this case the cycle  $A \rightarrow B \rightarrow A$  dissipates no energy. A simple mechanical example of an irreversible process is a switch (Figure R11). It is typical for any system which allows for irreversible changes. (1) It possesses two (or more) metastable positions separated by an energy barrier that must be overcome to change from one to the other. (2) The systems current state depends upon previous physical influences: it serves as a memory.

Natural magnetic systems usually contain a huge number of different metastable magnetization states which give rise to irreversible magnetization processes whenever external variables like magnetic field, temperature, or pressure change. These processes are usually very complex, but as was firstly shown in Stoner and Wohlfarth (1948), there is one important magnetic analog to the mechanical switch: a coherently rotating single-domain (SD) particle.

#### Single-domain particles

In sufficiently small magnetic particles, quantum mechanical exchange coupling keeps all spins aligned. The most simple case where the particle contains a single axis of preferred spin direction is discussed in many textbooks (Dunlop and Özdemir, 1997; Bertotti, 1998; Hubert and Schäfer, 1998). This is one of the few situations where a complete analytical treatment of magnetic hysteresis is possible. Most of our ideas on physical interpretation of hysteresis implicitly or explicitly are founded on this ideal situation. As sketched in Figure R12a, the magnetic energy of the particle varies during rotation of the magnetization. When a magnetic field  $\mathbf{B}$  is applied, the particle behaves as a magnetic switch. When *K* denotes its uniaxial anisotropy constant

**Figure R11** Reversible and irreversible physical processes in a switch. Slowly increasing the force between A and B is a reversible process through a series of well-defined equilibrium states. In contrast, the state transition from B over C to D is irreversible. There are no equilibrium states between C and D. Slowly decreasing the force in position D to the value at B does not reinstall the position of the switch.

**Figure R12** Stoner-Wohlfarth theory of hysteresis loops in coherently rotating single-domain particles. (a) Each particle has a preferred easy axis of magnetization and an energy barrier  $E_B$  opposes the rotation. It can result from magnetostatic-, crystal-, or stress-induced anisotropy. Thermal activation  $k_B T$  is assumed to be small in comparison to  $E_B$ . (b) Application of an external field with components  $B_{\parallel}$  and  $B_{\perp}$  with respect to the easy axis results in a magnetization deflection  $\phi$ . (c) Plotting the magnetization component  $m_B$  versus B results in single particle hysteresis loops. Their shape depends upon the angle between easy axis and external field B. (d) The switching instability traces an asteroid in the  $h_{\parallel} - h_{\perp}$  space. For field vectors inside the asteroid the system is bistable, outside the asteroid the magnetization state is unique. (e) Averaging over an isotropic ensemble of identical single-domain particles results in the shown Stoner-Wohlfarth hysteresis loop. More realistic ensembles average in addition over a distribution of anisotropy constants.

and  $M_{\rm s}$  its spontaneous magnetization, the particles' energy as a function of the deflection angle  $\varphi$  is given by

$$e(\varphi) = K \sin^2 \varphi - \mu_0 B_{\parallel} M_s \cos \varphi - \mu_0 B_{\perp} M_s \sin \varphi.$$
 (Eq. 2)

Solving the system of equations  $e'(\phi) = e''(\phi) = 0$ , yields a parametrization of the critical line in field space where the magnetization becomes unstable and switches direction

$$h_{\parallel}^* = -\cos^3 \varphi, \quad h_{\perp}^* = \sin^3 \varphi,$$

where  $h = BM_s/(2K)$  is the normalized field strength and  $\varphi$  serves as parameter. This curve is the Stoner-Wohlfarth asteroid (Bertotti, 1998; Hubert and Schäfer, 1998) (Figure R12d).

Plotting the magnetization component parallel to the field versus the field yields the Stoner-Wohlfarth hysteresis loops in Figure R12. For simple numerical mixing experiments, a useful approximation for a Stoner-Wohlfarth particle ensemble is  $m_{SW}(h) = \tanh(0.8h) \pm 0.5 \operatorname{sech}(1.9h)$ .

#### Hysteresis in multidomain particles

In magnetic particles beyond the critical SD size, magnetostatic selfinteraction overcomes the strong quantum mechanical exchange coupling and deflects a part of the spins to form an inhomogeneous internal magnetization structure which minimizes the energy by partial magnetic flux closure. In large particles the optimal magnetization configuration is a subdivision of the grain in different relatively large magnetic domains, nearly homogeneously magnetized along some preferred axes and separated by relatively small domain walls wherein the magnetization changes continuously. To a certain extent, it is easy to change the magnetization of a multidomain grain by moving its domain walls such as to enlarge one domain and diminish another (Figure R13). One mechanism of hysteresis in multidomain grains originates from impeding the continuous motion of a domain wall by pinning it to a local defect or stress source which creates an energy barrier which must be overcome to proceed with the motion. By larger field variation, the energetically optimal number of domains changes and a global reorganization of domain structure occurs by nucleation or denucleation of domains. In all these cases, one can envisage the self-demagnetizing field as the driving force which adjusts the internal structure to the prescribed external field. Only beyond the saturation field  $B_{sat}$ , the internal magnetization structure is homogeneous and essentially rotates like an SD particle into the field direction. Because this rotation is a reversible process, the branches of the hysteresis curve coincide for  $B > B_{sat}$ .

While a quantitative description of the physical processes in multidomain particles is extremely difficult, a general understanding of multidomain hysteresis in terms of the self-demagnetizing field  $H_d$ , as given by Néel (1955), is very easy. In this simplified picture the MD particles' average magnetization M creates an average internal demagnetizing field

$$H_{\rm d} = -NM,$$

where the numerical demagnetizing factor 0 < N < 1 nearly does not depend on the domain configuration. The total internal field  $H_i$  inside the particle then is the sum  $H + H_d$  of external and demagnetizing field. Assuming that anhysteretic magnetization and internal field are linked by an internal susceptibility  $\chi_i$  one obtains

$$M(H) = \chi_{i}H_{i} = \chi_{i}(H + H_{d}) = \chi_{i}(H - NM(H))$$

**Figure R13** Hysteresis in multidomain particles is effected by changes of the domain structure. Domains grow or shrink by domain wall movement which can be impeded by pinning at lattice defects. An example is irreversible pinning of a 180° domain wall as observed in a single crystal iron film (after Hubert and Schäfer 1998). Changing the number of domains requires global reorganization of the magnetization pattern (nucleation). For example nucleation of domains as observed in a 15-µm titanomagnetite (after Halgedahl and Fuller 1983). In high fields the sample becomes saturated with essentially homogeneous magnetization which in increasing field rotates toward the field direction.

Solving for M(H) yields

$$M(H) = \frac{\chi_{\rm i}}{1 + N\chi_{\rm i}} H \approx H/N,$$

where the last approximation assumes large  $\chi_i$ . For given  $H_c$ , the two hysteresis branches then are  $M^{\pm}(H) \approx (H \mp H_c)/N$ , from which for H = 0 Néel (1955) obtains

$$\frac{M_{\rm rs}}{M_{\rm s}} = \frac{1}{NM_{\rm s}}H_{\rm c}.$$
(Eq. 3)

## **Overview of typical measurements**

#### Instrumentation

There are two commonly used techniques to measure the magnetization of a sample in dependence of an applied field.

Firstly, magnetization can be determined by measuring the stray field generated by the magnetic moment of a sample. Commonly used instruments in rock magnetism applying this principle are vibrating sample magnetometers (VSMs). During the measurement the sample is vibrating and its magnetization is registered by measuring the flux change of the magnetic field through a system of pickup coils. The inducing external field is homogeneous and constant through time and therefore does not contribute to the measurement signal. One of the advantages of VSMs is the quick magnetization measurement, which allows to sample the hysteresis loop with typically up to 1000 evenly distributed data points. Despite this large number, measurement of a complete hysteresis loop typically does not take longer than one minute. Other instruments use superconducting quantum interference devices (SQUIDs) to measure the stray field of a magnetized sample. These devices are more common in the measurement of remanent magnetization but can also be used for measuring magnetization in applied fields. This technique is realized in the magnetic property measurement system (MPMS).

The second class of instruments measures the force which is exerted by a magnetic gradient field on the magnetized sample in order to determine its magnetization. The classical instrument using this technique is the magnetic balance. Here, the sample is suspended from a force measuring system and is positioned between the pole pieces of the electromagnet generating the inducing field. In order to generate a measurable force, the sample is not positioned in the area of homogeneous magnetic field but rather at the edges of the pole pieces where a large field gradient is present. Another frequently used configuration involves pole pieces which are shaped in a special way so that the inducing field is not homogeneous but has a well-defined gradient which is exerting a translational force on the sample (Collinson, 1983). The field gradient is generally dependent on the strength of the inducing field **B** so that the measurement of **M** is not independent of **B**.

This disadvantage of the magnetic balance can be overcome by separating the source of the gradient field from the inducing homogeneous field. The variable field translation balance (VFTB), a modified magnetic balance, uses this approach by supplying the gradient field through an additional set of coils. In addition, this gradient field is oscillating, forcing the sample to oscillate as well. Thus, the force acting onto the sample and eventually the magnetization can be determined dynamically from the sample's oscillation amplitude. This yields a higher sensitivity in comparison to the static force measurement of the classical magnetic balance. A similar approach is used in the alternating gradient field magnetometer (AGFM) where the sample is mounted on a quartz rod, which itself is attached to a piezoelectric transducer recording the force acting on the sample.

#### Measurement procedures

The basic interpretation of hysteresis properties requires determination of the four parameters saturation magnetization  $M_{\rm s}$ , saturation remanence  $M_{\rm rs}$ , coercive field  $B_{\rm c}$ , and coercivity of remanence  $B_{\rm cr}$ . The first three quantities are determined from the hysteresis loop, whereas  $B_{\rm cr}$  can only be determined from the so-called backfield curve.

Measurement procedures for hysteresis loops depend on the speed of data acquisition and thus the number of data points. For instruments like the VSM and AGFM with typically 600–1000 data points per loop, field steps are chosen equidistantly to obtain a quasicontinuous loop. In the case of instruments with slower data acquisition and typically 20–40 field steps (e.g., VFTB, MPMS), nonequidistant spacing is advisable in order to properly sample all features of the loop shape.

von Dobeneck (1996) proposed the following series yielding increasing field increments toward the field maxima

$$B(i) = \frac{|i|}{i} \frac{B_{\max}}{\lambda} [(\lambda + 1)^{|i|/n} - 1]$$

with i = -n, ..., -1, 0, 1, ..., n (2*n* number of data points per branch) and  $\lambda > 0$  defining the accumulation of field steps toward the origin. This provides a good sampling of the bends in the region of irreversible magnetization changes and a less dense spacing in the region of the approach to saturation.

As magnetic hysteresis is temperature dependent, a proper temperature control during hysteresis loop measurement is crucial to obtain high-quality data.

For measurement of the backfield curve the sample is first brought into magnetic saturation by applying the maximum magnetic field in positive field direction. The sample's remanent magnetization is then measured in zero field being equal to  $M_{rs}$ . Subsequently, successively higher fields are imparted in negative field (or backfield) direction and after each field-on step, the remanent magnetization is again measured in zero field. The field at which the remanent magnetization switches from positive to negative values is called the coercivity of remanence  $B_{cr}$  As the backfield measurement always consists of discrete steps, the crossing of the abscissa is usually determined by interpolation. For instruments where the inducing field is generated by an electromagnet with pole pieces, it is necessary to compensate the residual magnetic field of these pole pieces in order to conduct a proper zero field measurement. Usually, this is accomplished by an additional set of coils.

## Typical measurement results

Some results of hysteresis loop measurements and associated backfield curves are shown in Figure R14. The loop of synthetic MD magnetite (Figure R14a) shows the typical ramp-like shape and a quick saturation below 500mT. Note also the comparatively low  $B_c$  of 3.5mT and the small area inside the loop corresponding to a small  $E_{hys}$ . The high  $B_{cr}/B_c$  ratio is characteristic for multidomain particles. The young ocean basalt sample (Figure R14b) has a fairly low  $B_c$  as well. For the herein contained titanomagnetite, however, much higher fields are

necessary for magnetic saturation. Although irreversible processes (causing the difference between the two loop branches) do not occur above  $B \approx 0.4$  T, the loop shows significant curvature up to fields of 1.4T due to reversible rotation of magnetic moments. Older ocean basalts, where titanomagnetite is transformed into titanomaghemite by low-temperature oxidation often show almost perfect single-domain behavior as represented by the hysteresis loop in Figure R14c. Both the  $M_{\rm rs}/M_{\rm s}$  and  $B_{\rm cr}/B_{\rm c}$  ratio are approaching the ideal values for noninteracting uniaxial single-domain particles (see Table R5). Natural titanomaghemites as found in ocean basalts have even higher saturation fields than titanomagnetites.

The grain size dependence of hysteresis loops and parameters will be discussed in the following section. More hysteresis loops of rock forming minerals can be found in the literature, e.g., Chevallier and Mathieu (1943) (Hematite) and Keller and Schmidbauer (1999) (Titanomagnetite).

**Figure R14** Three examples of room temperature hysteresis curves and corresponding backfield measurements. (a) Synthetic multidomain mangetite (average grain size  $12 \mu m$ ) dispersed in CaF<sub>2</sub> and measured with a VFTB. (b) Young (0.7 Ma) ocean basalt sample containing titanomagnetite. (c) 32-Ma old ocean basalt sample containing single-domain titanomagnemite. Both ocean basalts were measured with a Princeton Measurements VSM.

**Table R5** Theoretical values of hysteresis parameters for isotropic noninteracting single-domain particle ensembles (after Joffe and Heuberger 1974)

	Prolate	Oblate	Cubic: $K < 0$	Cubic: $K > 0$
$B_{ m cr}/B_{ m c}$	1.09	1.15	1.08	1.04
$M_{ m rs}/M_{ m s}$	0.5	0.638	0.866	0.831

#### Interpretation of hysteresis loops

## Constituents of the hysteresis loop

The initial curve of a hysteresis loop starts at zero field and zero remanence (Figure R10a). There exist many different magnetization states having zero remanence and accordingly many different initial curves are possible. While the most symmetric choice is the thermally demagnetized initial state, usually the alternating field (AF) demagnetized state is regarded in the literature. In sufficiently small fields the initial curve of multidomain particle ensembles can be described by the Rayleigh law:

$$M(B) = \kappa_0 B + \alpha B^2.$$

The first term accounts for reversible changes (wall movements) whereas the second term is associated with irreversible processes. In rock magnetic applications, the initial susceptibility  $\kappa_0$  is often used as a relative proxy for magnetic mineral concentration.

The part of the hysteresis curve measured between maximum + and maximum - field is called upper hysteresis branch, the subsequent measurement between maximum - and maximum + field is termed lower hysteresis branch. With only a few exceptions (associated with a certain type of magnetic interaction; Meiklejohn and Carter, 1960), the two branches are point symmetric with respect to the origin. The intersections of the hysteresis branches with the ordinate and abscissa give the values for saturation remanence  $M_{\rm rs}$  and  $B_{\rm c}$ , respectively. The area between the two branches defines the total hysteresis branches is the grain size of magnetic minerals. Figure R12e shows the idealized loop shape for an ensemble of uniaxial single-domain grains, whereas Figure R14a shows the typical ramp-like shape of a sample containing multidomain grains.

An important difficulty in hysteresis measurements is the determination of the saturation magnetization  $M_s$  from the loop. It requires to estimate the limit value of magnetization toward high fields. The *approach to saturation* occurs in the high field region where irreversible magnetization changes are completed. The loop is a single branch which in case of pure rotation theoretically is described by:

$$M(B) = \chi_{\rm pd}B + M_{\rm s} - \frac{a_2}{B^2} + \cdots$$

Experimental evidence rather indicates an expansion

$$M(B) = \chi_{\rm pd}B + M_{\rm s} - \frac{a_1}{B} - \frac{a_2}{B^2} + \cdots$$

Deviations from the ideal case result mainly from small stress centers of point defects, dislocation dipoles, or inclusions (Kronmüller and Fähnle, 2003). In rock magnetic applications it is sometimes difficult to ensure that a sample is sufficiently saturated since some natural minerals saturate only in high fields and especially titanomagnetites may be extremely sensitive to stress.

A natural generalization of the hysteresis measurement procedure is the variation of start and end fields. Any zigzag sequence of fields  $B_1, B_2, \ldots, B_n$  may be applied to the sample to produce a sequence of higher order hysteresis branches. All these branches lie inside the region outlined by the main hysteresis curve between the maximal field values  $\pm B_{\text{max}}$ . The additional information contained in higher order curves may be helpful for a detailed sample characterization. In the framework of Preisach theory it is possible to infer theoretical relations between different higher order curves. Especially, it is possible to show that the complete information of any Preisach system can be retrieved from its first-order curves, which result from the field sequences  $B_{\text{max}}$ , B,  $B_{\text{max}}$  (Mayergoyz, 1991).

The most basic interpretation of the backfield curve yields a single value for the coercivity of remanence  $B_{\rm cr}$  of the bulk sample. The curve shape, however, does also contain information about the distribution of coercivities due to a mixture of different magnetominerals or a distribution of grain sizes of the contained magnetic phase. It is important to know that the  $B_{\rm cr}$  value of a mixture of different magnetic minerals or grain sizes cannot be explained by simple linear mixing theory (e.g., Dunlop 2002a).

#### Hysteresis parameters

Saturation magnetization  $M_s$  is a material constant being independent of grain size. In rock magnetic applications  $M_s$  is thus dependent on the type of magnetic mineral and its concentration. In contrast to  $M_{\rm s}$ , saturation remanence  $M_{\rm rs}$  is a grain size sensitive parameter. Meaningful interpretation of this parameter therefore almost always requires normalization to  $M_s$  as it is also dependent on mineral type and concentration. It can then be compared to theoretical domain state threshold values to determine the magnetic grain size as discussed in the next section. The coercivity parameters  $B_{cr}$  and  $B_{c}$  are independent of concentration and can be interpreted in terms of the stability of magnetic remanence. Coercivity is controlled by magnetomineralogy, grain size and the anisotropies controlling the magnetic energy. In minerals being dominated by magnetostrictive anisotropy, e.g., titanomagnetite, the coercivity parameters are strongly dependent on internal and external stresses acting onto the mineral grains. Other important factors controlling coercivity are grain shape, crystal impurities, and lattice imperfections.  $B_{cr}$  is generally normalized by  $B_{c}$  in order to yield independent granulometric information.

#### The Day plot

It was observed by Nagata (1953) that  $B_c$  varies linearly with  $M_{rs}/M_s$  in igneous rocks. As seen in (3), Néel (1955) explained this linear dependency as a direct effect of the self-demagnetizing field. His theory implies that  $M_{\rm rs}/M_{\rm s}$  and  $B_{\rm c}$  do not represent independent grain size information and that the slope of  $M_{\rm rs}/M_{\rm s}$  versus  $B_{\rm c}$  strongly depends upon  $M_s$  and thus on mineralogy (Wasilewski, 1973). In Day et al. (1977) it was reported for titanomagnetites that besides  $M_{\rm rs}/M_{\rm s}$  also the ratio  $B_{cr}/B_{c}$  well reflects grain size variations, but is independent of mineral composition. They therefore suggested to plot  $M_{\rm rs}/M_{\rm s}$  versus  $B_{\rm cr}/B_{\rm c}$  and delineated regions containing predominantly SD or MD remanence carriers (Day et al., 1977) (Figure R15). This Day plot has since been extensively used in rock magnetism to characterize magnetic grain size. Between the SD and MD region lies a broad transitional interval which is attributed to pseudo-single-domain (PSD) behavior. Several reasons for this peculiar behavior are discussed in the literature (see, e.g., Dunlop and Özdemir, 1997). Among these are SD-like moments in larger MD grains caused by dislocations or surface defects, the magnetic moments of domain walls, unusual domain states such as vortex structures or mixtures of MD and SD grains. Recent theoretical and experimental studies investigate this influence of grain size mixtures upon the Day plot (Dunlop, 2002a,b; Carter-Stiglitz et al., 2001; Lanci and Kent, 2003).

Table R5 after Joffe and Heuberger (1974) gives the theoretical SD values of  $B_{\rm cr}/B_{\rm c}$  and  $M_{\rm rs}/M_{\rm s}$  for isotropic noninteracting particle ensembles. With increasing temperature the value of  $B_{\rm cr}/B_{\rm c}$  for uniaxial random SD ensembles approaches 1 (Joffe, 1969).

**Figure R15** The Day plot classifies hysteresis curves in terms of the grain size sensitive quantities  $M_{rs}/M_s$  and  $B_{cr}/B_c$ . For magnetite and titanomagnetites the shown grain size classes have been originally defined in Day *et al.* (1977) and recently revised by Dunlop (2002a). The indicated theoretical trends for mixtures are taken from Dunlop (2002a) and Lanci and Kent (2003). While in case of the extensive quantities  $M_{rs}$  and  $M_s$  normalization is necessary to remove the volume dependence, using the ratio of the intensive quantities  $B_{cr}$  and  $B_c$  intends to remove dependencies of these quantities upon mineral composition. Exemplary hysteresis loops are shown inset. Loops are centered on the respective  $M_{rs}/M_s$  and  $B_{cr}/B_c$  values. Black: calculated synthetic loops. Gray: hysteresis loops of synthetic magnetite samples measured with an alternating gradient field magnetometer (maximum field 300mT).

#### Hysteresis shape

The possible shapes of magnetic hysteresis loops cover a wide range and only few general rules can be stated. (a) If saturation is reached, all magnetic memory is erased and the loop is point symmetric  $M^+(B) = -M^-(-B)$ . In most materials the coupling between magnetic system and lattice is very weak and the magnetic free energy obeys the thermodynamic laws. (b) After correcting for para- or diamagnetic slope, each hysteresis branch increases monotonically:  $B_1 \leq B_2$  implies  $M(B_1) \leq M(B_2)$ . (c) The area  $E_{\rm hys}$  of the loop corresponds to the energy dissipated by the magnetic system which implies  $E_{\rm hys} \geq 0$ .

In rock magnetism the general outline of hysteresis loops has been classified into constricted (wasp-waisted) rectangular (normal) and rounded (pot-bellied) shapes (Wasilewski, 1973; Muttoni, 1995; Roberts *et al.*, 1995; Hodych, 1996; Tauxe *et al.*, 1996). Extreme shape variations usually result from mixtures of samples with anhysteretic loops of very different saturation behavior and coercivity (Bean, 1955; Wasilewski, 1973; Hejda *et al.*, 1994). Figure R16 demonstrates shape changes for a simple system of noninteracting SD particles mixed with an SP fraction of varying anhysteretic slope (e.g., grain size). While the vertical loop difference is unchanged by this process, the horizontal difference reflects the degree of constriction from potbellied to wasp-waisted loops. To quantitatively describe constriction the ratio between maximal and minimal horizontal difference has been used (Xu *et al.*, 2002; Gee and Kent, 1999). Another possibility is the parameter

$$\sigma_{\rm hys} = \log\left(\frac{E_{\rm hys}}{4M_{\rm s}B_{\rm c}}\right),\tag{Eq. 4}$$

where log denotes the natural logarithm (Fabian, 2003). For constricted loops  $\sigma_{hys} > 0$  whereas for round loop shapes  $\sigma_{hys} < 0$ .

**Figure R16** Three hysteresis shapes result from linear mixture of the same primary hysteresis loop with Langevin functions of different susceptibility. The vertical loop difference is unchanged by this process, whereas the horizontal difference clearly reflects the rounded or constricted shape of the loops.

**Figure R17** A noninteracting ensemble of rectangular switching curves as in (a) is a very general system with hysteresis. If *a* and *b* denote downward and upward switching fields, respectively, the systems hysteresis properties are completely characterized by the Preisach function p(a, b) (b), which is defined for  $a \ge b$ . In (c) the magnetization change of the system is determined by integration over the Preisach plane. Shaded areas correspond to upward switched loops and count positively, while unshaded areas count negatively (see (Eq. 5)).

# Stress control and annealing

An important factor influencing the hysteresis properties of natural and synthetic samples is stress. It originates either from external sources (hydrostatic or shear stress) or from internal sources like defects, dislocations, twin boundaries, or changes in lattice constants due to oxidation or ion diffusion. A further intrinsic stress source for magnetic materials is magnetostriction. It denotes the lattice deformation in reaction to the local magnetic moment vector. Any inhomogeneous magnetization structure creates a magnetostrictive stress field which compensates for the incompatible local deformations (Hubert and Schäfer, 1998).

The inverse effect is that the magnetization structure adapts to external stress patterns. In a material with isotropic magnetostriction constant  $\lambda_s$  an external stress  $\sigma$  leads to an additional uniaxial anisotropy along the stress axis with anisotropy constant  $K = \frac{3}{2}\lambda_s\sigma$ .

Stress effects both, reversible and irreversible magnetization patterns. Reversible processes which govern the approach to saturation are influenced by the increased anisotropy (Dankers and Sugiura, 1981; Hodych, 1990; Özdemir and Dunlop, 1997), while irreversible processes, reflected by coercive fields as  $B_c$  and  $B_{cr}$  or remanences as  $M_{rs}$ , are enhanced by stress-induced pinning sites. Since characteristic domain sizes scale with  $\sqrt{K}$  if all other material parameters are constant (Hubert and Schäfer, 1998), the apparent magnetic grain size, as observed, e.g., in the Day plot, changes with  $1/\sqrt{\sigma}$  when stress anisotropy prevails.

## Decomposition of hysteresis curves

Conceptually, a hysteresis loop traces a continuous magnetization process and contains much more information about the sample than represented by a few remanence, coercivity or shape parameters. Especially in environmental magnetism one wishes to use all available information to analyze compositional variations within large sample collections. Several procedures have been put forward to exactly describe the hysteresis loop by large parameter sets. Among them are Fourier decomposition (Jackson *et al.*, 1990) and a representation by hyperbolic basis functions (von Dobeneck, 1996). Ideally, such methods attempt to use hysteresis loops and other magnetization curves (Robertson and France, 1994) to decompose a set of given mixed loops into their end members which can be attributed to different sources. In case of linear mixing this kind of decomposition is possible (Thompson, 1986; Carter-Stiglitz *et al.*, 2001). However it is not possible to uniquely identify end members from only mixed samples. Moreover, unmixing procedures which synchronously use different magnetization curves should take into account mutual interdependencies between these curves (Fabian and von Dobeneck, 1997). The extreme case of complete sample description is based on the measurement of the samples Preisach function or—equivalently—its FORC distribution.

## Preisach model

Preisach (1935) put forward a simple mathematical concept which allows to understand many fundamental properties of hysteresis loops and other magnetization curves. His model replaces the magnetic sample by a collection of rectangular switching processes characterized by their respective downward and upward switching fields (a, b) (Figure R17a). The weight of (a, b) for the sample is given by the Preisach function p(a, b) (Figure R17b). Whether a loop is in its *up* or *down* position depends on the previous field history. In Figure R17c shaded *a*-*b* areas represent loops in *up* position. Increasing the field *B* switches loops with a < B in the *up* position, decreasing *B* switches loops with b > B in their *down* position. When p(a, b) is known, the sample magnetization after an arbitrary field history is

$$m = \int_{S^+} p(a,b) da \, db - \int_{S^-} p(a,b) da \, db,$$
 (Eq. 5)

where  $S^+$  and  $S^-$  denote the subsets of the *a-b* plane with, respectively, upward or downward switched loops. The Preisach model has been used in rock magnetism to investigate interaction (Dunlop, 1969; Dunlop *et al.*, 1990), viscosity (Mullins and Tite, 1973), and grain size (Ivanov *et al.*, 1981). Mapping of the Preisach function yields detailed information about the sample (Hejda and Zelinka, 1990). A special measurement scheme for mapping of the Preisach function, originally developed and studied by Girke (1960), is now routinely used in rock magnetism (Pike *et al.*, 1999, 2001). Using the Preisach model it is also possible to obtain general theoretical relations between different magnetization processes (Fabian and von Dobeneck, 1997). There is extensive literature on using this or similar models in engineering and mathematics (Mayergoyz, 1991; Visintin, 1991).

Magnetization, Isothermal Remanent Magnetization, Thermoremanent Paleomagnetism Rock Magnetism

# **ROCK MAGNETOMETER, SUPERCONDUCTING**

Superconducting Rock Magnetometers, often abbreviated as SRM, are the most commonly used magnetometers in modern Paleomagnetism. The SRM uses superconducting quantum interference devices (SQUIDs), superconducting magnetic flux transformers, superconducting magnetic shielding, and a liquid helium temperature environment of 4.2 K to measure the remanent and induced magnetic moment in samples inserted into the instrument. These samples are usually measured at room temperature. There have been many different configurations of superconducting sensors used for paleomagnetic measurements but, we will focus on the instrument designs that are, or have been commercially available and that have been the most widely used in these magnetic studies.

# History

The SRM had its beginning in 1967 with the first development made by the author after meeting Dr. Richard Doell and Dr. Brent Dalrymple of the US Geological Survey at Menlo Park, CA and Prof. Alan Cox of Stanford University. They were conducting research on the reversals of the earth's magnetic field (Cox *et al.*, 1964). The author was at Stanford Research Institute in Menlo Park, CA studying the recently discovered quantum interference properties of superconducting devices. These devices were being used as very sensitive detectors of magnetic fields (Deaver and Goree, 1967). In discussions with Doell and Cox it became clear that the use of these superconducting devices could be helpful in the measurement of magnetic properties of geophysical samples.

The standard paleomagnetic measurement systems in use in the 1960s were the astatic, the induction coil spinner, and the fluxgate spinner. See Collinson (1983) and Fuller (1987) for complete descriptions of these instruments. The meetings with Cox, Doell, and Dalrymple in 1967 and 1968, and later discussions with Prof. Michael Fuller at the University of Pittsburgh led to the design and construction of the first SRM by the authors group, then at Develco, Inc., Mountain View, CA. Fuller envisioned many applications of the SRM in the study of magnetic properties of rocks and obtained funding from the US National Science Foundation to buy the first SRM. Fuller's scientific and technical expertise was fundamental in defining the instrument features so that this instrument could be used for many different measurements important to paleo- and rock magnetism (Goree and Fuller, 1976). Figure R18 is a photograph of this first SRM design installed at the University of Pittsburgh in 1970. This instrument was the foundation for design evolution that has resulted in over 200 SRMs used in laboratories throughout the world.

This first SRM was horizontally orientated with a straight through, room temperature access. This design proved to be somewhat complex for the existing state of the art in SQUID and thermal insulation technology, and only two of these systems were constructed. For the next 13 years all SRMs were a more conventional vertical cryogenic design with sample access from the top end, as shown in Figure R19. In this design the superconducting components were installed in a probe that was lowered into a conventional liquid helium dewar. The advantage of this design was primarily that the probe could be easily removed to gain access to the SQUIDs, superconducting shield and cryogenic vacuum seals. The primary disadvantages were the high liquid helium loss rate due to thermal load down the large dewar and probe neck tubes, and the fact that the room temperature access could not be straight through the magnetometer. Therefore the design was not suitable for long core measurements. The typical SRM of this design had a helium loss rate of about  $3 \ l day^{-1}$ . Several vertical systems were constructed with cryocoolers mounted on the dewar to intercept much of the thermal load, and the loss rate was reduced to about  $1 \ l day^{-1}$ .

The author reintroduced the horizontal straight through access system in 1981 and incorporated the cryogenic components with

Figure R18 First SRM design.

Figure R19 Conventional liquid helium dewar with vertical SRM insert.

#### Table R6 SRM manufacturers

Company	SRMs delivered	
Develco, Inc., 1969–1973	30	
Superconducting Technology, Inc., 1973–1975	45	
Cryogenic Consultants, Ltd, 1977-1994	15	
CTF Systems, Inc., 1977–1990	15	
CEA-LETI, France, 1978	3	
2G Enterprises, 1981-August 2005	104	

the SQUIDs and superconducting shield to provide an integrated design that eliminated the large neck tube heat load between room temperature and liquid helium. This new design has been sold through a marketing arrangement between the authors company (William S. Goree, Inc.) and William Goodman's company (Applied Physics Systems, Inc.) as 2G Enterprises. The new design eliminated all cryogenic fiberglass-epoxy vacuum parts, thereby removing the diffusion of helium gas into the high vacuum insulation volume. These vacuum changes combined with improved superinsulation and mechanical supports and a cryocooler to intercept much of the thermal load resulted in systems with liquid helium loss rates below 0.11 day<sup>-1</sup>. These very low helium loss rates provided operating times exceeding 3 years on a single fill of helium and made it practical to use the SRM in laboratories where liquid helium was very expensive and/or difficult to obtain.

There have been six different companies, starting in 1969 that have built various styles of the basic SRM. Table R6 list the companies and the approximate number of instruments built by each as of August 2005.

#### Instrument description

The SRM is an instrument that uses SQUIDs (Kleiner et al., 2004) to measure the magnetic field of a sample typically at room temperature. The SQUID is the world's most sensitive detector of magnetic fields and, with the use of superconducting flux transformers, large samples can be coupled to the very small sensor (Goree and Fuller, 1976). One of the first design parameters used in the SRM was the concept of a very homogeneous measurement region. For a "standard" paleomagnetic sample of 2.5-cm diameter by 2.5-cm long it was desired to measure the three orthogonal components of the samples magnetic moment with a single insertion of the sample into the measurement volume. The measurement should be done quickly, in a few seconds, and should be independent of the exact location of the magnetic sources within the sample. A complete magnetic measuring system as used in most paleomagnetic laboratories consists of the SRM for the accurate measurement of the magnetic moment of the sample, sample handling equipment to place the sample into the center of the measurement region of the SRM, alternating field demagnetization coils to produce precise demagnetization of the sample at any desired field strength up to approximately 300 mT, ARM coils used in conjunction with the demagnetization coils, IRM coils to produce large induced moments in the sample, and thermal demagnetization furnaces. Each of these measurement techniques is described in other sections of this encyclopedia.

Many of the SRM systems in use today incorporate the AF demagnetization, ARM and IRM in-line with the SRM and all computer controlled so that very detailed studies of samples can be done without changing samples. The thermal demagnetization is most often done in a separate furnace where up to 100 samples are heated and cooled, then measured with the SRM. This thermal demagnetization is repeated for sequential temperature steps.

The use of the SRM for the measurement of long cores was first envisioned by Fuller and shown to be almost as accurate as cutting a core into discrete samples and measuring each sample independently (Goree and Fuller, 1976). This technique was incorporated in the first long core system specifically designed for the Ocean Drilling Program (ODP, 1985). The ODP system, shown in Figure R20, was the first use

Figure R20 Ocean Drilling Program ship and SRM.

Figure R21 Sensitivity profile for high-resolution pickup coils.

of an SRM on an ocean going ship. This SRM was used continuously by ODP from 1985 until 1992 when it was replaced with an improved design SRM that used DC SQUIDs for better sensitivity. This SRM is still in use on the ODP ship as of 2005. It has been estimated that ODP scientists with the two SRMs have measured 200 000 m of ocean core. Most of the measurements were done on semicircular half cores 150-cm long, and the cores were often passed through the magnetometer many times with sequential AF demagnetization. As of 2005 there have been ten long core SRMs installed.

Carlo Laj and colleagues at GIF Sur Yevette, France became interested in measuring long sediment samples with better axial resolution of the magnetic moment. Tauxe *et al.* (1983) suggested a U-channel sample configuration to obtain a clean section of sediment cores. These samples were 2 cm by 2 cm cross-section by 150-cm long cut from near the center of a circular core. The first U-channel SRM was delivered to GIF in 1991 (Weeks *et al.*, 1993). The pickup coil construction for U-channel systems was optimized for sampling a smaller volume of the sample and is called a high-resolution (HR) pickup coil. (Figure R21 shows sensitivity profiles for HR pickup coils.) A second U-channel system was installed at IPGP, Paris in 1992 to measure discrete samples as well as U-channels (Nagy and Valet, 1993). Many laboratories have adopted the use of the highresolution pickup coil system to measure both U-channels and discrete samples since 1992. There have been seventy-two 2G SRMs built since the GIF system was delivered in 1991 and 14 of these have used the high-resolution U-channel design.

If a 150-cm long core or U-channel is measured every cm of its length, with AF, ARM, and IRM sequences, it may take on the order of 10h to complete a full measurement cycle where thousands of individual measurements are made. A study with this detail using an astatic magnetometer of the 1960s would have taken years of measurement time.

# Superconducting quantum interference device

The SQUID is a very small device with a magnetic field sensitive area of the order of  $10^{-6}$  m<sup>2</sup> (Deaver and Goree, 1967) and is the heart of an SRM. The SQUID is basically a superconducting loop with a diameter of less than 1mm. The optimum energy sensitivity of an RF SQUID is obtained when the energy of a quantum of flux in the SQUID,  $\emptyset_0^2/2L$  is larger than the thermal energy, kT, where  $\emptyset_0$  is the flux quantum (2.07  $\times 10^{-15}$  weber), L is the SOUID loop inductance, k is the Boltzmann constant, and T is the absolute temperature of the SQUID (Zimmerman and Campbell, 1975). The optimum energy sensitivity for a DC SQUID scales as  $T (LC)^{1/2}$  (Kleiner *et al.*, 2004). Thus, the SQUID must have a very small capacitance, C, and a very small inductance, L. The SQUID capacitance is set by the junction technology and is about 1pF for thin film niobium junctions. The inductance is about 100 pH, which gives a SQUID loop diameter of less than 1 mm. This very small SQUID area requires that most samples to be measured must be coupled to the SQUID using a superconducting flux transformer that will be discussed in the next section, rather than being placed within the SQUID. The SQUID responds to changes in the magnetic flux that links the body of the SOUID. A unique quantum mechanical property of a SQUID is that the magnetic flux linking the SQUID area is quantized in units of h/2e, where h is Planck's constant and e is the charge of an electron. This fundamental property of superconductors gives the SQUID a digital output in units of the flux quanta  $\emptyset_0$ . In an SRM each measurement axis is calibrated by determining the magnetic moment applied at the center of the pickup coil that will produce one flux quanta change at the SQUID. A typical calibration number for an SRM with 4.2-cm diameter room temperature access is  $5 \times 10^{-8} \text{Am}^2$  per flux quanta. The noise level of a SOUID is often measured in terms of the fraction of single flux quanta that can be resolved. This can approach one part in  $10^6$  for DC SQUID instruments.

The first SRMs used radio frequency driven single junction SQUIDs (Kleiner *et al.*, 2004) beginning with a cylindrical SQUID approximately 1-mm diameter. Later this type was replaced with a toroidal niobium body SQUID. These SQUIDs were driven at radio frequencies of about 20MHz. The noise level of the RF SQUID was typically  $10^{-4}$  flux quanta and, in the early instruments this noise was approximately equal to the noise from the magnetometer produced by vibration of magnetic impurities within the pickup coil region and Johnson noise in the thermal insulation. After about 10 years of SRM development the instrument noise was reduced to less than the RF SQUID noise.

A major improvement in the SRM sensitivity came with the use of DC SQUIDs in an SRM in 1994. The DC SQUID uses two Josephson junctions connected in parallel (Kleiner *et al.*, 2004). It is operated by applying a DC voltage across the two junctions, which then oscillate at the Josephson frequency of 500 MHz  $\mu$ V<sup>-1</sup>. The applied voltage is normally tens of microvolts so the SQUID frequency is about 10 GHz. This very high operating frequency results in a greatly improved SQUID noise level. A typical DC SQUID has an intrinsic noise level of a few by 10<sup>-6</sup> flux quanta. This is about 100 times lower than the RF SQUIDs used in the earlier SRMs. After many changes in the internal construction of the SRM a usable sensitivity of less 10<sup>-5</sup> flux quanta has been obtained. This gives a magnetic moment noise level of about  $3 \times 10^{-13}$  Am<sup>2</sup> dipole moment for a 4.2-cm access DC SQUID SRM compared to about  $8 \times 10^{-12}$  Am<sup>2</sup> for the RF SQUID

SRM or an improvement of over 20 to 1. Further improvements in the DC SQUID SRM sensitivity can be expected as the noise from the superinsulation is reduced.

### Pickup coils and flux transformers

The desire to measure large samples with relatively uniform sensitivity over the sample volume can be achieved by using the zero resistance property of a superconductor. A two axis superconducting magnetic flux transformer is used in the SRM as shown in Figure R22 (Goree and Fuller, 1976). The SRM normally uses three orthogonal superconducting pickup coils cocentered about the sample position. The axial pickup coils are typically constructed in a Helmholtz configuration (Helmholtz, 1849), and the transverse pickup coils are saddle-shaped coils. The large superconducting pickup coil is connected to the SQUID input coil. Efficient energy transfer from this large coil to the small SQUID is obtained if the inductance of the pickup coil is equal to the inductance of the SQUID input coil. This inductive matching transfers one-half of the magnetic field energy applied to the pickup coil to the SQUID input coil (Deaver and Goree, 1967).

## Superconducting shields

Another crucial element of an SRM is the superconducting magnetic shield. The magnetic field sensitivity of an SRM is of the order of  $10^{-14}$  T where the earth's magnetic field is approximately  $5 \times 10^{-4}$  T. In order to use the extreme sensitivity of the SQUID system, very effective magnetic shielding is a necessity. A superconducting shield is the best magnetic shield known. In order to provide sample access inside the shield the typical SRM uses a superconducting shield that is open at one or both ends. If an external magnetic field is applied to the open end of a superconducting cylinder the net field at any cross-section of the cylinder will be zero, but the distribution of the field change will be such that the field along the cylinder axis is

Figure R22 Two axis pickup coils.

886

in the same direction as the applied field and the field near the inner walls of the cylinder will oppose the applied field. In the design of a magnetic shield for the SRM the field change measured along the shield axis is normally used to determine the required shield length. The on-axis attenuation of axially applied fields is given by  $31^{(x/r)}$  where *x* is the on-axis distance into the cylinder from an open end and *r* is the radius of the superconducting shield. The on-axis attenuation of fields applied transverse to the shield axis is given by  $36^{(x/2r)}$  (Deaver and Goree, 1967). A typical design attenuation for transverse fields is  $10^6$  and this gives a minimum shield length of 7.7 times shield radii. For this shield length and transverse attenuation of  $10^6$  the axial attenuation will be  $31^{(7.7r)/r} = 3.0 \times 10^{11}$ . Thus, the axial attenuation of a cylindrical shield is orders of magnitude better than its transverse attenuation, and it is important to place the SRM where the ambient magnetic transverse field noise is a minimum.

### Cryogenics

Another important performance variable in an SRM is the cryogenic environment. The SRM normally uses liquid helium as the thermal environment. A few SRMs have used liquid nitrogen as a secondary coolant, but most have used superinsulated dewar construction (Kropschot et al., 1968). In a superinsulated dewar the liquid helium reservoir and SQUID volume are enclosed in a vacuum region surrounded by many layers of aluminized mylar placed within this vacuum. Thermally conducting shields are also placed within this region and are cooled by utilizing the heat capacity of the evolving helium gas. The first SRMs used about 31 of liquid helium per day. Since the initial development of the SRM cryocoolers have been incorporated into the thermal design. The cryocooler is used to provide external cooling to the thermal shields placed within the superinsulation. A typical two stage cryocooler as used with the 2G Enterprises SRM will absorb about 0.5 W of heat at 15 K and 15 W at 80 K (CTI model 350, 2004). The extra cooling provided by the cryocooler will reduce the helium loss rate to below 0.11 day<sup>-1</sup> in a properly designed dewar. This greatly reduced loss rate has made it practical to use SRMs in laboratories where liquid helium is difficult to obtain and/or is very expensive.

It is also possible to use cryocoolers that will either reduce the helium loss rate to essentially zero, or produce the required low temperature without a reservoir of liquid helium. Cryocoolers that will produce 4K temperatures and/or liquid helium have been available for many years but the cost and poor long-term reliability have made them unacceptable for use with SRMs. Recent developments with pulse tube cryocoolers appear to change this situation. The author, in October 2004, began the development of a new magnetometer that would not use any liquid helium. The first SRM using this new pulse tube cryocooler technology (Cryomech, Inc., 2005) was completed and delivered to Dr. J. Hus at Dourbes, Belgium in May 2005 (Institut Royal Metrologique, Belgium). SQUID and superconducting shield temperatures of approximately 4.0K were obtained from room temperature to operation in about 3 days and the magnetic measurement performance is identical to that achieved with the liquid helium cooled systems. The pulse tube cryocooler has no moving mechanical parts at low temperatures and is predicted to have a very long mean time between failure, probably in excess of 15 years for the cold head, 10 years for the easily replaced drive motor, and about 10 years for the compressor. The projected excellent reliability of the pulse tube cryocooler has made it practical to use with this new SRM.

## High temperature superconductors

The discovery of materials that become superconducting at "high" temperatures in 1986 (Bednorz and Muller 1986) caused much excitement in all fields of superconductivity. If instruments could be built with these new materials and operate at 70–90 K the fabrication and operating cost could be dramatically reduced. Unfortunately, the high temperature materials that have been discovered to date (2004) are very brittle and it has been difficult to make high temperature

superconducting wires and SQUIDs. In particular, wires have not been produced where superconducting pickup coils and transformers can be constructed (Kleiner *et al.*, 2004).

# RUNCORN, S. KEITH (1922–1995)

I first met S.K. Runcorn in June of 1955. I had just graduated from Columbia College with a degree in Geology. He reached me at my grandparent's home on a Saturday morning and asked if I would like to be his field assistant working in Arizona for the summer and by the way I had to leave with him on Monday morning. I thought it was a joke but the longer we talked the more it seemed to be a real offer. So after a lot of discussion in the family I decided to take the risk on Runcorn so off we went on Monday to the wild west. Runcorn was supremely self-confident and somehow always expected things to turn out the way he wanted them to. By the end of the summer I was on my way to Cambridge England instead of Wyoming where I had expected to do my graduate studies. We first met when Keith was 33-years old having been born in 1922 in Southport Lancashire. He loved to swim and played rugby until he was past 40. He had a great interest in religion and during a trip to France, Italy, and Switzerland, which we took in late 1955, we made a tour of the great Cathedrals of France and northern Italy. In his later years he was to serve on the Vatican Council even though he was a lifelong member of the Church of England.

Without a doubt however his great love was science. His undergraduate education was obtained at Cambridge University where he was a member of Gonville and Caius College. He studied engineering, receiving his degree in 1943 and spent the rest of the war researching at the Royal Radar Establishment. In 1946 he was appointed to a lectureship in the Physics Department at Manchester University were P.M.S. Blackett was Department Chairman. Research in the Physics Department was dominated by cosmic ray research. However, Blackett was becoming interested in the generation of Earth's magnetic field and proposed a theory that rotating matter would generate a magnetic field and suggested that Runcorn get involved in this research. The competing theory was proposed by Elsasser and expanded by Bullard that the Earth's magnetic field arises from electric currents in the Earth's core. The simple test to differentiate between the two is to measure the field at the surface and at depth in the earth, if the field increases then the field is generated within the Earth. This experiment was carried out by Runcorn and others in the coalmines of Lancashire and Yorkshire. The field was shown to increase with depth showing that the field originated within the earth. This study served as Runcorn's PhD thesis.

Blackett had produced a very sensitive astatic magnetometer in his attempt to measure the magnetic field of a rotating gold ball, this failed but the magnetometer was put to work trying to find a record of secular variation in sediments and Runcorn became interested in this problem. Runcorn accepted a position at the department of Geodesy and Geophysics at Cambridge at about the same time (1950) that Blackett moved to Imperial College London, paleomagnetic research began at both institutions, which of course became a competition. When Runcorn arrived at Cambridge he found that paleomagnetic research had already begun on lavas from Iceland by Jan Hospers who found superimposed lavas of normal and reverse polarity, which were aligned along the axis of Earth's rotation however there was no laboratory. Runcorn set about to construct a new Paleomagnetic laboratory with the help of his students, K.M. Creer, E. Irving, D.W. Collinson, and J.H. Parry. The emphasis was still on secular variation but it soon became apparent that directions obtained by Irving in the pre-Cambrian and by Creer in Triassic red sediments were widely divergent from the present field and it became apparent that red sediments and igneous rocks gave internally consistent paleomagnetic results. The group used statistics developed by Fisher and the first apparent polar wander curve was produced by 1954. These results were interpreted as true polar wander an idea that was proposed by T. Gold. The early results from Runcorn's group were mostly from British rocks. However by 1954 Runcorn was traveling to the United States to collect rock samples and the first results had been obtained. By 1954 the original group began to disperse; Irving to Australia and Creer to the British Geological Survey.

Runcorn did not limit his research to paleomagnetism and he built a research group at Cambridge that studied various aspects of magnetic field behavior, e.g., R. Hide on convection in rotating fluids, P.H. Roberts on magnetohydrodynamics, F. Lowes on detecting earth currents which he believed might be leaking from the core. After the departure of Irving and Creer the paleomagnetic group at Cambridge consisted of J.C. Belshe, A.E.M. Nairn, D.W. Collinson, and J. Perry. This group was joined in the autumn of 1955 by N.D. Opdyke.

Runcorn was offered the position of Professor of Physics in the Department of Physics at the College of Newcastle on Tyne, which at the time was King's College of Durham University. He transferred the paleomagnetics laboratory to Newcastle and it was up and running in 1956. At the time of the move to Newcastle he was still maintaining that the data from North America and Europe could still be explained by Polar Wander alone. However the data was becoming better and a separation of the polar wander paths of Europe and North America persisted with the North American curve falling systematically to the West of the European curve. In the spring of 1956 he decided that the data could not be explained solely by Polar Wandering and he embraced Continental Drift. It is also true that new data was coming in from Australia that certainly could not be explained by Polar Wander alone. He became a fervent supporter of Continental Drift and lectured widely on the subject in Europe and North America where the Earth Science community was hostile to the idea. He and all paleomagnetists would see these ideas vindicated in the late 1960s by the success of the Plate Tectonic Theory. Runcorn adopted a strategy to convince the scientific community that crustal mobility was real. Ken Creer had rejoined him at Newcastle and was given the task of producing a polar wander curve for South America and Alan Nairn was sent to Africa were Anton Hales and Ian Gough were already working. Ted Irving had gone to Australia where his results were beginning to appear in print. The last of the easily accessible Gondwana continents was India where Blackett's group from Imperial College was working hard. It is interesting that Blackett was a supporter of Continental Drift in the early 1950s but did not say so in print until 1960. North American paleomagnetists were very skeptical of Continental Drift, in particular John Graham was a strong opponent of Continental Drift and he and Runcorn had some rather heated public debates, which on Graham's part became rather personal. Cox and Doell were not convinced that paleomagnetic data supported Continental Drift as late as 1960. Runcorn was always cool under verbal attack and I cannot ever recall him responding in kind. He was always interested by the idea of convection in the mantle and proposed that solid-state creep under stress from thermal and gravitational effects was responsible for the motion of continents.

He stopped doing active research in paleomagnetism in the mid-1960s and turned his attention to other scientific problems. He became fascinated by the origin and evolution of the Moon and the possibility of convection during the early history of the moon. He took advantage of the fact that the USA was going to the moon, which meant that funds would become available for lunar research. Moon rocks were returned from the moon in 1969 and in subsequent years till the end of the Apollo program. The magnetic properties of these rocks were studied at Newcastle and in other laboratories and all were found to be magnetic. Runcorn concluded that the Moon must have had a magnetic field early in its history and that this field must have been generated by magnetohydrodynamic motions in the Moon's core. Satellites orbiting the moon detected small magnetic anomalies, which Runcorn attributed to magnetizations being acquired at different times during the early history of the moon prior to 3.9-Ga years ago and resulting from the moon having a dipole field. The different pole positions he attributed to polar wander on the moon, which he suggested was caused by impacts on the Moon's surface. His last paper published in 1996 was titled "The Formation of the Lunar core."

Runcorn had a inquiring mind and during his career he published on many different subjects for example wind directions determined from eolian sandstone, the changing length of the day through time as recorded in coral growth, earth currents using abandoned cable in the Pacific, earthquakes and polar motion, excitation of the Chandler wobble, and convection in the Planets.

Runcorn was regarded highly by the scientific Community and this high regard resulted in many honors. He was elected a fellow of the Royal Society in 1965, the Indian National Academy of Science (1980), and he was an honorary member of the Royal Netherlands Academy of Arts and Sciences (1985), The Royal Norwegian Academy of Science and letters (1985), the Bavarian Academy of Science (1990), and the Royal Society of New South Wales (1993). He won a series of awards and medals beginning with the Napier Shaw prize of the Royal Meteorological Society (1959), the Charles Chree prize from the Institute of Physics (1969), the Vetlesen prize of Columbia University (1971), the John Adams Fleming Medal from the AGU (1983), the Gold Medal From the RAS (1984), and the Wegener Medal from the EGU (1987). He was appointed to Papal Academy of Sciences and helped to get Galileo reinstated by the Catholic Church.

Runcorn retired as the Professor of Physics at Newcastle in 1988 but he never stopped working. He was appointed to the Chapman Chair of Physical Sciences at the University of Alaska at Fairbanks, spending three months a year in Alaska teaching and doing research. He was found dead in his hotel room in San Diego on 5th December 1995 being the victim of a violent attack. He is mourned by many to whom he was a friend and mentor. He was a unique individual who was married to science and whose home was the Universe.

Neil Opdyke

# **RUNCORN'S THEOREM**

This remarkable theorem is concerned with the exterior magnetic field generated by magnetized materials at the surface of a planet. Usually magnetized materials above their Curie temperature lead to patterns of *magnetic anomalies* (q.v.); however, under idealized circumstances it transpires that some arrangements of magnetization lead to no external magnetic field, because of extremely subtle and fortuitous cancellation of the magnetic fields generated by one area of magnetization by the magnetic fields generated by another area of magnetization. The proof of this fact is quite complex, and the reader uninterested in the details should skip to the last two paragraphs to discover the application of this theorem.

We fix attention on the exterior magnetic field  $\mathbf{B}(\mathbf{r}_j)$  (at observation point  $\mathbf{r}_j$ ) generated by a magnetization distribution  $\mathbf{M}(\mathbf{r})$ enclosed in a spherical shell whose volume we denote by *V* and surfaces by  $\partial V$ . The field  $\mathbf{B}(\mathbf{r}_j)$  can be derived from a potential  $\phi_m$  as

$$\mathbf{B}(\mathbf{r}_i) = -\nabla \phi_m(\mathbf{r}_i),$$

where  $\phi_m$  is given by

$$\phi_m(\mathbf{r}_j) = \frac{\mu_0}{4\pi} \int_V \mathbf{G}(\mathbf{r}, \mathbf{r}_j) \cdot \mathbf{M}(\mathbf{r}) \mathrm{d}^3 \mathbf{r}, \qquad (\text{Eq. 1})$$

where the vector Green's function  $\mathbf{G}(\mathbf{r}, \mathbf{r}_i)$  is given by

$$\mathbf{G}(\mathbf{r},\mathbf{r}_j) = \nabla \frac{1}{|\mathbf{r}_j - \mathbf{r}|}.$$
 (Eq. 2)

The potential and thus the magnetic field is in general nonzero for arbitrary  $\mathbf{M}(\mathbf{r})$ . There are, however, a few distributions of  $\mathbf{M}(\mathbf{r})$  (termed *annihilators*) that generate no exterior, a simple example is the arrangement  $\mathbf{M}(\mathbf{r}) = A(r)\hat{\mathbf{r}}$  for arbitrary function A(r), a purely radial magnetization. This spherical arrangement is the equivalent of the infinite plane layer with constant magnetization in a Cartesian geometry, which also generates no external field. In the spherical case it generates no magnetic field because the radial part of the vector Green's function contains no spherical harmonic of degree zero (see (7) below), whereas the magnetization  $\mathbf{M}(\mathbf{r}) = A(r)\hat{\mathbf{r}}$  contains only degree zero; consequently the orthogonality of *spherical harmonics* (q.v.) leads to a zero result.

In 1975 Keith Runcorn proved that a more complex arrangement of magnetization was also an annihilator, namely that arising when a homogeneous material is magnetized by an arbitrary internal source. The theorem applies equally well to the case of remanent or induced magnetization, but we treat the case of induced magnetization here. Assuming that a linear relation exists between magnetization and applied magnetic field via a constant  $\alpha$ , we have an equation of the form

$$\mathbf{M}(\mathbf{r}) = \alpha \mathbf{B}(\mathbf{r})$$

(in SI the constant  $\alpha = \chi/\mu_0$ ; see Crustal magnetic field). It is the case that the inducing field is itself a potential field satisfying Laplace's equation, so we can write  $\mathbf{B} = -\nabla V_i$  where  $V_i$  is the internal potential (see Main field modeling); then the integral (1) reads

$$\phi_m(\mathbf{r}_j) = -\alpha \frac{\mu_0}{4\pi} \int_V \nabla \frac{1}{|\mathbf{r}_j - \mathbf{r}|} \cdot \nabla V_i \mathrm{d}^3 \mathbf{r}, \qquad (\text{Eq. 3})$$

where the "self-magnetization" due to terms of order  $\alpha^2$  have been dropped.

We expand  $V_i$  in terms of fully normalized spherical harmonics with coefficients  $\beta_l^m$ , analogous to the conventional Gauss coefficients  $\{g_l^m; h_l^m\}$ 

$$V_{i} = c \sum_{l=1}^{\infty} \sum_{m=-l}^{l} \left(\frac{a}{r}\right)^{l+1} \beta_{l}^{m} Y_{l}^{m}(\theta,\phi),$$
 (Eq. 4)

where *c* is the core radius; by assuming that the mantle is an insulator,  $V_i$  is harmonic everywhere outside of *c*. The spherical harmonics satisfy an orthogonality relation when integrated over the unit sphere  $\Omega$  on which |r| = 1 as follows:

$$4\pi \int_{\Omega} Y_l^m Y_p^q \mathrm{d}\Omega = \delta_{lp} \delta_{mq}.$$
 (Eq. 5)

For constant susceptibility, (3) can be written as

$$\phi_m(\mathbf{r}_j) = -\alpha \frac{\mu_0}{4\pi} \int_{\partial V} \hat{\mathbf{n}} \cdot \nabla \frac{1}{|\mathbf{r}_j - \mathbf{r}|} \mathbf{V}_i(\mathbf{r}) d^2 \mathbf{r}$$
(Eq. 6)

by an application of Gauss' Theorem, where  $\hat{\mathbf{n}}$  is a unit normal and  $\partial V$  represents both the inner and outer surfaces of the shell. We use the expansion of the reciprocal distance in spherical harmonics for  $|\mathbf{r}_i| > |\mathbf{r}|$ 

$$|\mathbf{r}_{j} - \mathbf{r}| = \frac{1}{r_{j}} \sum_{l=0}^{\infty} \sum_{m=-l}^{l} \frac{1}{2l+1} \left(\frac{r}{r_{j}}\right)^{l} Y_{l}^{m}(\theta, \phi) Y_{l}^{m}(\theta_{j}, \phi_{j})$$
(Eq. 7)

to obtain

$$\phi_m(\mathbf{r}_j) = -\alpha \frac{\mu_0}{4\pi} \int_{\partial V} \sum_{l,m} \frac{l}{2l+1} \left(\frac{r}{r_j}\right)^{l+1} Y_l^m(\theta,\phi) Y_l^m(\theta_j,\phi_j) \\ \times c \sum_{p,q} \left(\frac{c}{r}\right)^{p+1} \beta_p^q Y_p^q(\theta,\phi) d\Omega$$
(Eq. 8)

We invoke equation(s) and find that the orthogonality of the  $Y_l^m$  couples *l* and *p* in the sums, leading to

$$\phi_m(\mathbf{r}_j) = -\alpha \mu_0 \int_{\partial V} \sum_{l,m} c\beta_l^m \frac{l}{2l+1} \left(\frac{c}{r_j}\right)^{l+1} Y_l^m(\theta_j, \phi_j) \mathrm{d}\Omega.$$
(Eq. 9)

Since the integrand consists of two spherical surfaces with opposing outward normals, then each surface integral gives a contribution of the same absolute value but of opposite sign, and therefore the external potential generated is zero. This is Runcorn's (1975a,b) theorem. Note that the theorem also allows  $\alpha$  to be a function of *r* simply by noting that the theorem applies equally well to infinitesimally thin shells; each shell generates no field even when  $\alpha$  is different in each one.

The importance of this theorem was in explaining the absence of any appreciable exterior field outside Earth's moon, despite the presence of apparently significantly magnetized rocks on the Moon's surface. Runcorn (1975a,b) hypothesized that the mantle rocks had been magnetized by an internally generated dynamo field (now switched off) as they cooled through their Curie temperature; provided the Curie isotherm is everywhere spherical and the remanent susceptibility is everywhere only a function of radius, this even allows a time-dependent internal source field.

For a higher order analysis in  $\alpha$  and the treatment of an ellipsoidal Earth, see Jackson *et al.* (1999) and Lesur and Jackson (2000). Further description of the general form of annihilators can be found in Arkani-Hamed and Dyment (1996) and Maus and Haak (2003).

## SABINE, EDWARD (1788–1883)

General Sir Edward Sabine (Figure S1), soldier-scientist, made many of the first magnetic surveys to include magnetic force using Gauss' newly devised method for determining absolute intensity, was instrumental in setting up magnetic observatories and Ross' magnetic survey of the Antarctic regions, and completed the definitive survey of the geomagnetic field for epoch 1818–1876.

Born in Dublin to a distinguished military family, he was educated at Marlow and Woolwich where he excelled in mathematics. He obtained his first commission in 1803 at the age of 15, rising to General in 1870. After service in Canada, which involved capture by the American privateer the *Yorktown* after a running fight of 24 h and a close engagement of an hour with a greatly superior force, he began his work on terrestrial magnetism and gravity in 1816. In 1827 he obtained from the Duke of Wellington general leave of absence from military duties as long as he could usefully be employed

**Figure S1** Bust of Edward Sabine by Joseph Durham. It currently stands in the cafeteria of the Royal Society of London (reproduced with permission of The Royal Society, © The Royal Society).

in scientific pursuits. He was knighted in 1869 and served as President of the Royal Society of London from 1861–1871.

His work on gravity, influenced by Henry Kater, dominated over his work on magnetism early in his career (Anon, 1892) but we shall not dwell on it here. His first expedition was as astronomer to John Ross' expedition to find a northwest passage in 1818; this was followed by Parry's expedition in the following year. Gravity occupied most of his time on these early expeditions, but he also observed magnetic inclination, for the first time in many places, thus forming the basis for later measurements of secular variation.

In 1834, while posted in Ireland, he began the first systematic magnetic survey of the British Isles, starting in Ireland before moving on to Scotland and finally completing England and Wales in 1837, working with Rev. *Humphrey Lloyd* (q.v.) and John Ross. They repeated the survey twenty three years later, from 1858–1861. A meeting with Baron Alexander von Humboldt in Berlin in 1836 led to von Humboldt's urging the British Government to set up magnetic observatories throughout the Empire. Sabine played a major role in recommending the establishment of observatories in both hemispheres (Toronto, St Helena, Cape of Good Hope, and Hobart Tasmania) and in recommending a magnetic survey of the Antarctic regions. The magnetic observatories were run by Lieutenants of the Royal Artillery trained by Lloyd in Dublin, and the magnetic survey was carried out by John Ross's expedition of 1840.

Sabine's campaign for global magnetic surveys is regarded by historians of science as the first scientific endeavor requiring substantial government support, both financial and in kind in the form of navy ships and army logistics. It is known as the Magnetic Crusade and is described in detail by Cawood (1979).

Sabine was almost fanatical in his collection and archiving of observations, which he believed to be the essential foundation of advancement of knowledge. His main scientific legacy is his survey of all magnetic observations made from about 1818 until 1876, when his scientific activity ceased. The compilation is thorough and accurate; it is published in fifteen contributions to the Philosophical Transactions of the Royal Society, a gigantic task. His compilation forms the major part of modern models of the geomagnetic field for the first half of the 19th century (Bloxham, 1986; Bloxham *et al.*, 1989; Jackson *et al.*, 2000); so carefully was it constructed that it could be used virtually unedited in a modern inversion. Sabine's work was certainly not restricted to data compilation: by careful statistical analysis he demonstrated a relationship between sunspots and magnetic storms (Sabine, 1851, 1852), thus heralding the start of a completely new discipline of solar-terrestrial physics.

# SEAMOUNT MAGNETISM

It has been estimated that there are more than a million seamounts in the oceans of the world (Smith and Jordan, 1988). These rise from all depths in the oceans and may reach the ocean surface or even rise above the surface. If they rise above the surface they are called islands. Although many oceanic islands have the same origin as seamounts, they will not be discussed here. Shallow water corals are frequently found on the top of seamounts. Because the seamount is denser than the surrounding seafloor they may sink with time so the coral tops are now deeply underwater.

## Seamount shape and location

Most seamounts are approximately conical in shape, many with a base diameter of 100 km or more and sides with slopes of about 5°. In recent decades, many shipboard surveys and even submarine investigations have been made of seamounts. Many seamounts are isolated features; however, they frequently lie in a chain, with the direction of the chain extending away from a present or past mid-ocean spreading center. Some, however, exist in clusters, do not display a conical shape, and may appear more like a small underwater plateau. Most are believed to have been formed as a rapidly cooled volcanic eruption near the axis of mid-ocean spreading centers. While this would make a linear progression in age along a chain of seamounts, there are some chains that do not have a simple increase in age with distance along the chain. Why seamounts form in some areas and not in others is unknown. When the magma forming the seamount cools it is magnetized in the direction of the Earth's magnetic field at that time. Because it is on a moving plate, both the location of the seamount and the direction of the Earth's magnetic field change with time. Studies of seamount magnetism attempt to learn about each or both of these two variables. Such studies are aided by knowing the age of the seamount from radiometric or other absolute dating means; however, this absolute age is frequently not known.

If one takes the direction of the past geomagnetic field as known, then finding the direction of magnetization of the seamount will give its age. That can be compared to the age of the adjacent seafloor, as determined from magnetic anomalies, and provide information about tectonic plate motions.

## Why to study seamount magnetization?

To a first approximation the two-dimensional magnetic anomaly pattern over a seamount is like that of a magnetic dipole; however, for many seamounts, especially those of an irregular shape, this is a poor approximation. When a reference field, such as the IGRF, is subtracted from the observed magnetic field reading, the anomaly pattern generally shows a high area and a low area. If the anomaly *high* is on the equator side of the seamount, then it is approximately normally magnetized. If the high is on the polar side it is largely reversely magnetized. Model calculations can be made to better determine the strength and direction of magnetization of different parts of the seamount.

Alternatively, the magnetization of a seamount may be studied from the magnetization of rocks recovered by dredging or deep-sea drilling cores. Dredging allows the intensity of magnetization to be determined, but not its direction, since the *in situ* orientation of the dredged rock is unknown. Drilled rocks allow the intensity and inclination (or dip) of magnetization to be determined, but the azimuth is less well known because the azimuth of the core is not accurately determined.

In principle both the magnetic anomaly pattern and the rocks could be studied for the same seamount, but that has rarely been done. Opinion is divided as to which method gives the more accurate information about the direction of magnetization of the seamount. Furthermore, in seamount magnetic studies it is usually assumed that the seamount was formed quickly, i.e., all in the same place and with little change, or secular variation of the geomagnetic field during formation. Studies have not clearly shown that the body of the seamount has different magnetizations in its different parts, except some models that indicate a nonmagnetic cap on the top.

#### Some seamount magnetization studies

In the 1960s, when marine magnetometers came into use, the first magnetic surveys were made over simple, conical seamounts. A review of early geomagnetic studies, especially for Pacific Ocean seamounts, has been given by Grossling (1970). One early study was made of Vema Seamount, which lies in the South Atlantic Ocean about 1000 km west of Cape Town. It was discovered in 1959 that Vema Seamount rises from a depth of 4600 m, coming to within 40 m of the sea surface. This seamount was found to be approximately reversely magnetized. Model studies showed it has a magnetization of about 0.0015 emu, which is characteristic of basalt (Heirtzler and Hadley, 1966). This study had no ages for this seamount.

Several magnetic field studies have been made over the New England seamounts in the North Atlantic. Mayhew (1986) treated the magnetic field over several of these seamounts as due to a dipole. From Bear Seamount, nearer to shore, to Nashville Seamount, further off shore, the radiometric ages vary from 103 to 83 my and are of the same age as the adjacent seafloor as determined by magnetic anomalies and the basal age of sediments. The direction of the equivalent geomagnetic dipole was about what is expected for this Cretaceous normal epoch and showed that this simple means of determining the magnetization direction may be useful.

In the eastern central Pacific Ocean, studies have been made of the northern Cocos Seamounts (McNutt and Batiza, 1981), of the magnetism of the Line Island Seamounts (Sager and Keating, 1984), and a rather different type of study of the Emperor Seamounts (Tarduno *et al.*, 2003). McNutt and Batiza (1981) studied the magnetic survey data from six scattered seamounts, ranging in page from 1 to 7 my in age in the Cocos plate in the eastern Central Pacific. Over this time the magnetization of the seamounts showed a counterclockwise rotation of  $30^{\circ}$  agreeing with models of plate motion. Model studies showed a magnetization of up to  $10 \text{ Am}^{-1}$  is required, with better fits to observations if the upper layer of the seamount is not included in the body shape.

The Line Islands form a 4200 km chain in the central equatorial Pacific, south of the Hawaiian Islands. Several investigators have studied these features. Sager and Keating (1984) have studied eight of these seamounts. Paleomagnetic directions of four, with ages of 72–85 my, agree with other geomagnetic data. Some central seamounts are much younger (Eocene) in age. Model studies show that they have magnetizations of 3-5 Am<sup>-1</sup>.

After the Ocean Drilling Program drilled several seamounts of the Emperor Seamount chain in the northwest Pacific Ocean, Tarduno *et al.* (2003) studied the magnetic properties of recovered rocks with radiometric ages of 81–47 my after reasoning that secular variation of the geomagnetic field did not influence their measurements. Paleolatitude determinations indicated a progressive change and that the seamounts were formed by a rapid motion over the Hawaiian hotspot.

## Model calculations

The calculations of magnetic anomalies due to magnetic bodies of irregular shape have advanced considerably since the 1960s, largely due to the use of digital computers. Special computer codes have been written for seamounts. One of the earlier codes calculated the anomaly due to a thin "pancake" with its individual magnetization and approximated the seamount structure as a stack of pancakes, and summing the anomaly components of the entire stack (Talwani, 1965). In contrast to this forward modeling technique, it is possible to start with the observed anomalies and calculate the approximate magnetization constrained by the shape of the body (Parker, 1991). This can yield information about how magnetization is distributed over the body structure although the solutions are not unique.

# SECULAR VARIATION MODEL

The secular variation of Earth's magnetic field has been studied for almost as long as paleomagnetic measurements have been made. Many models have been proposed to explain the latitudinal variation of the secular variation. It was found simpler to study the scatter of the virtual geomagnetic poles (VGPs) rather than the directions because VGPs usually have a uniform scatter around a mean pole whereas directions can have an elongated distribution for observations made close to the equator. A short history of secular variation models will be presented, where it will be shown that the present day field has been an important factor in determining many model parameters. It will be argued that one of the drawbacks of most models is the practice of ignoring data that give low-latitude VGPs falling within a certain band, centered on the equator, whose width varied from model to model. No rigorous explanation is produced for the specific choice of the width of the band. The model proposed here uses information from VGPs falling in all latitude bands following the Camps and Prévot (1996) model which used VGPs from all latitudes. The model has a central dipole and a number of off-centered dipoles arranged within the core, to represent the nondipole field. The strength of all the dipoles is allowed to vary statistically in a predetermined manner, and the scatter of VGPs is calculated for various observational latitudes. The model fits the data as well as the Camps and Prévot model. It has a larger number of offcentered dipoles close to the geographic poles than to the equator, this being necessary to give the higher scatter of VGPs at high observation latitudes compared to low observation latitudes.

### Introduction

The study of Earth's magnetic field has been materially influenced by the measurements of Earth orbiting satellites, starting by MAGSAT, which was launched in 1979 and measured the field for about 6 months before its orbit decayed. Satellites launched more recently are Ørsted, Champ, and SAC-C. A good source of information about recent geopotential field satellites is given at http://denali.gsfc.nasa. gov/terr\_mag/e\_missions.html. Although these satellites allow a very accurate picture of Earth's magnetic field to be seen, they do not give the full picture of the field because of the long time scale of field changes. For this we have to turn to paleomagnetic methods.

The advantage of paleomagnetic methods is that they cover a much wider range of time than do direct observations. The disadvantage is that the coverage of measurements over Earth's surface is usually quite poor, and so it is difficult to obtain viable spherical harmonic representations of the field. We are, therefore, left with spot readings of the geomagnetic field at certain locations on Earth's surface, from which we need to infer something about the geomagnetic field. The quantity that paleomagnetists have chosen to look at is the scatter of directions or VGPs as a function of observation latitude. It turns out that this is frequently a useful parameter to work with because it does tell us something interesting about the generation of the geomagnetic field.

Edmund Gunter (the inventor of a precursor to the slide rule and also of Gunter's chain, still used in surveying today) was the first

person to notice that the variation or declination of a compass needle from true north changed with time. Gellibrand, who was Gunter's colleague at Gresham's College, published the first paper attempting to describe the secular variation measured using compass needle directions (Gellibrand, 1635).

## A parade of secular variation models

Model A (Irving and Ward, 1964) supposed that the field was due to an axial dipole field plus randomly directed fields at the surface. These surface fields are expected to be spherically symmetric with respect to the axial dipole field, and in the first use of this model the surface perturbing fields were uniform as a function of latitude and constant. This resulted in a total field dispersion (as measured by the angular standard deviation) that decreased with absolute latitude. Irving and Ward (1964) showed that this dispersion was very close to the dispersion obtained when the present day field was rotated around the geographic pole. These results are shown in Figure S2. The data used for demonstration of this model are not those used by Irving and Ward (1964), who gave no list of the data. They come from Creer (1962) who proposed model B and who generated the results from the rotation of the 1945 field around the spin axis of Earth that is shown in Figure S2 too. Model A proposes that the scatter in directions becomes lower by a factor of 2 on going from equator to pole, and as can be seen this is roughly what the 1945 field does and what the paleomagnetic data suggest. This is a direct result of the strength of the dipole field, which increases by a factor of 2 on going from equator to poles, and of the fact that the perturbing field was of constant size.

Model B (Creer et al., 1959) simply uses a dipole wobble to explain the angular scatter. The data studied in this paper were from the Paleozoic Great Whin Sill which has roughly horizontal directions of magnetization. These directions form an elongated pattern but when used to calculate VGPs, give circularly symmetric patterns, thus suggesting that they are caused by dipole wobble with a Fisherian (1953) distribution of dipole directions. This observation has meant that many of the SV models proposed have been based on an analysis of VGP scatter rather than on direction scatter. One other notable thing is that this model gives no latitudinal variation of VGP scatter. Creer et al. (1959) also showed that angular dispersion of field data was lower in the northern hemisphere than in the southern hemisphere.

Creer (1962) used a number of different geomagnetic field models and rotated them around the spin axis to determine angular standard deviation of field directions. He compiled four data sets from 1882 to 1955 and suggested that the hemispheric difference was likely to be temporary. So he combined the northern and southern hemispheres and showed that the angular dispersion of the field was similar for each of the data sets. A curve drawn through the data showed a drop from about 21° at the pole to 10° at a latitude of 60°. This was compared with scatter data from igneous rocks (shown here in Figure S2) and there was considerable agreement.

When going from Fisherian poles to directions or Fisherian directions to poles, there are equations that determine the ratio of scatter (Merrill et al., 1996). Two different equations have been suggested for the transformation of Fisherian VGPs to directions (Creer, 1962; Cox, 1970). The solution to this dilemma is shown in Figure S3. The Monte Carlo distributions were done using 4000 randomly generated VGPs with a precision parameter of 60. The upper of these two curves was calculated using the input precision parameter of 60 and the lower curve was calculated using the calculated VGP precision parameter for the 4000 generated VGPs. It can be seen that the Cox (1970) version of the ratio is closer to the experimental results than is the equation of Creer (1962).

Model C was proposed by Cox (1962). He allowed for both dipole wobble and variations in the nondipole field. He also advocated the use of VGPs rather than directions because dipole wobble is simple to deal with when using VGPs as there is then no latitudinal variation.

Angular standard deviation of direction degrees Paleomagnetic data Model A 20 1945 Field 15 10 Model A 5 0 30 60 Latitude, degrees

Factor (field scatter/VGP scatter) Monte Carlo using input k 3 2 0 0 30 60 90 Latitude

Figure S2 This shows the angular standard deviation of the field as a function of latitude. Model A is from Irving and Ward (1964). The line marked by diamonds is the scatter observed at a specific point when the 1945 field is rotated through 360°. The black dots are results obtained from igneous rocks collected at different latitudes.

Figure S3 This shows the ratio of field scatter to VGP scatter (as calculated by the ratios of the precision parameters) as a function of latitude. The curve marked by triangles uses the equation for Fisherian directions to poles from Cox (1970), for comparison purposes. The two curves marked by diamonds and plusses are from Cox (1970) and Creer (1962). The Monte Carlo curves were calculated as described in the text.

He showed that the VGPs calculated from the field as it rotates around the geomagnetic pole, thus showing the variation of the nondipole field only, has a low angular standard deviation (ASD) at the equator of about  $8^{\circ}$  which rises as the pole is approached, so that close to the pole the ASD is about  $16^{\circ}$ . He also showed that there was a hemispheric difference, the high-latitude reading for the South Pole being  $8^{\circ}$  greater than that close to the North Pole. Cox used an equation proposed by Runcorn (1957) to express the precision parameter of VGP scatter from both dipole and nondipole sources, which is

$$\frac{1}{k_{\rm T}} = \frac{1}{k_{\rm D}} + \frac{1}{k_{\rm N}},\tag{Eq. 1}$$

where k is Fisher's precision parameter for polar scatter, T shows total contributions, N shows nondipole contributions and D shows dipole contributions. The corresponding equation for angular standard deviation is

$$\delta_{\rm T}^2 = \delta_{\rm D}^2 + \delta_{\rm N}^2. \tag{Eq. 2}$$

Cox did not compare his model of the present day VGP dispersion with paleomagnetic data. The results of his calculations are shown in Figure S4. The bottom curve shows the result of adding a dipole field scatter equivalent to half of the poles lying within 11.5° of the geographic pole, giving a  $k_D$  of 34.5. The scatter, therefore, rises from 16° at the equator to 20° at the poles.

Model D was also proposed by Cox (1970). Cox allowed for changes in intensity and direction of the nondipole field, and also changes in the direction and intensity of the dipole field. The nondipole field intensity was described by Rayleigh (1919) function that was calculated to explain the directions of magnetization in small rock samples when there was a random component added to some stable component. It is not clear whether this is a reasonable distribution for the nondipole field portion of Earth's magnetic field. This distribution is given by:

$$p(f) = \left(\frac{4f^2}{\sqrt{\pi}f_R^3}\right) \exp\left(\frac{-f^2}{f_R^2}\right),$$
 (Eq. 3)

**Figure S4** Cox's (1962) model C. Nondipole field scatter shown by the top three curves, and dipole plus nondipole scatter shown on the bottom curve.

where  $f_{\rm R}$  completely specifies the distribution and is the mode. This is not the same as the more usual Rayleigh function that describes things like the distribution of wave heights given by:

$$p(f) = \left(\frac{2f}{f_{\rm R}^2}\right) \exp\left(\frac{-f^2}{f_{\rm R}^2}\right).$$
 (Eq. 4)

This distribution function produces a value for the angular variance of the population of nondipole (f) and dipole (F) fields:

$$\sigma^{2} = \left(\frac{f_{\rm R}(\lambda)}{F_{0}}\right)^{2} \left(\frac{1}{(1-r^{2})^{3/2}}\right) \left(\frac{1}{1+3\sin^{2}\lambda}\right).$$
 (Eq. 5)

Assuming that the VGPs are distributed according to Fisherian distribution and not the field directions, Cox determined that the variance in pole positions should follow the equation below.

$$S^{2} = S_{\rm D}^{2} + \frac{2}{5} \left( \frac{f_{\rm R}(\lambda)}{F_{0}} \right) \left( \frac{1}{(1 - r^{2})^{3/2}} \right) W_{\rm NP}^{2}.$$
 (Eq. 6)

 $S_{\rm D}$  is the contribution from dipole wobble and so has no latitudinal variance. In the variable  $W_{\rm NP}$ , N stands for the nondipole part of the field and P stands for the poles that are Fisherian in distribution.  $W_{\rm NP}$  is given by:

$$W_{\rm NP} = \left(5 \frac{1+3\sin^2 \lambda}{5+3\sin^2 \lambda}\right)^{1/2}.$$
 (Eq. 7)

This function increases by a factor of 1.6 on going from equator to pole. Since the rotated 1945 field produces poles whose scatter rises by a factor of more than 2 on going from equator to pole, it is natural to suppose that the function  $f_R(\lambda)$  must produce a scatter that rises modestly by a factor of 1.3 on going from equator to pole. No attempt was made by Cox to compare his models with paleomagnetic results. Figure S5 shows some of the results from Cox's model recalculated for this paper. The red line marked by diamonds is the "observed" scatter, obtained by rotating the present day field around the geomagnetic pole axis and adding an 11° dipole wobble. The green curve marked by circles is the model result using a dipole wobble of 11° plus a non-dipole field that is constant, i.e., it does not depend on the dipole field. The blue curve marked with plusses uses the same dipole wobble but assumes that the nondipole field is directly related to the dipole field (i.e., it increases by a factor of 2 on going from equator to pole).

Model E was proposed by Baag and Helsley (1974). They wished to explain why the green dotted curve in Figure S5 does not increase enough with latitude to match the red diamond curve. They suggested that the nondipole and dipole fields were correlated by some amount, as expressed by the following:

$$S_{\rm T}^2 = S_{\rm D}^2 + S_{\rm N}^2 + 2\rho_{\rm DN}S_{\rm D}S_{\rm N},$$
 (Eq. 8)

where  $\rho_{DN}$  is variable correlation coefficient between the dipole field and the nondipole field. This means that the following holds:

$$S_{\rm D}^2 + S_{\rm N}^2 \le S_{\rm T}^2 \le (S_{\rm D} + S_{\rm N})^2,$$
 (Eq. 9)

thus allowing us to have lower and upper bounds to the angular standard deviation. Figure S6 shows all five models discussed so far using the angular standard deviation of VGP distribution as the common ordinate, so that comparisons may be made (data from Baag and Helsley, 1974). The data shown by Baag and Helsley (1974) show a general increase of scatter with latitude, with several results falling above most of the curves except  $E_{\rm U}$ .

Many of the models discussed above have not considered the growing number of paleomagnetic results that might contribute to

**Figure S5** Model D (Cox, 1970). Angular standard deviation of VGPs as a function of latitude. The red line marked by rhombi is the present day nondipole field variation to which has been added an 11° dipole wobble. The green line (dots) is model D using a nondipole field that does not vary with latitude. The blue line (plusses) is model D using a nondipole field that varies in intensity in the same way that a dipole field does. This is equivalent to model M.

**Figure S6** VGP angular dispersion as a function of latitude plotted for models A-E. Model A is in red (plusses), model B is in blue (squares), model C is in yellow (rhombus) (same as model  $E_L$ ), model D is in green (circles), and model  $E_U$  is in gray (triangles).

understanding the variation of angular standard deviation as a function of latitude. The paper introducing model M (McElhinny and Merrill, 1975) made the first serious attempt to analyze paleomagnetic data.

Figure S7 Model proposed by Harrison (1980) compared with data compiled by McElhinny and Merrill (1975).

They used information for the past 5 Ma and rejected data whose average VGP was further than 40° away from the poles to remove results showing transitional directions that might be recording a reversal. This is a more extreme position that other workers who have often used directions more than 45° away from the poles to signify transitional behavior. Their data showed that the VGP scatter rose from about  $12^{\circ}$  at the equator to almost  $20^{\circ}$  at high latitudes. Data from the Brunhes epoch showed similar results, with slightly less scatter at high latitudes but with significantly greater uncertainty, rendering the two results indistinguishable. A minor error (Harrison, 1980) rendered model M incorrect in that it predicted a much greater latitudinal variation of VGP scatter than actually existed in the data that they presented. Model M is basically similar to the blue curve (marked by plusses) in Figure S5, in which the latitudinal variation of the nondipole field was equivalent to the latitudinal variation of an axial dipole field. Harrison (1980) suggested a modification to model M in which the nondipole field had two components, one of which increased with latitude like a dipole field and another component that depended on the rate of change of angular momentum in a rising convection cell, a function that is responsible for creating core surface current rings that are probably responsible for the nondipole field. Figure S7 shows an excellent agreement between model and data. With the low latitude cutoff proposed by McElhinny and Merrill (1975) VGP scatter rose from about  $13^{\circ}$  at the equator to  $20^{\circ}$  at high latitudes.

Model F was proposed by McFadden and McElhinny (1984). It assumes that the VGPs are symmetrically distributed about the mean, as was done for some earlier models. This agrees with observation and also is convenient because dipole wobble in this system is latitude-independent. The VGP scatter is usually written as:

$$S^{2} = S_{\rm D}^{2} + S_{\rm N}^{2} W^{2}(\lambda).$$
 (Eq. 10)

They point out that using paleosecular variation data cannot solve for the unknowns in this equation because they cannot separate out dipole from nondipole effects. The authors, therefore, suggest that the model predict a value of  $W(\lambda)$  that is consistent with the latitudinal variation of the present day nondipole field. They then have an extended discussion concerning the distribution of field directions that will result in a Fisherian distribution of VGP positions. Numerical mapping was then used to determine the angular variance in field directions as a function of latitude, which is in radians:

$$\delta_{\rm d}^2(\lambda) = \left(\frac{2}{3}\right) \frac{1+a\,\exp(-b\lambda^2)}{\sqrt{1+3\sin^2\lambda}} \left(\frac{f}{F}\right)^2 \tag{Eq. 11}$$

where f and F are nondipole and dipole field intensities, respectively, and a, b are numerically determined numbers. The top part of the latitudinal term is plotted in Figure S8 (the top three curves, asymptotic to 1). The whole of the latitudinal term is plotted as the bottom three curves asymptotic to 0.5. What these curves mean is that if the ratio of f/F is constant, then the variance in direction will fall by a factor of somewhat greater than 2 on going from the equator to the poles. This latitudinal term was found numerically. McFadden and McElhinny (1984) believed that f/F was in fact constant, i.e., the nondipole field varied with latitude just like the dipole field. Numerical techniques also have to be used to transfer field variance into VGP variance. The result is that the nondipole latitudinal variation of VGP scatter increases by a factor of about 1.93 ( $W(\lambda)$ ) on going from equator to pole. A fit to the 1965 IGRF nondipole field is shown in Figure S9. Figure S10 shows the fit of model F to the paleomagnetic data aged less than 5 Ma, and it can be seen that there are no serious deviations. But it should be stressed that this fit was achieved by the omission of low-latitude VGPs, to allow the nondipole part of model F to fit in general with the 1965 IGRF (Figure S9).

Model G was proposed by McFadden *et al.* (1988), and was described by Merrill *et al.* (1996) as the only phenomenological model of the paleosecular variation. It is based on separation of the field into a dipole family and a quadrupole family. The dipole family consists of the axial dipole plus all spherical harmonics whose degree and order add up to an odd number. The quadrupole family consists of those spherical harmonics whose sum of degree and order is even. They found out that, using the 1965 IGRF, if the field generated by the dipole family is rotated around the spin axis, the resulting scatter of VGPs, as a function of latitude, is zero at the equator and grows linearly with latitude up to  $70^{\circ}$  where it is about  $15^{\circ}$ . When the quadrupole family plus the axial dipole are rotated around the spin axis, the VGP scatter scarcely varies and is about  $13^{\circ}$ . Since the scatters from the

**Figure S8** Top latitude term in (11) is given by upper curves asymptotic to 1, as a function of three equatorial field scatters. Bottom curves asymptotic to 0.5 show total latitudinal term from (11).

quadrupole and dipole families are independent due to the large size of the axial dipole, model G is just the quadrature sum of the dipole and quadrupole families and is given by the following equation:

$$S = \sqrt{\left(A^2\lambda^2 + B^2\right)},\tag{Eq. 12}$$

where  $S(\lambda)$  is the VGP scatter, A is the constant showing rise of dipole scatter with latitude,  $\lambda$ , and B is the constant quadrupole scatter. With  $A = 0.21 \pm 0.01$  and  $B = 13.6 \pm 0.3^{\circ}$  (both showing 95% confidence) the fit to the 1965 IGRF is excellent as is the fit to the VGP scatter obtained from paleomagnetic samples over the past 5 Ma, provided that high latitudes are not considered (Figure S11).

Figure S9 Fit of model F to 1965 IGRF. The nondipole parts of these are shown here.

**Figure S10** Model F fit to the paleomagnetic data aged <5 Ma.

**Figure S11** Model G fit to IGRF65 rotated around geographic axis and to paleomagnetic data <5 Ma old from which low latitude results have been removed.

Unfortunately if other periods of time when the field is well known are looked at, the shape of the scatter produced by the field changes considerably (Harrison, 1995; Hulot and Gallet, 1996). Basically, the latitudinal variation has grown continuously for well over 200 years. In 1770, the scatter rose from  $12^{\circ}$  (equator) to  $13.5^{\circ}$  at high latitudes. In 1840, the change was from  $12.5^{\circ}$  to  $17^{\circ}$ , and in 1990, the change was from  $13^{\circ}$  to  $22^{\circ}$ . So it is just coincidental that the paleomagnetic field and the 1965 field gave similar results in 1965. At other epochs the similarity is not there.

There are, however, aspects of the recent measurements of the Earth's magnetic field that do not change very much over 300 years. The equivalent of the power spectrum in two-dimensional signals is replaced by a different function when measurements are taken over a spherical surface. In this case it has been shown by Mauersberger (1956) and Lowes (1966) that the mean square value of the field over the sphere as a function of degree of harmonic is given by the following function:

$$\mathbf{R}_{n} = (n+1) \sum_{m=0}^{n} \left[ \left( g_{n}^{m} \right)^{2} + \left( h_{n}^{m} \right)^{2} \right].$$
 (Eq. 13)

The degree of harmonic is roughly equivalent to the wavenumber in a linear system. This function is plotted for the IGRF for 5-year intervals in Figure S12. There are some obvious errors in the data, i.e., there are some peculiarities in the higher degrees of harmonic in the middle years of this presentation. But in general the power falls off as a function of degree of harmonic quite uniformly from one representation of the field to the next. Analyses of the field back to 1690 (Harrison, 1994) show similar behavior, with some possible small changes due to the fact that the earlier field models lacked data to define the higher degree harmonics accurately.

## Models based on spherical harmonics

The Giant Gaussian Distribution model of Constable and Parker (1988) attempted to derive a spherical harmonic spectrum for the

**Figure S12** Lowes-Mauersberger function for the IGRF between 1900 (bottom) and 1995 (top). Each graph is displaced by a common multiple (equal to  $10^{5/19}$ ) from its nearest neighbors for clarity. The red and blue straight lines are best fitting lines through degrees 1 to 6 for the 1900 and 1995 fields.

geomagnetic field based on the supposition that the power spectrum (Lowes-Mauersberger function) for degrees 2-12 evaluated at the core-mantle boundary is statistically flat. The Gauss coefficients are chosen from a zero-mean Gaussian distribution with the appropriate standard deviation for each degree. However, no statistical variation as a function of order is allowed. Because of this, this model, despite its elegance, does not produce any variation of VGP scatter as a function of latitude, and since this is one of the main findings of paleomagnetic work on younger lava flows, it fails as a model. Later attempts to modify this model, while giving a more satisfactory latitudinal variation of VGP scatter, make the model much less elegant, one of the attractive features of the original model. For instance, Constable and Johnson (1999) produced a model in which the standard deviation of Gauss coefficients changed as a function of harmonic order, but only for degree 2. Quidelleur and Courtillot (1996) and Kono and Tanaka (1995) have also suggested modifications to the Giant Gaussian Distribution to explain the VGP scatter variation as a function of latitude. We shall see that modifications to the Gauss coefficients are necessary to obtain a reasonable model.

# Another model of the geomagnetic field

One other model that deserves mention is that suggested by Camps and Prévot (1996). They used a field model (i.e., they specified the statistical properties field components at two latitudes). Their dipole field was drawn from that produced by a normal distribution of dipole strength, in which the standard deviation was 45% (high latitude) or 50% (low latitude) of the mean. The nondipole field was modeled by Maxwell Boltzmann probability density function (in which each Cartesian field coordinate is drawn from a zero-mean Gaussian distribution, all with the same standard deviation). In contrast to almost all models already discussed they did not use the present day field to constrain their model, neither did they restrict their data to lava flows that only gave high latitude VGPs (to quote from their paper "... implies that paleosecular variation is physically distinct from the reversing regime. We know of no observation that has confirmed this view."). However, their model did not provide a complete description of the field because they essentially divided up the observations into high latitude and low latitude, and did not try and join the two.

# Source models of the geomagnetic field

Several people have produced source models of the geomagnetic field. Dodson (1980) used a series of dipoles buried within the core to represent the nondipole field of Earth. He used up to 20 dipoles located at the CMB for this purpose and found that he had to concentrate the off-centered dipoles close to the geographic axes to achieve the necessary variance of VGP scatter as a function of observation latitude. Kono (1971) developed a model in which the nondipole field was represented by small dipoles oriented either parallel or antiparallel to the central dipole with uniform moment. One of his models had 80 dipoles whose intensity was equal to the central axial dipole divided by 80. If the central axial dipole has a strength of 30  $\mu$ T (like that of today), then the noncentral dipoles will have a strength of 375 nT.

# A new source model of the geomagnetic field

Model H (after model G of McFadden *et al.*, 1988), is presented here. A complete explanation is found in Harrison (2004, 2006). The model is summarized in Table S1. The model is a variation of the one proposed by Dodson (1980) and consists of dipolar sources placed within the core to simulate the electric currents that cause the geomagnetic field. The central dipole source is assumed to be axial and is allowed to vary about its mean value that is taken to be a simple number close to the axial component today (30  $\mu$ T). Since directions are determined by ratios of Gauss coefficients there is no loss of generality in choosing the central dipole source in this way. No allowance is made for far sided effects. The off-centered dipoles are buried sufficiently deeply within the core so that the correct slope to the Lowes-Mauersberger function is obtained (Figure S12). This is at a depth of 0.4R<sub>e</sub>. If the dipole sources are placed at the CMB (Dodson, 1980) the absolute

 Table S1 Methods of determining model parameter values

slope is far too small. Deep burial well below the CMB achieves the correct observed slope of -0.55. Note that this aspect of the Lowes-Mauersberger function is about constant for the past 300 years, in contrast to the VGP scatter as a function of latitude that varies considerably over this time period. Benton and Alldredge (1987) suggested a depth of  $0.404R_e$ . The present day field variation of VGP scatter as a function of latitude is not used to constrain the model, because it has changed considerably over the past few hundred years. With this constraint gone, there seemed to be no reason to try and separate the field behavior into a "secular variation" mode and a "reversal or excursion" mode, and so VGPs from all latitudes were considered, following Camps and Prévot (1996).

How does the latitudinal variation of VGP scatter come about? This is determined by the fact that analysis of the present day field reveals that there is a variation in strength of Gauss coefficients as a function of order within each degree. This is shown in Figure S13. Figure S13, which shows the relative strength of the squared Gauss coefficients which are normalized so that mean squared values of the reduced coefficients in each degree are equal to 1. This is equivalent to the following:

$$\sum_{m=0}^{n} \left[ \left( G_{n}^{m} \right)^{2} + \left( H_{n}^{m} \right)^{2} \right] = n + 1,$$
 (Eq. 14)

where

$$G_n^m = c_n \cdot g_n^m, \tag{Eq. 15}$$

$$H_n^m = c_n \cdot h_n^m, \tag{Eq. 16}$$

and  $c_n$  is a constant for degree n.

Figure S13 demonstrates that the high-order harmonics within each degree tend to be smaller. The zeroth degree harmonics (m = 0) tend to be the highest of all, while the sectoral harmonics (m = n) are mostly small, especially in 1995.

Figure S14 shows the difference between low-order harmonics and high-order harmonics in all harmonics up to degree 8. The harmonics are normalized in the same way as in Figure S13. The

Item	Parameter	Method of determination

3	Off-centered dipole depth (constant for a specific model)	Chosen to fit the Lowes-Mauersberger function for geomagnetic field over past $300$ years (Figures S12). Depth is at $0.4R_e$
4	Number of off-centered dipoles	Chosen to fit the latitudinal distribution of Icelandic VGPs. For each number of dipoles their intensity, as given by the standard deviation of a zero-mean Gaussian distribution, was varied so as to give the best fit to the Icelandic data. The number of dipoles which gave the best fit was 90, the number used in later calculations
5	Polar concentration of off-centered dipoles	Chosen by comparison with VGP scatter calculated for different latitudinal observations (Figure S10). Random numbers used to choose hemisphere (equal probability), absolute latitude (according to a Fisher distribution). The Fisher precision parameter, $\kappa$ , is 3
6	Longitude of off-centered dipoles	Chosen by random number so that probability of any longitude is uniform
7	Variation of off-centered dipoles	Zero-mean Gaussian distribution with standard deviation fixed by comparison with Icelandic VGP data. See item 4. With 90 dipoles, the standard deviation is 1040 nT To fit more restrictive data sets the standard deviation has to be reduced to 740 nT (see Figure S10)

**Figure S13** Squared values of reduced harmonics are plotted against relative order (*m*/*n*). Harmonics are reduced so that in each degree, the average squared harmonic is 1. Left, field for 1900 with harmonics in the same degree connected by lines; Right, field for 1995. Each degree is plotted using a different color and symbol.

**Figure S14** Low-order harmonics and high-order from degrees 2 to 8, and normalized so that in each degree the harmonics average unity, plotted against epoch. Standard errors are shown.

low-order harmonics ( $m \le n/2$ ) were averaged and the high-order harmonics (m > n/2) were separately averaged and plotted as a function of time. It can be seen that the average of the low-order harmonics is consistently more than twice as large as the average of the high-order harmonics. During the last few decades the low-order harmonics are on an average greater than three times as large as the high-order harmonics. This effect is seen in models of the field going back more than 300 years (Harrison, 1994), if the analysis is restricted to degrees lower than 6. This will include almost all of the information necessary for paleomagnetic observations of direction, since harmonics higher than five make almost no difference to directional observations. This indicates that the difference between high and low harmonics is a more permanent aspect of the geomagnetic field than the difference between northern and southern VGP scatters.

The characteristic of the low-order harmonics being in general greater than the high-order harmonics is closely connected with the necessity of having greater scatter in VGPs observed at high latitudes compared with the scatter at low latitudes. The gradual increase in the difference between low-order and high-order harmonics is mirrored by the gradual increase on the difference in VGP scatter from low-latitude observations to high-latitude observations. By having low orders stronger than high orders, low-latitude observation points have in general smaller nondipole fields than do high-latitude observation points. This is because in the expression for spherical harmonics of order *m* there is a term in  $\sin^m \theta$ , which is concentrated more and more at the equator as *m* is increased. This is illustrated in Figure S15 with one example, which shows all of the degree 6 associated Legendre polynomials as a function of colatitude,  $\theta$ .

**Figure S15** Associated Legendre polynomials for degree 6. As the order is increased the harmonics take on very low values for latitudes close to the poles.

In order to achieve the higher scatter of VGPs at high latitudes, it was found that the nondipole sources (radial or vertical dipoles placed at a depth of  $0.4R_e$ ) had to be concentrated towards the poles and this was done by distributing them according to Fisher (1953) distribution. This distribution was used by Dodson (1980) in his model. The Fisher distribution is given by the following equation:

$$P_{\theta} d\theta = \frac{\kappa}{2 \sinh \kappa} e^{\kappa \cos \theta} \sin \theta d\theta.$$
 (Eq. 17)

 $P_{\theta}d\theta$  is the probability of finding a dipole within an angular distance between  $\theta$  and  $\theta + d\theta$  from the mean (in this case the poles).  $\kappa$  is the Fisher precision parameter and is equivalent to 1/variance in a normal distribution. Large values of  $\kappa$  give tight groupings. A double-sided distribution is used. The best value of  $\kappa$  was found to be 3. This is smaller than the value used by Dodson (1980) and smaller than the value suggested by the scatter in the present day field. But it does give a factor of 10 difference between frequency of sources at the equator and sources at the poles if the double-sided distribution is used where both hemispheres of the distribution are added together. In other words, the value of (e<sup>3</sup> + e<sup>-3</sup>)/2e<sup>0</sup> is about 10.

Table S2 Agreement with observations

Each separate representation of the field is determined in the following way. Ninety off-centered dipoles are placed at a radius of 0.4Re. Each longitude is random and determined using a random number generator. The hemisphere of each dipole is randomly determined by another random number such that each hemisphere has an equal chance of being chosen. The strength of each dipole is taken from a zero-mean Gaussian distribution using another random number. The latitude of each dipole is chosen from a distribution given above, using another random number. The central dipole is chosen from a Gaussian distribution whose mean is 30  $\mu$ T and whose standard deviation is relatively small (less than 10% of average). All of these values are chosen to fit specific distributions of VGPs from lava flow data from Iceland. Because of my belief in Camps and Prévot's statement that there is no rational way of choosing the boundary between "normal" field directions and "abnormal" field directions or VGPs, I used VGPs of all latitudes. Once a model has been completely specified the field so produced is rotated around the spin axis to generate a field variation at any specified observation latitude, from which a VGP scatter is obtained, as well as other parameters such as field strength, etc. The whole process is repeated sufficiently often to enable statistical characteristics to be obtained. The model calculations are then compared with observations.

Basic characteristics are obtained by comparison with the frequency plot of VGP latitudes observed in Icelandic lavas. This enabled us to fix the central dipole standard deviation to be small compared with its mean, and the number and standard deviation of the off-centered dipoles (90 dipoles and an SD of 1040 nT). Depth of off-centered dipoles is governed by the desirability of producing the correct slope to the Lowes-Mauersberger function plotted against degree of harmonic. Polar concentration of off-centered dipoles is chosen to give the best fit to the VGP scatter as a function of observation latitude determined from paleomagnetic information.

This model agrees with other data, as shown in Table S2. This model then, predicts several aspects of the Earth's magnetic field as well as or better than any other model. But are there other things that the model predicts which will make it stand out from its competitors? It turns out that there is one further property in which the model agrees with Icelandic data. Figure S16 shows how the magnetization intensity varies as a function of VGP latitude. If magnetizations are separated into those that come from VGPs lying within the longitudinal quadrant centered on Iceland, the reduction in intensity as the VGP latitude is decreased is smaller than for those results whose VGPs lie within the other three quadrants (Harrison, 2004). An alternative more sophisticated model is to measure the fraction of variance of magnetization that is explained by the distance of the VGP from the pole. This is 0.178 for the observed data and 0.355 for 2000 model data. Then further calculations are done where the distance from a point between the geographic pole and Iceland is used instead of colatitude. As this point is moved from the geographic pole toward Iceland, the fraction of variance explained increases and then decreases. Results are shown in Figure S17. The fact that the model data show a higher degree of variance, explained by distance from pole or other location close to the pole, is because in contrast to the Icelandic data, there are no spurious effects causing magnetization to vary in the model data compared to the Icelandic data. This experiment is another prediction from the model that is mirrored in the observations from Icelandic lava flows.

Observation	Reference
Symmetrical distribution of directions at high latitudes	Camps and Prévot (1996)
Assymetric distribution of directions at low latitudes	Tanaka (1999)
Symmetric distribution of VGPs at high latitudes	Camps and Prévot (1996)
Symmetric distribution of VGPs at low latitudes	Tanaka (1999)
Agreement with paleofield intensity in Iceland as a function of VGP latitude	Harrison (2004)
Agreement with paleofield intensity distribution from Iceland	Harrison (2004)

## Implications

 $e^{\kappa} + e^{-\kappa}$ 

Model H predicts that the nondipole field should have stronger sources at high latitudes. The ratio of source strength at the poles to the source strength at the equator is given by:

**Figure S16** Relative intensity of Icelandic lava flow magnetization plotted against VGP latitude and compared with results generated by model. Both ordinates are logarithmic.

where  $\kappa = 3$  is the value of Fisher's precision parameter necessary to give the correct polar concentration of nondipole sources. This is a "double" Fisher distribution, with the distribution from the back half of the sphere added to the front half, to mimic what is done to VGPs, which are represented by their antipoles if they fall in the southern hemisphere. This expression is equal to 10. Modelers who have studied the generation of Earth's magnetic field have frequently remarked on the importance of the tangent cylinder to the inner core. This tangent cylinder (whose axis is parallel to the rotation axis) impinges on the surface of the outer core at a latitude of 70°. Busse (1975) emphasized the importance of convective rolls running parallel to the spin axis and tangent to the inner core in his discussion of Earth dynamos. Gubbins and Bloxham (1987) pointed out that patches of high flux were located close to the tangent cylinder. Others have shown that there is more activity within the tangent cylinder. Kuang and Bloxham (1997) showed that there was more differential circulation within the tangent cylinder than elsewhere, and Glatzmaier and Roberts (1995) showed that there were strong toroidal fields and differential rotation within the tangent cylinder, suggesting that these might be strong sources for the nondipole field preferentially happening at high latitudes.

The radial dipoles placed within the outer core used in this model represent the sources of the nondipole field. They are deeply buried within the outer core because the slope of the Lowes-Mauersberger function requires this. These dipoles may represent core-surface sources that are spread out over a finite area. For instance, core surface current loops of finite radius will produce Lowes-Mauersberger functions that slope at about the right amount if they have a radius of about 1600 km (Harrison, 1994). A loop of this radius also gives a low power for degree 8, as is observed in the present day field (Figure S12). The off-centered radial dipoles could on the other hand represent sources deep within the core, unless conductivity considerations prevent sources at this depth from influencing the relatively rapidly changing core surface nondipole field. Further details of this model are to be found in Harrison (2006).

Christopher G.A. Harrison

**Figure S17** Fractional variance of logarithmic intensity explained by distance from a point lying between the North Pole and Iceland. The left-hand graph shows results from 2000 model calculations. The maximum is observed at a displacement of 7.4°. The right-hand graph shows magnetization results from Icelandic lavas. The maximum is observed at a displacement of 5.6°. Parabolas in blue are used to determine maximum values.

# SEDI

SEDI is an international scientific organization dedicated to the study of the Earth's deep interior. The ultimate goal of SEDI is an enhanced understanding of the past evolution and current thermal, dynamical, and chemical state of the Earth's deep interior, and of the effect that the interior has on the structures and processes observed at the surface of the Earth. The "deep interior" is generally considered to be the core and lower mantle, but interest may extend to the surface, for example, in the study of mantle plumes or dynamics of descending lithospheric slabs. The scientific questions and problems of interest to SEDI include the geomagnetic dynamo and secular variation, paleomagnetism and the evolution of Earth's magnetic field, composition, structure and dynamics of the outer core, dynamo energetics, structure of the inner core, core cooling and the core-mantle boundary region, core-mantle boundary shape, coupling and the rotation of the Earth, lower mantle: structure, convection and plumes, nature and location of deep geochemical reservoirs, etc.

Since its inception in 1987, SEDI has been a Union Committee of the International Union of Geodesy and Geophysics (IUGG). It provides a bridge across the traditional discipline-oriented bounds of the associations of the IUGG (particularly the International Associations of Geodesy, Geomagnetism and Aeronomy, Seismology and Physics of the Earth's Interior, and Volcanology and Chemistry of the Earth's Interior), which normally study the Earth from a particular point of view. The intent of SEDI is to amalgamate all sources of data and all points of view to generate the most coherent and consistent picture of the workings of the Earth's deep interior.

SEDI is guided by an Executive Committee, headed by a Chairman, a Vice Chairman, and a Secretary General. The officers and committee members are chosen at open business meetings held at the quadrennial IUGG General Assemblies. The term of these three offices is 4 years, with the current term running from September 1, 2003 to August 31, 2007. The officers for the present term are Chairman: Bruce Buffett (University of Chicago), Vice Chairman: Gauthier Hulot (Institut de Physique du Globe, France), and Secretary General: Michael Bergman (Simon's Rock College of Bard, Great Barrington, MA). In contrast to the associations of IUGG, which are formally structured and which have national membership dues, membership in SEDI is open to all individuals and there are no membership dues. The member list is essentially an e-mail list maintained by the secretary. To apply for membership, inform the current Secretary General of your desire.

SEDI serves the interests of science in three ways (1) serving as an information conduit for scientific activity related to the deep interior of the Earth, (2) organizing scientific symposia and sessions, and (3) providing an organizational framework for scientific projects. Symposia, which are held every two years, include:

1988: Structure and Dynamics of the Core and Adjacent Mantle; Blanes, Spain

1990: Reversals, Secular Variation and Dynamo Theory; Santa Fe, NM 1992: The Core-Mantle Boundary Region: Structure and Dynamics; Mizusawa, Japan

1994: The Earth's Deep Interior; Whistler Mountain, BC, Canada 1996: Untitled; Brisbane, Australia

1998: Voyage to the Center of the Earth; Tours, France

2000: SEDI 2000; Exeter, UK

2002: Geophysical and Geochemical Evolution of the Deep Earth; Tahoe City, CA

2004: SEDI 2004; Garmisch-Partenkirchen, Germany

2006: 10th Symposium of SEDI, Prague, Czech Republic

The Doornbos Memorial Prize, in memory and honor of the Dutch seismologist Durk Doornbos, is presented to several young scientists at the biennial symposia in recognition of their outstanding work on the Earth's deep interior. Past winners are:

1994: R.E. Cohen, R. Hollerbach, J. Tromp
1996: R. van der Hilst, X. Song, S. Widiyantoro
1988: D. Andrault, A. Tilgner, L. Volcado
2000: M. Bergman, E. Dormy, I. Sumita
2002: D. Alfie, R. Holme, S. Labrosse
2004: A. Deuss, C. Farentani
2006: J. Aubert, K. Koper, J. Mound

The activities of SEDI for its first 12 years of existence are documented in a set of annual newsletters (the SEDI Dialogs), edited by David Loper, found at www.sedigroup.org.

# SEISMIC PHASES

The body wave portion of a seismogram is marked by the arrival of distinct bursts of energy which we associate with different classes of propagation path through the Earth, as illustrated in Figure S18, where the arrivals are marked with their phase code. The individual seismic

arrivals sample different parts of the Earth in their passage between the source and the receiver and their properties are dictated by the structure they encounter. Thus the time of arrival of PcP which is reflected from the core-mantle boundary is a strong function of the radius of the core. Information from many different phases, with sensitivity to structure in different parts of the Earth, is used in the construction of models of seismic wavespeed.

The phase code describing each propagation path is built up by combining the different elements of the path though the major zones in the structure of the Earth (see *Earth structure, major divisions*):

- 1. A leg in the mantle is denoted by P or S depending on wave type.
- 2. A compressional leg in the outer core is labeled as K.
- 3. A compressional leg in the inner core is indicated with *I*, the corresponding shear wave leg would be denoted *J*.
- 4. Waves leaving upward from the source are indicated by lowercase letters so that *pP* represents a surface reflection for *P* near the source and *sP* a reflection with conversion above the source.
- 5. Reflected waves from major interfaces are indicated by lowercase letters: m for the Mohorovičić discontinuity (Moho), c at the core-mantle boundary and i at the boundary between the inner and outer cores.

A *P* wave which returns to the surface after propagation through the mantle and is then reflected at the surface to produce a further mantle leg will be represented by *PP. PKIKP* is a *P* wave which has traveled through the mantle and both the inner and outer cores, whilst *PKiKP* is reflected back from the surface of the inner core. Similarly an *S* wave reflected at the core-mantle boundary is indicated by *ScS*, and if conversion occurs in reflection we have *ScP*.

PKJKP (q.v.) would correspond to a wave that traversed the inner core as a shear wave, a number of claims have been made for the observation of this phase but none have been confirmed. However, a very careful analysis by Duess *et al.* (2000) indicates that the arrival *SKJKP* has been detected using recordings from many stations for a deep in the Flores sea, Indonesia.

The "depth phases" (pP, sP and pS, sS) can be very distinct for deep events, and their separation in time from the main phases P, S provides a useful measure of depth.

An understanding of the way in which seismic energy travels through the Earth to emerge at the surface can be gained by looking at the nature of the ray paths and wavefronts associated with different classes of arrivals. Figures S19-S22 show the behavior for major P and S phases for a surface source in the model AK 135 of Kennett *et al.* (1995). P wave legs are shown in black and S wave legs are indicated by using grey tone. The time progression of the waves through the Earth are shown by marking the wavefronts with ticks on the ray paths at one minute intervals; the spreading and concentration of the ray paths provides a simple visual indication of the local amplitude associated with each phase.

An extended treatment of the nature of seismic wave propagation within the Earth with illustrations of the seismograms for the major phases can be found in Kennett (2002). Shearer (1999) shows stacks of seismograms recorded around the globe that reveal the complexity of the range of propagation paths through the Earth.

The direct *P* waves refracted back from the velocity gradients in the mantle extend to about  $100^{\circ}$  away from the source but then reach the core-mantle boundary at grazing incidence. *P* waves with steeper take-off angles at the source are either reflected from the core-mantle boundary (*PcP*) or refracted into the core (*PKP*). The refracted *PKP* waves have a relatively complex pattern of propagation in the core. The absence of shear strength in the fluid outer core means that the *P* wavespeed at the top of the core is markedly less than at the base of the mantle. From Snell's law *P* waves entering the core therefore have a much steeper inclination than in the wavespeed gradients in the outer core produce a pronounced *PKP* caustic with a concentration

**Figure S18** Three-component seismogram from an intermediate depth earthquake in Vanuatu recorded in Kazakhstan at approximately 100° from the source, showing a rich set of seismic phase arrivals.

Figure S19 Ray paths for major P phases. Wavefronts are indicated by ticks on the ray paths at 1 min intervals.

of arrivals near  $145^{\circ}$  from the source. The apparent "shadow zone" with no *P* arrivals from  $100^{\circ}$  to  $145^{\circ}$  led to the discovery of the core by Oldham at the end of the 19th century. Reflection from the boundary between the inner and outer cores (*PKiKP*) and refraction through outermost part of the inner core (*PKiKP*) produce small amplitude arrivals which help to fill in the gap between direct *P* out to  $100^{\circ}$  and the *PKP* caustic. The identification of these arrivals lead to the discovery of the inner core by Inge Lehmann. Note that the presence of the *PKP* caustic means that there are no turning points for *P* waves in the upper part of the core.

For *S* waves (Figure S20) the pattern of propagation in the mantle is similar to that for *P*. However, since the *P* wavespeed in the outer core is slightly higher than the *S* wavespeed at the base of the core, it is possible for an *SKS* wave to travel faster in the core and overtake the direct *S* wave traveling just in the mantle. For distances beyond 82°, the *SKS* phases arrives before *S*. Unlike the *PKP* waves, the *SKS* family of waves (including underside reflections at the core-mantle boundary as in *SKKS*) sample the whole of the core.

The *P* reflections from the major internal boundaries of the Earth can often be seen as distinct phases. In Figure S21 we show the ray paths for *PcP* reflected from the core-mantle boundary and *PKiKP* 

reflected from the inner-core boundary. The reflections can sometimes be seen relatively close to the source but their time trajectories cut across a number of other phases and so they can often be obscured by other energy. The *P* wave refracted in the mantle and the *PcP* wave reflected from the core-mantle boundary have very similar ray paths for near grazing incidence, and so their travel time curves converge close to 90° epicentral distance.

The strong contrast in physical properties at the core-mantle boundary has the effect of inducing conversion between *S* and *P* waves. An incident *S* wave at the core-mantle boundary can give rise to the converted reflection *ScP* which can be quite prominent out to  $60^{\circ}$ from the source. In addition conversion on transmission into the core generates *SKP* as illustrated in Figure S22.

The Earth's surface and the underside of the core-mantle boundary can give rise to multiply reflected phases (Figure S23) with very clear internal caustics. The surface multiples can be tracked for P and S to great distances and can often be recognized as distinct phases for the third or higher multiples (*PPP*, SSS, etc.). The internal core reflections also carry energy to substantial distance, and retain the character of the original wave system. Thus *PKKP* only has strong sensitivity to P wave structure in the upper part of the core near the bounce point at

Figure S20 Ray paths for major S phases for the AK 135 model of seismic wavespeeds.

Figure S21 Ray paths for the reflected phases *PcP* and *PKiKP*.

the core-mantle boundary, whereas *SKKS* samples the *P* wavespeed distribution through the whole core. The higher order multiples *SKKKS*, etc. provide the closest probing of the structure in the outermost parts of the core.

Multiply reflected waves from the core-mantle boundary are of particular significance for horizontally polarized shear waves (*SH*), since the solid-fluid interface is close to a perfect reflector. With efficient reflection at the Earth's surface, a long train of multiple  $(ScS)_H$  can be established that carry with them information on the internal structure of the Earth, in terms of the influence of internal discontinuities.

#### Branches of core phases

The propagation of P waves into the Earth's core in the PKP wave group includes refraction back from the velocity gradients in the outer core and reflection (PKiKP) and refraction (PKIKP) from the inner core. The components of the wave group are also commonly designated by a notation based on the different branches of the travel-time curve (Figure S24).

The patterns of the travel times and the associated ray paths can be followed in Figure S24, where the critical slowness points corresponding to the transition between branches are clearly labeled. The details of the positions of these critical slownesses vary slightly between different models for the Earth's core, but the general pattern is maintained.

The  $PKP_{AB}$  branch corresponds to the waves entering the core at the shallowest angles and  $PKP_{BC}$  to waves refracted back from the lower part of the outer core. The CD branch corresponds to wide-angle reflection from the inner boundary (the extension of the *PKiKP* phase). The *PKP*<sub>DF</sub> phases, which is equivalent to *PKIKP* is refracted through the inner core. Rays penetrating into the upper part are strongly bent and emerge near 110° at the D point, steeper entry leads to more direct propagation through the inner core with the F point at 180° corresponding to transmission without deflection.

The concentration of rays near the *PKP* caustic at B is reflected in localized large amplitude arrivals for *PKP* near  $145^{\circ}$ . The observations

Figure S22 Ray paths for the converted phases ScP and SKiKP.

Figure S23 Ray paths for multiply reflected phases (a) PP, PKKP, (b) SS, SKKS.

of the BC branch tend to extend beyond the ray theoretical predictions. For epicentral distances beyond the C point, there is the possibility of diffraction around the inner core. At the B caustic the real branch does not just stop and there will be frequency dependent decay into the shadow side of the caustic. In addition scattering in the mantle from *PKP* produces short-period arrivals as precursors to *PKIKP* that can be seen because they arrive in a quiet portion of the seismic record. The envelope of possible precursors is indicated in Figure S24.

The pattern of branches for the *SKS* phase is somewhat different because the P wavespeed at the top of the core is higher than the S at the base of the mantle.

The AC branch extends from S incident on the core-mantle boundary that can just propagate as P at the top of the outer core and emerge at  $A - 63^{\circ}$ , through to grazing incidence at the inner core boundary at C. Diffracted waves around the inner core can extend the branch beyond the formal C point. The DF branch (*SKIKS*) again corresponds to refracted waves in the inner core. The postcritical reflections from the inner core boundary (*SKiKS*) form the CD branch and connect directly into the precritical reflection at shorter distances than the D point at 104° (Figure S25).

When the refraction just begins at A, the *S* wave path to the same epicentral distance is shorter and *SKS* is about 75 s behind *S*. However, as the proportion of faster *P* wave path in the core increases, the discrepancies in *S* and *SKS* travel time are reduced. Eventually, the travel time of *SKS* becomes less than that for *S* at the same epicentral distance. Beyond  $83^{\circ}$  *SKS* becomes the onset of the shear wave group

**Figure S24** Rays and travel times for *PKP* for the AK135 model, wavefronts are indicated by tick marks at 60 s intervals. The critical points for the various *PKP* branches are indicated on both the travel time curve and the ray pattern. The dashed segment indicates the locus of precursors to *PKIKP* from scattering at the core-mantle boundary.

**Figure S25** Rays and travel times for *SKS* for the AK 135 model. *S* legs are plotted in grey and wavefronts are indicated by tick marks at 60 s intervals. The critical points for the various *SKS* branches are indicated on both the travel time curves and the ray pattern.

and vertically polarized *S*, *Sdiff* have to be sought in the *SKS* coda. The transversely polarized *S* wave is very distinct and small precursory *SKS* contributions (as in Figure S18) can arise from either anisotropy of heterogeneity in passage through the mantle.

# SEISMO-ELECTROMAGNETIC EFFECTS

Seismo-electromagnetic effects refer to electromagnetic (EM) signals generated by fault failure processes in the Earth's crust. These may occur slowly (when associated with plate tectonic loading, slow earthquakes, postseismic slip, etc.) or rapidly preceding, during and following earthquakes. Several different physical processes related to crustal failure can contribute to the generation of seismo-electromagnetic (SEM) effects. Unambiguous observations of SEM effects provide new independent information about the physics of fault failure. Causal relations between co-seismic magnetic field changes and earthquake stress drops have been clearly documented. However, despite several decades of high quality monitoring, clear demonstration of the existence of precursory EM signals has not been achieved.

## **Brief history**

Suggestions that electromagnetic field disturbances are a consequence of crustal failure processes have been made throughout recorded history. Unfortunately, much of the earliest work was recognized as spurious by Reid (1914) who showed that transients recorded by magnetographs located close to earthquake epicenters resulted from earthquake shaking, not earthquake source processes. This invalidated earlier reports from magnetic variometers (suspended magnets) and other instruments sensitive to ground displacement, acceleration, and rotation common in epicentral regions during the propagation of seismic waves. Other early problems resulted from inadequate rejection of ionospheric, magnetospheric, and man-made noise (Rikitake *et al.*, 1966).

Since the mid-1960s, these problems have been avoided through the use of absolute magnetometers installed in regions of low magnetic field gradient to reduce sensitivity to earthquake shaking and by the application of new noise reduction techniques. As a consequence, unambiguous observations of EM variations related to earthquakes and tectonic stress/strain loading, have now been obtained near active faults in many countries (Japan, China, Russia, USA, and other locations). However, careful work still needs to be done to convincingly demonstrate causality between "precursory" EM signals and earthquakes and consistency with other geophysical data reflecting the state of stress, strain, material properties, fluid content, and approach to failure of the Earth's crust in seismically active regions.

## Physical mechanisms involved

The loading and rupture of water-saturated crustal rocks during earthquakes, together with fluid/gas movement, stress redistribution, change in material properties, has long been expected to generate associated magnetic and electric field perturbations. The primary mechanisms for generation of electric and magnetic fields with crustal deformation and earthquake related fault failure include piezomagnetism, stress/ conductivity, electrokinetic effects, charge generation processes, charge dispersion, magnetohydrodynamic effects, and thermal remagnetization and demagnetization effects. Physical limitations, constraints, and frequency limitations placed on these processes are discussed in Johnston (2002).

#### **Basic measurement limitations**

The precision of local magnetic and electric field measurements on active faults varies as a function of frequency, spatial scale, instrument type, and site location. Most measurement systems on the Earth's surface are limited more by noise generated by ionosphere, magnetosphere, and cultural noise than by instrumental noise. Thus, systems for quantifying these noise sources are of crucial importance if changes in electromagnetic fields are to be uniquely identified. For spatial scales of a few kilometers to a few tens of kilometers comparable to moderate magnitude earthquake sources, geomagnetic, and electric noise power decreases with frequency as  $1/f^2$ , similar to the "red" spectrum behavior of most geophysical parameters. Against this background noise, transient magnetic fields can be measured to several nanotesla over months, to 1 nT over days, to 0.1 nT over minutes, and 0.01 nT over seconds. Long term changes and field offsets can be determined if their amplitudes exceed about a nanotesla. Comparable electric field noise limits are 10 mV km<sup>-1</sup> over months, several mV km<sup>-1</sup> over days, 1 mV km<sup>-1</sup> over minutes and 0.1 mV km<sup>-1</sup> over seconds. EM noise increases approximately linearly with site separation. Cultural noise further complicates measurement capability because of its inherent unpredictability. This largely precludes measurements in urban areas. At lower frequencies (microhertz to hertz) for both electric and magnetic field measurements, the most common technique involves the use of reference sites with synchronized data sampling in arrays using site spacing comparable to the expected source sizes of a few tens of kilometers. Adaptive filtering, use of multiple variable-length sensors in the same and nearby locations further reduce noise by about a factor of 3.

These same techniques can be applied to electromagnetic field measurements at higher frequencies (100 Hz to MHz) but much less is known about the scale and temporal variation of noise. These frequencies may be less important since basic physics precludes simple propagation of high-frequency EM signals from seismogenic depths (5–100 km) on active faults in the Earth's crust where the electrical conductivity is more than 0.1 S m<sup>-1</sup>.

## **Recent results: general constraints**

If reliable magnetic and electric field observations are indeed source related, clear signals should occur at the time of large local earthquakes because the primary energy release occurs at this time. These signals should scale with the earthquake moment (size) and source geometry. In fact, co-event observations provide a determination of stress sensitivity since the stress redistribution and the source geometry of earthquakes are well determined. With this "calibration," SEM effects can be quantified and spurious signals identified. Observations without consistent and physically sensible co-seismic effects are generally considered suspect.

High-resolution strain data at the epicenters of moderate to large earthquakes show that precursive moment release during the months to minutes before rupture is less than 0.1% of that occurring coseismically (Johnston and Linde, 2002). This strongly limits the scale of precursive failure and the expected "size" of precursive effects.

### Examples of seismomagnetic effects

The primary features of seismomagnetic effects are shown in Figure S26 from Mueller and Johnston (1998). It is apparent that maximum signals are not more than a nanotesla or so and these signals occur only for larger earthquakes (M > 6) for which corresponding strain changes are about a microstrain or so. An example of a magnetic record observed at the epicenter of the 1986 M5.9 North Palm Springs earthquake and 17 km from the 1992 M7.4 Landers earthquake is shown in Figure S27. For this, and some 40 other earthquakes with magnitude between 5.5 and 7.4, no significant precursory magnetic signals were observed.

# Seismoelectric effects

Seismoelectric observations that show expected scaling with both earthquake moment release and inverse distance cubed are difficult to make because of the sensitivity of electrode contact potential to earthquake shaking. Measurements of electrical resistivity to better than 1% have been made since 1988 in a well designed experiment installed near Parkfield, California (Park, 1997). An expected M6 earthquake together with several M5 earthquakes have occurred beneath this array since 1990. None of these earthquakes generated any observable changes in resistivity above the measurement resolution (Park, 1997; Langbein *et al.*, 2005).

Indirect observations of possible SE signals might be obtained using the magnetotelluric (MT) technique to monitor apparent resistivity in seismically active regions. Even with the best designed systems using remote referencing systems to reduce noise and obtain stable impedance tensors, it is difficult to reduce errors below 5% for good soundings and 10–40% for poor soundings.

**Figure S26** Co-seismic magnetic field offsets as a function of seismic moment scaled by hypocentral distance. The shaded region shows the 2-sigma measurement resolution (from Mueller and Johnston, 1998). Geodetically based seismomagnetic models (Sasai, 1991) fit each offset.

# Possible high-frequency precursory effects

A number of observations purported to be high-frequency SEM effects have been recently reported (Hayakawa, 1999). Interest in these higher ULF frequencies primarily resulted from the fortuitous observation of elevated ULF noise power on a single 3-component magnetometer near the epicenter of the M7.1 Loma Prieta earthquake of October 18, 1989. However, similar records were not obtained with the 1992 M7.4 Landers earthquake, the 1994 M6.7 Northridge earthquake, the 1999 M7.1 Hector Mine earthquake, the 1999 M7.4 Izhmet, Turkey earthquake and the 2004 M6 Parkfield, Ca, earthquake.

Though controversial, increased interest in tectonoelectric (TE) phenomena related to earthquakes has resulted from suggestions in Greece and Japan that short-term geoelectric field transients (SES) of particular form and character precede earthquakes with M > 5 at distances up to several hundreds of kilometers. These transients appear to have a spatially uniform source field on the scale of the array but no clear corresponding magnetic field transients and no sensible coseismic effects. The SES have been empirically associated with subsequent distant earthquakes and claimed as precursors (Varotsos *et al.*, 1996).

Careful study of the SES recordings indicates that the SES signals have the form expected from rectification/saturation effects of local radio transmissions from high-power transmitters on nearby military bases. Without any clear physical explanations describing how the SES signals are earthquake generated yet coseismic effects related to the much larger earthquake source are not observed, these observations have been extremely controversial (Debate on VAN, 1996).

Another enigma concerns the generation of high-frequency (>1 kHz) electromagnetic emissions associated with subsequent moderate earthquakes but, again, with no coseismic effects. Such emissions are reported to have been detected at great distances from these earthquakes (see summary by Hayakawa and Fujinawa, 1994) and by magnetometers onboard satellites. However, the statistical significance of these observations is under dispute.

The generation of high-frequency electromagnetic radiation can be easily demonstrated in controlled laboratory experiments involving

Figure S27 Magnetic field differences between stations OCHM and LSBM before, during and after the July, 1986 M5.9 North Palm Springs and the June, 1992 M7.4 Landers earthquakes (from Johnston *et al.*, 1994).

rock fracture in dry rocks. However, the Earth's crust in seismically active areas is quite conducting (0.3–0.001 S m<sup>-1</sup>) and propagation of very high-frequency (VHF) electromagnetic waves even short distances through the crust is difficult to justify physically. Propagation from earthquake source regions (10–100 km in depth), and in some cases through oceans with conductivities of 1 S m<sup>-1</sup>, is physically implausible. More significantly, the amount of allowable rock fracturing prior to earthquakes is strongly constrained by high sensitivity crustal strain measurements in the near-field of many earthquakes. These measurements indicate moment release ( $\mu \times slip \times area$ ) prior to earthquake is at least three orders of magnitude smaller than that released at the time of an earthquake (Johnston and Linde, 2002). Appeal to secondary sources at the Earth's surface may avoid this difficulty but the expected associated near-field crustal strain and displacement fields are not observed.

High-frequency disturbances are generated in the ionosphere as a result of coupled infrasonic waves generated by earthquakes and are readily detected with routine ionospheric monitoring techniques and global position system (GPS) measurements. In essence, displacement of the Earth's surface by an earthquake acts like a huge piston, generating propagating pressure waves in the atmosphere/ionosphere waveguide. Thus, traveling waves in the ionosphere (traveling ionospheric disturbances or TIDs) are a consequence of earthquakes (and volcanic eruptions). EM data at VHF frequencies recorded on ground receivers or by satellite require correction for TID and other disturbances before any association can be made to source processes or earthquake precursors.

# SHAW AND MICROWAVE METHODS, ABSOLUTE PALEOINTENSITY DETERMINATION

The Shaw technique is used to determine the strength of the Earth's magnetic field from igneous rocks and man fired artifacts. In this technique (Shaw, 1974) the natural remanent magnetization (NRM) of the sample is demagnetized using alternating field (AF) demagnetization but is remagnetized by heating to above the Curie temperature and cooling in a known field to form a full thermoremanent magnetization (TRM) in a known field strength. By comparing the NRM and TRM values it is possible to calculate the strength of the field in which the NRM was formed. There are checks for alteration of the sample and also several variations of the original technique that are described below.

### The original Shaw technique

This technique used anhysteretic remanent magnetizations (ARMs) to check for any alteration in the sample due to the laboratory heating. There are four demagnetization stages to the experiment:

- 1. AF demagnetize the NRM in steps to a maximum AF value.
- 2. Give the sample an ARM in a known constant field in the maximum AF used in 1 (ARM1) and AF demagnetize in the same steps used in 1.
- 3. Give the sample a full TRM in a known constant laboratory field strength and AF demagnetize in the same steps used in 1.
- 4. Give the sample an ARM in the same known field as used in 2 (ARM2) and AF demagnetize in the same steps used in 1.

The basic premise is simply that if a sample can be demagnetized between two AF values then it can also be remagnetized with an ARM between those values. The value of the ARM is not simply related to the value of the NRM (or TRM) lost between those AF values but it is a function of the samples' ability to retain magnetization between those two AF values. If the sample becomes altered during heating to form the TRM in such a way that the ability to retain magnetization (TRM or ARM) between those two values changes, then the value of ARM2 (given after heating) between the two AF values will be different from the value of ARM1 (which was given before heating and, therefore, before alteration).

By plotting the demagnetization values of ARM1 against ARM2 and using the value of the AF demagnetizing field as a parameter, the slope of the line should be unity if there has been no alteration of the sample. If there has been alteration, then the slope will not be unity. By selecting the continuous AF demagnetization region where the slope is unity (if such a region exists) and plotting NRM against TRM it is possible to calculate the ratio NRM/TRM (Figure S28)

**Figure S28** Shaw technique paleointensity analysis, the high AF region of the ARM1/ARM2 graph is linear with slope 1 (marked with double ended arrow). The same AF region on the NRM/TRM graph is also linear and as this AF region is unaltered the paleointensity value can be calculated from the slope.

**Figure S29** The data in this figure analyzed using the Rolph and Shaw correction where changes in ARM are used to correct for changes in TRM. In the Rolph and Shaw technique only data with peak AF values above 0.1 T were used in order to restrict the analysis to single or pseudosingle domain grains.

which is the same ratio as the ancient field strength/laboratory field strength (Nagata, 1943).

# Kono, and Rolph and Shaw corrections

Kono (1978) proposed that samples with altered TRMs could be used for paleointensity analysis provided that the NRM/TRM graph has a linear segment and that the equivalent ARM1/ARM2 graph is also linear. He proposed multiplying the paleointensity obtained from the NRM/TRM linear section by the inverse of the slope of the equivalent ARM1/ARM2 section in order to correct for laboratory thermal alteration.

Rolph and Shaw (1985) proposed that the degree of alteration of the TRM was reflected in the degree of alteration of ARM2 and so it should be possible to use the ARM data to continuously correct for alteration in the TRM. In order to achieve this, the final highest AF field value of NRM, TRM, ARM1, and ARM2 are subtracted from

their respective data. Each TRM value is then multiplied by the ratio of ARM1/ARM2 for the same AF value. A new graph plotting NRM against TRM  $\times$  ARM1/ARM2 should correct for any alteration of the TRM due to laboratory heating (Figure S29).

## Double heating technique

Following on from the Rolph and Shaw correction, Tsunakawa and Shaw (1994) applied a second heating to form a second TRM (TRM2) in the same field as the first TRM (TRM1). If both the first and second heatings cause thermal alteration, then it is possible to check if the ARM correction proposed by Rolph and Shaw works by plotting TRM1 against ARM corrected TRM2. The slope of the line should be unity if the correction works. This adaptation of the Shaw technique is lengthier because of the need for two heatings and a third set of ARM measurements but it gives confidence to final result if the TRM2 correction works.
912

Low temperature demagnetization double heating technique

Tsunakawa *et al.* (1997) and Yamamoto *et al.* (2003) used low temperature demagnetization (LTD) in conjunction with the double heating technique. The low temperature demagnetization (to liquid nitrogen temperature) removed the magnetization formed during high temperature oxidation of the magnetic grains. Although the technique is lengthy, it has provided accurate paleointensity determinations from recent Hawaiian lavas.

# SHOCK WAVE EXPERIMENTS

# Introduction and background

Shock wave experiments have a special place in the study of the Earth's interior and the interiors of the terrestrial planets because virtually the entire pressure (to 470 GPa) and temperature (to 6000 K) ranges existing with these objects can be achieved, via this technique, in the laboratory. The study of the properties of iron and alloys, solid and molten, relevant to core composition via shock compression to high pressures and temperatures of the Earth and planetary cores has continued to challenge mineral physicists.

The geomagnetic field is thought to be generated by complex convective flows of electrically conducting Fe-rich fluids in the fluid outer core. The author has measured physical properties under shock compression which provide information on where possible Fe-rich materials are fluid and, hence, where convection and generation of the geomagnetic field occurs.

Dynamic compression of cosmochemically candidate metal-like compounds which, in the molten state, are soluble in molten iron such as FeS, FeO, FeC, FeSi, and FeH<sub>2</sub> continue to be of interest to theories of the formation and evolution of the molten conductive cores that generates the Earth's and other planetary magnetic fields (see *Core composition*). The electrical resistivity of iron alloys and compounds under shock compression are compared to approximate bounds for the Earth that are derived theoretically. Recent compositional and thermodynamic models of the Earth's core (see *Core, adiabatic gradient*) have been strongly revised (Anderson and Ahrens, 1994; Poirier, 1994; Stacey, 2001; Anderson and Isaak, 2002) in part, on account of new shock wave data for iron and its alloys.

Here we present a summary of modern techniques for shock wave equation of state (EOS) (pressure-volume-energy) measurements which are applicable to condensed matter, in general, and specific to iron and its alloys. The study of compression behavior of other standard materials and phase transitions in selected materials have provided standards for the more widely used diamond and multianvil high pressure apparatuses (Holzapfel, 1996). Improvements in techniques for measuring sound, or rarefaction velocity in shock-compressed material (Brown and McQueen, 1986; McQueen, 1992; Chen and Ahrens, 1998) have continued to complement the EOS measurements for these materials and provide data specifying whether materials in various shock states are in solid, partially or completely molten form. Such data also provide firm constraints on the high-pressure and high-temperature Grüneisen parameter of iron and iron alloys (see Grüneisen's parameter for iron and Earth's core). As discussed below, knowledge of the Grüneisen ratio of iron is crucial to reducing shock wave data to pressure-volume isotherms and isentropes so that it may be compared to data from other sources, as well as to constrain the thermodynamic models of the Earth's core.

# Shock wave generation and the Rankine-Hugoniot equation

The shock waves used for dynamic compression research must be maintained for time intervals of  $\sim 10^3$  times the intrinsic rise-time  $\tau_s$  of the shock front (Figure S30).

The impact of gun and explosively launched flyer plates both provide the requisite nearly steady waves in materials. For steady waves, a shock, with velocity U with respect to the laboratory, independent of time, can be defined and conservation of mass, momentum, and energy across a shock front can be expressed as:

$$\rho_1 = \rho_0 U / (U - u_1), \tag{Eq. 1}$$

$$P_1 = \rho_0 u_1 U, \tag{Eq. 2}$$

$$E_1 - E_0 = P_1(1/\rho_0 - 1/\rho_1)/2 = 1/2u_1^2,$$
 (Eq. 3)

where  $\rho$ , u, P, and E are density, particle velocity, shock pressure, and internal energy and, (as indicated in Figure S31), the subscripts 0 and 1 refer to the state in front of and behind the shock front, respectively. It should be understood that in this section, pressure is used in place of stress in the indicated wave propagation direction. Actually stress, in the wave propagation direction, is what is specified by (2). A detailed derivation of (1)–(3) is given in Melosh (1989). Equation (3) also indicates that the material achieves an increase in internal energy (per unit mass) which is exactly equal to one-half of the kinetic energy per unit mass.

Upon driving a shock of pressure  $P_1$  into a material, a final shock state is achieved which is described by (1)–(3). This shock state is shown in relation to other thermodynamic paths in Figure S32 in the pressure-volume plane. Here  $V_0 = 1/\rho_0$  and  $V = 1/\rho$ . In the case of the isotherm and isentrope, it is possible to follow, as a thermodynamic path, the actual isothermal or isentropic curve to achieve a state on the isotherm or isentrope. A shock or Hugoniot state is different, however.

Р

Hugoniot

**Figure S32** Pressure-volume compression curves. For isentrope and isotherm, the thermodynamic path coincides with the locus of states, whereas for the shock, the thermodynamic path is a straight line (from point 0,  $V_0$ ) to point ( $P_1$ ,  $V_1$ ) on the Hugoniot curve (from Ahrens (1987)).

**Figure S30** Generation of shock waves by flyer plate impact. Impact induces steady flat-topped shock wave and this is followed by a rarefaction wave (from Ahrens (1987)).

**Figure S31** Profile of a steady shock wave, rise time  $\tau_s$ , imparting a particle velocity  $u_1$ , pressure  $P_1$ , density  $\rho_1$ , and internal energy density  $E_1$ , propagating with velocity U into material that is at rest at density  $\rho_0$  and internal energy density  $E_0$  (from Ahrens (1987)).

The Hugoniot state  $P_1$ ,  $V_1$  is achieved via a thermodynamic path given by the straight line called Rayleigh line (Figure S32). Thus successive states along the Hugoniot curve cannot be achieved, one from another, by a shock process. The Hugoniot curve itself then just represents the locus of final shock states.

To achieve such shock waves with flat-topped stress pulses, flat plates called flyer plates are launched with guns (Figure S33) or explosive devices (Figures S34 and S35). The flyer plate impacts the sample or a "driver plate" upon which the sample is mounted and drives a shock into the driver plate and the sample. Although the various plate launching systems depicted in Figures S33–S35 operate over an enormous velocity range, all actual systems have shortcomings. Corrections for converging flow must be made in the case of explosive imploding systems of Figure S35. Tilt and flyer plate distortion, must be taken into account in the case of all explosive and gun launched impactors, as for example, indicated in Figure S36.

**Figure S33** Diagrams of propellant gun launching system to impact metallic targets up to 2.6 km s<sup>-1</sup>. The iron target is preheated with radiofrequency induction coils. Resulting target temperature is monitored using the optical signal reflected from gold mirror (M). Abbreviations: W: window; L: lens; M: mirror; M (Au): gold mirror; T: EOS turning mirror. About 1 s before launching projectile, EOS turning mirror is inserted in front of the target free-surface (after Chen and Ahrens (1998)).

# Comparison of electrical resistivity of shocked iron, iron alloys, and compounds to Earth

Our understanding of the conditions required to generate the Earth's magnetic field provides some constraints on the electrical conductivity of the Earth which may be usefully compared to the conductivity of

**Figure S34** Explosive flyer plate launching (to ~5 km s<sup>-1</sup>) apparatus. (1) and (2) Explosive plane-wave lens is point detonated at upper (downwards pointing) arrow. (1) Fast detonating explosive, (2) slow detonating explosive, (3) main explosive. (8) Plexiglas buffer plate, (4) metal flyer plate, (5) driver plate, (6) specimens under study, (7) electrical contactor pin switches that detect shock wave arrival (after Al'tshuler *et al.* (1999)).

solid and molten iron and alloys as a function of temperature and pressure.

The resistivity of the Earth's core is thus constrained to be sufficiently low, such that magnetic field lines and unable to diffuse out of the core on the timescale of  $\sim 10^4$  years approximately obtained by assuming radius of the core (usually assumed to be the inner core) ( $\sim 1200$  km), divided by the westward drift velocity (of features of the magnetic field such as mapped by Bloxham and Gubbins (1985) from the years 1715 to present). Using this loose constraint, Matassov (1977) first showed that the core should have a resistivity of

$$\rho < 10^{-5} - 10^{-4} \,\Omega \,\mathrm{m}. \tag{Eq. 4}$$

These low resistivity values assume that the magnetic field will not diffuse out of the core over the  $10^4$  year time scale field deflation.

By assuming a fixed value of 8-12% of the total Earth heat flow (44 TW) across core-mantle boundary, a lower limit resistivity of the core region of

$$\rho < 10^{-6} \,\Omega \,\mathrm{m} \tag{Eq. 5}$$

is obtained. This rather simple constraint limit is obtained by taking the extreme assumption that the heat flow across the CMB is totally resulting from ohmic heating by the core of the geodynamo.

As can be seen in Figure S37, upon extrapolation, the mostly lower pressure shock data for iron, and its alloys and compounds

**Figure S35** Hemispheric implosive flyer plate launching devices for ultra-high pressure shock wave research. (a) Single stage apparatus launches metal flyer plates to velocities of  $9-11 \text{ km s}^{-1}$ . (b) Explosive charge is multiply point detonated at outer surface of explosive hemisphere. (1) Main charge, (2) hemispherical primary flyer plate. Upon acceleration of primary flyer plate to  $\sim$ 5–7 km s<sup>-1</sup> impact onto (6) secondary explosive charge induces an overdriven detonation wave. Overdriven detonating wave in secondary charge accelerates (7) secondary flyer plate to velocities of up to 14 km s<sup>-1</sup>. Upon impact onto (3) driver plate, shock waves with pressures in 1400–1800 GPa are driven into (4) specimens. Resulting shock velocities are measured via (5) electric contactor pin switches (after Al'tshuler *et al.* (1999)).

to 135–450 GPa, the resistivity of these media lies in the  $10^{-6}-10^{-5}$   $\Omega m$  range in agreement with the very loose theoretical expectations described above.

At least three sources of energy for powering the geodynamo are recognized:

- 1. Hydrodynamic flow of core fluid induced by the difference in dynamic ellipticity of the whole Earth versus that of the core.
- 2. Thermal convection of core fluid driving the geomagnetic dynamo also appears possible. Such thermal convection could be driven by radioactivity of the core, such as for example, supplied by  $^{40}$ K in the core.
- Another source of sufficient thermal energy to operate the geodynamic dynamo is the latent heat of crystallization of the inner, solid core.

#### Shock wave equation of state (EOS) measurements

In the simplest case when a single shock state is achieved via a shock front, the Rankine-Hugoniot equations involved six variables  $(U, u_1, \rho_0, \rho_1, E_1-E_0, \text{ and } P_1)$ ; thus, measuring three, usually  $U, u_1$ , and  $\rho_0$ , determines the shock state,  $\rho_1, E_1-E_0$ , and  $P_1$ .

**Figure S36** (Upper) Schematic illustration (highly exaggerated) of projectile tilt and bowing, and their effect on the streak record. Particle-velocity vector (up) is normal to target (seen edge-on) despite tilt. The arrival on the streak record corresponding to the shock-wave entering the sample could significantly be curved due to the bowing of the projectile (after Jeanloz and Ahrens (1980)). (Lower) (a) Experimental sample image taken through image converter camera, viewing the back-side of the target. The sample and mirror can be seen, as well as the location of the slit. (b) Streak photograph taken by sweeping the image of the slit towards the right (at nearly constant velocity) as the projectile impacted the target. Note the intense flash of light as the shock-wave crosses the sample/buffer mirror interface (after Jeanloz and Ahrens (1978)).

Careful measurement of sample volumes and mass can result in  $\rho_0$  to be determined within ~±0.3%. Projectile or flyer plate velocity is measured via successive closure of a series of contactor pin switches or via optical or flash X-ray techniques (Ahrens, 1987). In the simplest case where the sample and impactor are made of the same material, the shock-induced particle velocity is

$$u_1 = u_{\rm fp}/2,$$
 (Eq. 6)

where  $u_{\rm fp}$  is the flyer plate velocity which is measured to ~±0.5%.

Shock velocity is usually measured to  $\sim 1\%$  via streak camera photography (Figures S33 and S36) or via contactor pin closures (Figures S34 and S35) as indicated.

Shock compression data for candidate core constituents are tabulated by Ahrens and Johnson (1995). Upon shock compression to greater than 13 GPa, the Hugoniot data for iron demonstrates the onset of a 5% volume decrease upon transition from the low pressure, bcc,  $\alpha$ -phase to the high pressure hcp,  $\varepsilon$ -phase. Moreover, the phase change demonstrates hysteretic unloading (for example, as seen from 23 GPa shown in Figure S38). The shock wave data for iron (up to 200 GPa were originally obtained using explosively launched flyer plates, Figure S34) and extended to 900, and later, 1400 GPa using the techniques sketched in Figures S35a and b by Al'tschuler and co-workers in the former Soviet Union (now Russia) (Ahrens and Johnson, 1995). Shock wave data for Fe-Si (Matassov, 1977), pyrrhotite (FeS) (Brown *et al.*, 1984), pyrite (FeS<sub>2</sub>) (Ahrens and Jeanloz, 1987), and wüstite (FeO) (Jeanloz and Ahrens, 1980) may be used to estimate the fraction of light elements in the core by correcting Hugoniot temperatures to those of the Earth (as for example as shown in Figures S39 and S44) (see *Inner Core composition* and *Core temperature*).

# Strategy for applying shock wave data to modeling the Earth's core

#### Theoretical temperature models of the Earth's core

Thermal models of the outer core of the Earth have been anchored to estimates of the pure iron melting point at 330 GPa, the pressure of the inner core-outer core (IC-OC) boundary (see *Melting temperature of iron in the core, theory* and *Melting temperature of iron in the core, experimental*). Since the temperature variation  $T_{oc} = T_{oc}(\gamma/V_{oc})$  in the outer core (which is assumed to be in approximately adiabatic equilibrium) is usually modeled as an isentropic temperature distribution which is described by (see *Core, adiabatic gradient*):

$$T_{\rm oc} = T_{\rm ic-oc} \, \exp\left[-\int_{V_{\rm ic-oc}}^{V_{\rm oc}} \frac{\gamma}{V} \mathrm{d}V\right]. \tag{Eq. 7}$$

Here  $\gamma$  is the Grüneisen parameter of the molten material of the outer core (usually assumed to be approximately equal to that of molten

 $10^{-5}$   $Fe_{0.94}O$   $Fe_{75}Si_{25}$   $Fe_{92}Si_{a}$   $Fe_{9}Si_{a}$   $Fe_{9}Si_{a}$   $Fe_{9}Si_{a}$   $Fe_{9}Si_{a}$   $Fe_{9}Si_{a}$   $Fe_{9}Si_{a}$   $Fe_{9}Si_{a}$   $Fe_{9}Si_{a}$   $Fe_{9}Si_{a}$ 

**Figure S37** Measurements of the electrical resistivity of Fe<sub>0.94</sub>O under shock loading are compared with previous data for iron and two iron-silicon alloys, iron, iron alloys, and compounds versus shock pressure (after Knittle *et al.* (1986)). Upon extrapolating these data to the pressure range of core (135–450 GPa), it can be concluded that these iron-bearing minerals have resistivities of  $10^{-6}$ – $10^{-5} \Omega m$  at core pressures and temperatures.

**Figure S38** Hugoniot shock pressure versus reduced volume  $(V/V_0)$  data for  $\gamma$ -iron. Upon shock loading, the onset of phase change which  $\alpha$ -iron (bcc) transforms to  $\varepsilon$ -iron (hcp) with a 5% decrease in volume occurs at 13 GPa. Upon unloading from 23 GPa dynamic transformation from hcp to bcc-iron occurs at 10 GPa. The data are from Bancroft *et al.* (1956) and Barker and Hollenbach (1974). Dashed curve (Andrews, 1973) is theoretical curve.

**Figure S39** Shock-wave data for FeO (Jeanloz and Ahrens, 1980), Fe (McQueen *et al.*, 1970), Fe<sub>2</sub>O<sub>3</sub> and Fe<sub>3</sub>O<sub>4</sub> (McQueen and Marsh, quoted in Birch (1966); not corrected for porosity) (heavy curves) compared with the seismologically determined compression curve of the core. The Fe and FeO data, corrected to core temperatures, are shown as thin dashed curves. Hugoniots of mixtures of oxides and Fe corresponding to FeO are given as thin curves;  $\frac{1}{3}$ (Fe + Fe<sub>2</sub>O<sub>3</sub>),  $\frac{1}{4}$ (Fe + Fe<sub>3</sub>O<sub>4</sub>) and (Fe<sub>3</sub>O<sub>4</sub> – Fe<sub>2</sub>O<sub>3</sub>) are plotted but overlap; open squares are from Al'tshuler and Sharipdzhanov (1971). Hugoniots for only the high-pressure phase are shown, and the wüstite data are corrected for initial porosity and nonstoichiometry (after Jeanloz and Ahrens (1980)).

iron). The Grüneisen parameter is given by (see *Grüneisen's para*meter for iron and Earth's core):

$$\gamma = V \left(\frac{\partial P}{\partial E}\right)_V = \frac{\alpha K_s}{C_p \rho_0} = \frac{\alpha K_T}{\rho_0 C_V},$$
 (Eq. 8)

where,  $\alpha$ ,  $K_s$ ,  $K_T$ ,  $C_p$ , and  $C_v$  are the thermal expansion coefficient, isentropic and isothermal bulk modulus, and specific heat at constant pressure and volume. Equation (8) is used to evaluate  $\gamma$  at ambient pressures.

#### Determining Grüneisen parameter

The Grüneisen parameter at high pressure is obtained from the measured bulk sound velocity, *C*, behind the shock front and is given as (see *Grüneisen's parameter for iron and Earth's core*):

$$\gamma = \frac{\rho_0}{\rho s \eta^2} \left[ 1 + s \eta - R^{*2} (1 - s \eta) \right], \tag{Eq. 9}$$

when

$$\eta = u_1/U = (V_0 - V)/V_0 \tag{Eq. 10}$$

and

$$R^* = (\rho/\rho_0)(c/U).$$
 (Eq. 11)

The derivation of (9) assumes that the Hugoniot shock and particle relation are described by:

$$U = c_0 + su_1, \tag{Eq. 12}$$

where

$$c_0 = \sqrt{K_{\rm os}/\rho_0} \tag{Eq. 13}$$

and

$$s = (K'_{os} + 1)/4.$$
 (Eq. 14)

By measuring the free-surface velocity profiles of shock states being overtaken by rarefactions originating at the rear of the iron flyer plate, the sound velocity c (and hence  $\gamma$ ) of different states along the principal Hugoniot and 1373 K preheated Hugoniot of  $\gamma$ -iron may be obtained as a function of density or specific volume (Figure S40). From a series of free-surface profiles, such as shown in Figure S41, data on the value of c, and hence  $\gamma$  (Ahrens *et al.*, 2002a) can be obtained, for example, for preheated iron, using apparatus depicted in Figure S42.

#### Detection of shock-induced melting

As described above, the bulk sound velocities can be measured for shock states achieved in molten materials,

$$c = \sqrt{K_s/\rho_0}.$$
 (Eq. 15)

In the solid regime, the rarefaction wave propagates with the longitudinal elastic velocity which is given by:

$$V_p = \sqrt{\frac{K_s + \frac{4}{3}\mu}{
ho_0}}.$$
 (Eq. 16)

Thus by measuring the sound velocity as a function of shock pressure, the shock pressure upon which the sound velocity decreases sharply,

**Figure S40** Thermodynamic Grüneisen parameter  $\gamma$  of liquid iron versus density. The 1 bar, 1811 K datum is from Anderson and Ahrens (1994). "This study" with "Chen (1997)."

**Figure S41** Free-surface velocity profiles from VISAR experiments in geometry of Figures S33 and S42 on iron preheated to 1373 K. Shot numbers are shown near each wave profile. Vertical lines indicate initial unloading arrivals. Peak particle velocities are within 4% of impedance match solutions. Origin of time axis is arbitrary. Inset: detailed plot of first release wave arrival for shot 1008 (after Chen (1997)).

**Figure S42** Experimental arrangement for conducting VISAR sound speed measurements in preheated 1373 K iron (after Chen and Ahrens (1998)).

indicates where the Hugoniot curve enters the regime of transformation from the solid, into the partially molten and then completely liquid regime. Knowledge of the Grüneisen parameter at high pressure and temperature (9–11) and thermodynamic calculations allow construction of the high pressure-temperature phase diagram (Brown and McQueen, 1986; Ahrens *et al.*, 2002b; Nguyen and Holmes, 2004) (see *Melting temperature of iron in the core, theory* and *Melting temperature of iron in the core, experiment*).

Very extensive data for iron, centered at normal temperatures (Figure S43), demonstrates that shock-induced melting begins at 220 GPa (Brown and McQueen, 1986; Nguyen and Holmes, 2004). The sound velocity of the Hugoniot of other metals is also available for Al, Cu, Ta, Pb, Mo, W, V, and stainless steel (Dai *et al.*, 2002; Luo and Ahrens, 2004). Shock temperatures upon melting, for all these

**Figure S43** Sound velocity upon unloading rarefaction upon shock compression of  $\alpha$ -iron. Solid symbols exhibit a single solid-liquid transition along Hugoniot at 222  $\pm$  3 GPa (according to Nguyen and Holmes (2004)). Brown and McQueen's (1986) data are shown by open symbols. Open squares (triangles) represent (explosive driven) shock data (after Nguyen and Holmes (2004)).

metals and other materials of geophysical interest were calculated. These calculations are substantially verified by the, at present, limited shock temperature and high pressure melting data which are measured for iron (Williams *et al.*, 1987; Yoo *et al.*, 1993), V (Dai *et al.*, 2001), FeS and FeS<sub>2</sub> (Anderson and Ahrens, 1996), and stainless steel (Ahrens *et al.*, 1990). Moreover, recent studies of melting in the Fe-O and Fe-S system in diamond anvil apparatus indicate that eutectic melting temperatures of plausible iron alloys are lowered from those of iron by <500 K at core pressures (Boehler, 1992, 2000). The above referenced iron and iron alloys data have indicated the IC-OC melting temperature of approximately 6000  $\pm$  500 K. These values have profoundly influenced models of the core as discussed in the next section.

#### Influence of shock wave data on models of the core

Thermal models of the Earth's core of the 1970s (e.g., Stacey (1977)) were, in part, based on extrapolation of 10 GPa melting data for the FeS eutectic (Usselman, 1975a, b). Stacey and others modeled the outer core as having temperature of  $\sim$ 3200 K at CMB rising to 4200 K at the IC-OC boundary. The shock temperatures first calculated by Brown and McQueen (1986) on the basis of their pioneering study of the shock temperature upon melting along the principal Hugoniot of iron at 220 GPa (5000–5700 K) extrapolated to  $5800 \pm 500$  K for melting of iron at the IC-OC boundary. Later shock temperature measurements (Figure S44) supported these considerably higher temperatures. The shock temperatures for iron when applied to the core indicates higher (by ~1000 K) melting points than static high pressure diamond anvil melting data to 200 GPa (Boehler, 1993). Present models of the Earth's core assume IC-OC temperature of ~5000-6000 K (e.g., Poirier (1994), Anderson and Ahrens (1994), Boehler (2000), Anderson (2002)) are summarized by the temperature-pressure relation labeled Earth (representing the outer and inner core) in Figure S44, were influenced by the shock-induced melting data for iron. These rather higher values lead to rather larger predicted heat flows from the core of 6-10 Tw, compared to the previous assumed values of CMB heat flow of 4-5 Tw of Matassov (1977). High temperature core values lead to implausibly short model existence times of the solid Earth core (Labrosse et al., 2001). This then leads to possible, but still very poorly constrained models, of radioactive element contents of the core. Such models of radiogenic heat production lead to higher sustained core temperatures over the history of the Earth (Buffett, 2003).

**Figure S44** Shock temperature data for iron relative to the temperatures in the outer and inner core. States between 200 and 250 GPa are assigned to solid *\varepsilon* row to temperatures above melting line (Lindemann MC, melting curve). States above 270 GPa are believed to represent totally melted material. DAC MC is diamond anvil melting curve (after Luo and Ahrens (2004)).

**Figure S45** Core density deficit in terms of wt% of three cosmochemically acceptable elements. Four parallel lines represent the value of  $T_m$  at IC-OC (330 GPa) corresponding to temperatures indicated. Intersection of these parallel lines with curves for Si, S, and O indicate wt% values of element (after Anderson and Isaak (2002)).

As can be seen in Figure S45, as the model values of outer core temperatures are increased from 5000 to 7000 K, the calculated density deficit (with respect to molten iron at that temperature largely on the basis of shock wave data for FeS, FeO, and FeSi) goes down from 7 to 3.5% and the wt% of impurity of light element decreases drastically (see *Core, adiabatic gradient* and *Core composition*).

# SPINNER MAGNETOMETER

#### Introduction

The spinner magnetometer is an instrument for measuring remanent magnetization (RM) of rock specimens in studies of the magnetic properties of rocks.

Natural remanent magnetization (NRM) is the magnetic quantity, which was preserved in the rock during its formation in the presence of the prevailing magnetic field and then during its long-life existence when it was exposed to many physical and chemical factors. Thus, various sorts of RM may exist simultaneously and in different ratio in the same rock. RM is a vector quantity. If the rock is magnetically isotropic, the direction of the RM is identical with the direction of the magnetic field at the time of rock formation. Strong anisotropy usually causes a difference between the directions of the RM and the magnetizing field. The spinner magnetometer measures the total NRM, which is the sum of several RM vectors. The remanent magnetizations differ by their formation and have different stabilities. Magnetization strengths are in the order of  $10^{-6}$  Am<sup>-1</sup> for weakly magnetized sediments to  $10^2$  Am<sup>-1</sup> for strongly magnetized ores. Typical spinner magnetometer applications are:

Paleomagnetism: Changes in Earth's magnetic field in geological history can be investigated through the measurement of the rock's remanent magnetization and in the investigation of its stability, age-dating the rocks, solving some tectonic problems in particular terrains, dating the development of mineralization of ore deposits, and many other geological problems.

Archeomagnetism: Changes of Earth's magnetic field in human history. These investigations are mostly applicable to dating archeological materials.

Mineralogy: Impurities of ferromagnetic grains in para- or diamagnetic minerals can be investigated.

Magnetic fabric studies: Measurement of the anisotropy of isothermal remanent magnetization (IRM) can help in the separation of ferromagnetic and paramagnetic fractions of a rock.

Magnetometry: In the interpretation of ground or airborne magnetic measurements it is useful to know whether the rock's magnetization is due to its induced or remanent component. Investigation of RM can help to solve this problem.

#### Measuring principles

The principle of measurement is very simple, based on electromagnetic induction law formulated by Michael Faraday as early as 1831. Rock specimen of defined size and shape, fixed in a specimen holder rotates at a constant angular speed in the vicinity of a detector.

Provided that the spinning specimen has nonzero magnetic moment, an AC voltage is induced in the detector. The detector is shielded with a multilayer permalloy shield. At constant speed of rotation and constant specimen size, the amplitude and phase of the induced signal depend on the magnitude and direction of RM vector of the specimen. The voltage is amplified, filtered, digitized, and analyzed. In a specimen rotating about a single axis inside a pair of detector coils, the output voltage amplitude is proportional to the projection of the RM vector to the plane perpendicular to the rotation axis; the component of the RM vector parallel to the rotation axis induces no signal. The phase of the signal depends on the direction of projection of the RM vector into the plane perpendicular to the rotation axis. To measure the third RM component, the specimen must be at least once repositioned by turning it by 90° and re-measured. In practice, the standard measurement of the RM vector consists of successive measurements in three, four, or six positions to reduce the measurement errors. The specimen position change is performed manually or using special automatic manipulator, which turns the specimen between successive spinning steps around the imaginary body diagonal of a cube which has threefold symmetry. Thus, the automatic manipulator eliminates the need of manual specimen positioning during the measuring process and shortens the measuring time. The other solution is to use a special specimen holder simultaneously spinning the specimen about two or three axes. However, this solution usually results in decreasing the sensitivity of the instrument due to the occurrence of additional mechanical vibrations caused by the two axes spinning mechanism.

The induced signal is amplitude sensitive proportional to speed of rotation and phase sensitive due to the band pass filtration of the signal by the instrument hardware. For this reason a very precise stabilization of rotation speed is necessary. A reference signal synchronous to the specimen rotation is needed for phase calibration, speed control, filtration, induced signal scanning, and digital processing. The reference signal is generated by an optocoupler built right on specimen holder shaft or in some cases into the motor unit. The magnetometer calibration is a special measurement procedure of the standard, which yields the gain and phase for calculating the remanence vector components. Since the specimen is fixed in the specimen holder, the measurement procedure and specimen position design should eliminate the residual RM value of the holder. If this is not possible due to principal reasons, correction for the holder in the case of a weak specimen must be done by subtracting the empty holder values from the data measured.

In general, the properties of the instrument depend upon the geometric arrangement of the detector relative to the spinning specimen, the type of detector and its size, homogeneity and geometric precision, noise of detector, noise of electronic unit, speed of rotation, size and homogeneity (magnetic and physical) of the specimen, the type of specimen holder, the influence of external disturbing fields, the resistance to mechanical shock, and temperature.

#### Sensitivity of the spinner magnetometer

The signal detector is the heart of the instrument. The design of the detector together with the preamplifier of the induced signal significantly determines the sensitivity of the instrument. Since some rocks have very low amplitude of the RM vector, of the order of  $10^{-5}-10^{-6}$  Am<sup>-1</sup>, the sensitivity of the instrument should be at least in the order  $10^{-6}$  Am<sup>-1</sup>.

Spinner magnetometer measurements are disturbed by noise, which can be in three categories: First the thermal noise of the detector (pickup coils), second the noise of the electric circuits (preamplifier of the induced signal and the control unit), and third the noise whose source may be by various causes (impurities on the specimen holder, vibration of the pick-up coils, strange external magnetic fields, etc.). The sum of all of these is called the operating noise, and the sum of the first two categories is called the basic noise. Other sources of errors occur during removing and inserting of the specimen in cases of manual position change, or during specimen position change by the automatic manipulator. The sensitivity, in case we are able to remove all additional disturbing effects (except for basic noise), is called the limiting sensitivity or minimum detectable field. For practical use, it is significant to work with the standard deviation of repeated measurements of a weak specimen (at the lower limit of measuring range) using a standard measuring routine for a particular instrument. This standard

deviation characterizes the sensitivity of instrument. The value of the noise is usually lower than the sensitivity.

The sensitivity of instrument depends on the time of integration, the prolongation of measurement time (four times results in increasing the sensitivity two times). The limitation factor is the operating noise. Evaluation of the noise and sensitivity of the instrument is an essential step for instrument selection suitable for a particular application. For measurement of strong rocks specimens, ores for example, the sensitivity of the instrument is not critical but in the case of weakly magnetized sediments, it is the most important parameter to determine the suitability of the intended method of measurement.

Deviations in specimen size and shape will cause errors in position, and/or possibly increase of vibration during measurement and thus decrease the precision of measurement.

The detectors used in classical spinner magnetometers are a pair of Helmholtz coils, or a fluxgate sensor. Recently, the SQUID detector working at the temperature of liquid nitrogen, the so-called high temperature HT-SQUID has been used. HT-SQUID based spinner magnetometer is a compromise between the classical spinner and the low-temperature liquid helium cryogenic magnetometer.

The sensitivity of spinner magnetometer with a fluxgate sensor is about  $1.0 \times 10^{-4}$  Am<sup>-1</sup>, with a spinning rate of 6 Hz, an integration time of 24 s (Leaflet Molspin).

The sensitivity of the HT-SQUID spinner magnetometer expressed in terms of intrinsic noise is  $3.0 \times 10^{-7}$  Am<sup>-1</sup> (Leaflet F.I.T. Messtechnik). The detector output voltage is due to a different measuring principle in comparison with classical spinner independent of the spinning rate.

The measurements with the instrument using the two axes spinning specimen method and HT-SQUID sensor show a sensitivity of  $1.0 \times 10^{-5}$  Am<sup>-1</sup> (standard deviation) in measurement time of 13 s (Leslie *et al.*, 2001).

The sensitivity achieved with the standard Helmholtz coils is  $2.4 \times 10^{-6}$  Am<sup>-1</sup> for a spinning rate of 88 Hz, and 10 s integration time and about  $1.0 \times 10^{-5}$  Am<sup>-1</sup> for a slow spinning rate of 17 Hz (Agico, 2001).

#### Description of Agico spinner magnetometer

The JR-6/JR-6A dual speed spinner magnetometer is an innovated version of the instrument series based on classical spinner magnetometer design with pick-up unit Helmholtz coils. The instrument is equipped with up to date microelectronic components. Two microprocessors control and test the speed of specimen rotation, signal gain, acquisition of the data, carry out digital filtration, and control the autoposition manipulator. The magnetometer is fully controlled by an external computer via a serial channel RS232C.

The spinner magnetometer JR-6A, equipped with a specimen autoposition manipulator and an automatic specimen holder, enables the automatic measuring of all components of the RM vector.

The low speed of rotation increases the possibility of measuring fragile specimens, soft specimens placed in a perspex container and/or specimens with considerable deviations in size and shape. The integration time may be shortened or prolonged by a factor of 2. The repeat mode enables the repetition of measurement in the current specimen position without stopping the motor.

A nominal specimen is either a cube with an edge of 20 mm or a cylinder 25.4 mm (1 in.) in diameter and 22 mm long. Calibration relates to the nominal volume of the specimen. One side of a cubic specimen or the base of a cylindrical specimen is marked with an arrow, which defines the coordinate system of the specimen in which the RM vector is measured. The components of RM vector are calculated using Fourier harmonic analysis. The system of the measurement positions is identical for cubic and for cylindrical specimens. The sensitivity is  $2.4 \times 10^{-6} \text{ Am}^{-1}$  for a spinning rate of 87.7 rps and an integration time of 10 s, and for low-speed rotation of 16.7 rps, the sensitivity is  $1.0 \times 10^{-5} \text{ Am}^{-1}$ . The accuracy of measurement of the RM

components is 1%,  $\pm$  2.4  $\mu$ Am<sup>-1</sup>. The measuring range of the instrument in full auto range is from 0 (2.4  $\mu$ Am<sup>-1</sup>) to 12500 Am<sup>-1</sup> in seven decimal ranges.

# JR-6/JR-6A spinner magnetometer measurement procedure

Standard measurement of the RM vector consists of successive measurements in four positions of the specimen with regard to the holder using the manual specimen holder for four or six positions. The complete measurement yields four values for z component of the RM vector and two values of the x and y components from which the average values are calculated. This process eliminates any residual noncompensated value of the holder RM and reduces the measuring errors caused by inaccurate shape of the specimen and by instrument noise. The residual value of the remanent magnetization of the manual holder for measurement in four or six positions is fully eliminated even if the correction for the holder was not done. It is due to position design of manual positioning with respect to the holder.

If less than four positions are used, the residual components of the holder are not eliminated automatically. We must rely upon the correction of the holder by subtracting the empty holder values. No correction is made for errors due to irregular shapes of the specimens. It is therefore recommended to reduce the measuring cycle to two positions only, for approximate measurements.

Sometimes it may be useful to expand the measuring cycle to six measuring positions, especially in case of specimens of an irregular shape. If six measuring positions are used, the residual value of the RM vector of the holder is fully eliminated. All three components are always measured four times, so the statistics may be better.

Measurement with an automatic holder is available with model JR-6A. The specimen is fixed in the holder only once; the automatic manipulator changes the measuring position without the need for the operator intervention. The further advantage is that the specimen is not exposed to external magnetic fields during position change, as the specimen remains closed inside the triple permalloy shield during the three-position measurement routine. The automatic specimen holder consists of a partly spherical outer shell and a rotatable inner spherical core in which the specimen is secured by a plastic screw. The system of specimen orientation occurs by specimen rotation around the imaginary body diagonal of a cube, which has threefold symmetry. For this reason it is impossible to find a combination of positions which would eliminate the residual value of the remanent magnetization of the holder as with the traditional four- or sixorientation magnetometer measurement. It is necessary to rely entirely upon the correction done by the instrument. This fact may negatively influence the result, especially in case of very soft and weak specimens when small impurities, moving obligatory on spherical core, can generate unrealistic data. Specimens, which differ in size or shape from nominal values, could cause strong vibrations or imbalance while spinning. Such specimens cannot be measured using automatic holder. But in this case it is usually possible to use standard manual holder.

# STATISTICAL METHODS FOR PALEOVECTOR ANALYSIS

Our concern is with the statistical description of paleomagnetic vectors and the estimation of their mean and variance. These vectors may come from a number of different rock units or archeological samples, representing a range of acquisition times, and be useful for studies of the mean paleomagnetic field and *paleosecular variation*; alternatively, the vectors may come from individual measurements taken from a given rock unit or archeological sample, representing the same moment of acquisition, and be useful for studying the acquisition process itself. Directional data of a particular polarity are usually analyzed with a Fisher distribution (1953), and data of mixed polarities are usually analyzed with a Bingham distribution (1964). Occasionally, other directional distributions are used. For example, Bingham (1983) considered the projection of a three-dimensional (3D), scalar-variance Gaussian distribution onto the unit sphere, something he called the "angular-Gaussian" distribution. More recently, Khokhlov et al. (2001) considered a generalization of the angular-Gaussian distribution, one with a covariance matrix, which they used to analyze directional data from a number of sites. With respect to intensity data, they have traditionally been treated separately from paleodirections, analyzed with normal, log-normal, or gamma distributions. Here, for data of either a particular polarity or of mixed polarities, we summarize these works, and that of Love and Constable (2003), who developed a full-vector, scalarvariance, Gaussian-statistical framework for treating directional and intensity data simultaneously and self-consistently.

#### The distributions

In our statistical treatment, each paleomagnetic vector  $\mathbf{x}$  is considered to be an independent realization occurring in probability according to a statistical distribution. In Cartesian coordinates (*X*, *Y*, *Z*) the probability *P*( $\mathbf{x}$ ) that  $\mathbf{x}$  lies within the infinitesimal differential volume

$$d^3 \mathbf{x} = dX \, dY \, dZ \tag{Eq. 1}$$

is

$$P(\mathbf{x}) = \int p(\mathbf{x}) d^3 \mathbf{x},$$
 (Eq. 2)

where  $p(\mathbf{x})$  is the density function,

$$p(\mathbf{x}) = \frac{\mathrm{d}^3}{\mathrm{d}x^3} P(\mathbf{x}). \tag{Eq. 3}$$

With respect to the many different distributions of probability theory, the Gaussian occupies the most prominent position. This is due to the central limit theorem, which, roughly speaking, asserts that the distribution of the sum of independent, identically distributed random variables is approximately Gaussian. This theoretical underpinning is appealing, and, therefore, for the analysis of paleomagnetic vectors, we consider probability-density functions in a Cartesian three-space of orthogonal magnetic-field components consisting of nonzero mean Gaussian distributions. We model vectors recording data of a particular polarity with a unimodal, Gaussian probability-density function defined in terms of a mean paleomagnetic vector  $\mathbf{x}_{\mu}$  and an associated scalar variance  $\sigma^2$ :

$$p_{g_1}(\mathbf{x}|\mathbf{x}_{\mu},\sigma^2) = \frac{1}{(2\pi)^{3/2}\sigma^3} \exp\left[-\frac{1}{2\sigma^2}(\mathbf{x}-\mathbf{x}_{\mu})\cdot(\mathbf{x}-\mathbf{x}_{\mu})\right].$$
(Eq. 4)

We model vectors of mixed polarities with a bimodal, bi-Gaussian probability-density function, which, in Cartesian coordinates, is

$$p_{g_2}(\mathbf{x}|\mathbf{x}_{\mu},\sigma^2) = \frac{1}{2} \left[ p_{g_1}(\mathbf{x}|\mathbf{x}_{\mu},\sigma^2) + p_{g_1}(\mathbf{x}|-\mathbf{x}_{\mu},\sigma^2) \right].$$
(Eq. 5)

The relevant paleomagnetic coordinates are spherical, being the familiar quantities of magnetic intensity, inclination, and declination (F, I, D). In this case, the differential volume element is transformed according to

$$dX dY dZ \to F^2 \cos I dF dI dD, \qquad (Eq. 6)$$

and the Gaussian probability-density function is

$$p_{g_1}(\mathbf{x}|\mathbf{x}_{\mu},\sigma^2) = p_{g_1}(F,I,D|F_{\mu},I_{\mu},D_{\mu},\sigma^2) = F^2 \cos Iq(\mathbf{x}|\mathbf{x}_{\mu},\sigma^2),$$
(Eq. 7)

where

$$q(\mathbf{x}|\mathbf{x}_{\mu},\sigma^{2}) = \frac{1}{(2\pi)^{\frac{3}{2}}\sigma^{3}} \\ \times \exp\left[-\frac{1}{2\sigma^{2}}(F\cos I\cos D - F_{\mu}\cos I_{\mu}\cos D_{\mu})^{2}\right] \\ \times \exp\left[-\frac{1}{2\sigma^{2}}(F\cos I\sin D - F_{\mu}\cos I_{\mu}\sin D_{\mu})^{2}\right] \\ \times \exp\left[-\frac{1}{2\sigma^{2}}(F\sin I - F_{\mu}\sin I_{\mu})^{2}\right].$$
(Eq. 8)

The quantity  $F_{\mu}$  is the magnetic intensity, or the Euclidean length, of the mean vector  $\mathbf{x}_{\mu}$ , and  $I_{\mu}$  and  $D_{\mu}$  are the inclination and declination of the mean vector. In spherical coordinates the bi-Gaussian probabilitydensity function is

$$p_{g_2}(\mathbf{x}|\mathbf{x}_{\mu},\sigma^2) = p_{g_2}(F,I,D|F_{\mu},I_{\mu},D_{\mu},\sigma^2)$$
$$= \frac{1}{2}F^2 \cos I[q(\mathbf{x}|\mathbf{x}_{\mu},\sigma^2) + q(\mathbf{x}| - \mathbf{x}_{\mu},\sigma^2)].$$
(Eq. 9)

If we define  $\theta$  to be the off-axis angle between a particular unit paleomagnetic vector and the mean unit vector,

$$\hat{\mathbf{x}} = \frac{\mathbf{x}}{|\mathbf{x}|}$$
 and  $\hat{\mathbf{x}}_{\mu} = \frac{\mathbf{x}_{\mu}}{|\mathbf{x}_{\mu}|}$ , (Eq. 10)

then

$$\cos\theta = \hat{\mathbf{x}} \cdot \hat{\mathbf{x}}_{\mu}.\tag{Eq. 11}$$

For both the Gaussian and bi-Gaussian cases the vectorial variance is taken to be spherically symmetrical. That is, the three Cartesian vectorial components are assumed to be independent and to have equal

scalar variance. Such a situation is sometimes described as being one of "isotropic" variance. More generally, however, a Gaussian distribution can be defined in terms of a covariance matrix, where the Cartesian vectorial variance is ellipsoidal, the components having possibly different variances and, even, correlation. Such a situation that is sometimes described as being one of "anisotropic" variance. Of course, because the anisotropic distribution has a larger number of degrees of freedom, it will always fit a given dataset at least as well as the isotropic distribution. In either case, however, it is worth remarking that the Gaussian distributions are idealizations. We do not expect that they will fit all paleovector datasets, since the data themselves result from a myriad of physical processes that in all likelihood cannot be completely distilled down to simple mathematical descriptions. Instead, the utility of statistical distributions is as benchmarks for comparison, and in that sense, the isotropic unimodal and bimodal Gaussian distributions, being relatively mathematically simple, are the most practically attractive.

# **Marginal forms**

For paleomagnetic datasets consisting wholly of coincident intensity and directional measurements, the Gaussian distribution (7) and the bi-Gaussian distribution (9) are of obvious utility. However, in most circumstances, paleomagnetic data consist of only parts, or mixtures of different parts, of the full paleomagnetic vector. Then, what we need are the appropriately marginalized probability-density functions corresponding to the underlying Gaussian distributions. So, for example, most paleomagnetic data are only directional, they consist of inclination-declination pairs with no associated absolute paleointensity. To analyze such data we need the joint probability-density function for inclination and declination, obtained by integrating (7) and (9) over all intensities,

$$p_g(I, D|I_\mu, D_\mu, (\sigma/F_\mu)^2) = \int_0^\infty p_g(F, I, D) \mathrm{d}F.$$
 (Eq. 12)

Alternatively, if we are analyzing data from an azimuthally unoriented borecore, providing (say) intensity-inclination data, then we need the marginal density function

$$p_g(F, I|F_{\mu}, I_{\mu}, \sigma^2) = \int_0^{2\pi} p_g(F, I, D) \mathrm{d}D.$$
 (Eq. 13)

If the data consist only of inclinations then we integrate (13) over all intensities, etc. In each case, we integrate over the vectorial components that are either not available or are not needed. For reference, all required integrations are given in Love and Constable (2003). In Figure S46 we show the intensity, inclination, declination, and off-axis angular distributions corresponding to the Gaussian distribution (7) for a variety of different dispersions and mean inclinations.

#### Intensity

In recent years the analysis of paleointensity data, be they from within a particular epoch or spanning a much longer geological period of time, has become the subject of increasing interest to researchers. It is useful, therefore, to compare such data to the intensity distribution corresponding to the 3D Gaussian distributions. For both unimodal and bimodal cases the intensity density function is the same, obtained by integrating either (7) or (9) over all angles,

$$p_g(F|F_{\mu}, \sigma^2) = \sigma^{-1} \left(\frac{2}{\pi}\right)^{1/2} \left(\frac{F}{F_{\mu}}\right) \\ \times \exp\left[-\frac{1}{2} \left(\frac{F}{\sigma}\right)^2 - \frac{1}{2} \left(\frac{F_{\mu}}{\sigma}\right)^2\right] \sin h\left[\frac{FF_{\mu}}{\sigma^2}\right],$$
(Eq. 14)

which is a special case of the *n*-dimensional Rayleigh-Rician distribution. This function is invariant with respect to change in sign of intensity, although, of course, intensity is, by convention, taken to be a positive quantity. As an aside, we note that distributions of this type have application to digital communications and the radar identification of targets surrounded by Gaussian clutter.

Next, it is enlightening to consider the limiting form of the intensity distribution where  $\sigma \ll F_{\mu}$ . It is approximately that for a one-dimensional normal distribution,

$$p_n(F|F_{\mu},\sigma^2) = \frac{1}{\sqrt{2\pi\sigma}} \exp\left[-\frac{1}{2}\left(\frac{F-F_{\mu}}{\sigma}\right)^2\right],$$
 (Eq. 15)

which McFadden and McElhinny (1982) have suggested might be appropriate for paleointensity studies, after truncation of negative intensities. Note that (15) is not a log-normal distribution and it is not a gamma distribution, each of which have been employed on occasion in the analysis of paleointensity data. However, because it is directly linked to the 3D Gaussian distributions (7) and (9), which can be used for directional analyses as well, and because it applies to a complete and proper range of mean intensities and dispersions, (14) is suitable for paleointensity studies, even (say) during periods of reversal when one can expect that the mean intensity would be small, but the vectorial dispersion would be large.

#### Off-axis angle

For the Gaussian distribution, the marginal density function for offaxis angle is

$$p_{g_1}\left(\theta | (\sigma/F_{\mu})^2\right) = \frac{1}{2}\sin\theta \exp\left[-\frac{1}{2}\left(\frac{F_{\mu}}{\sigma}\right)^2\right] \\ \times \left\{\left[1 + \left(\frac{F_{\mu}}{\sigma}\right)^2\cos^2\theta\right] \exp\left[\frac{1}{2}\left(\frac{F_{\mu}}{\sigma}\right)^2\cos^2\theta\right] \\ \times \left[1 + \exp\left[\frac{1}{\sqrt{2}}\left(\frac{F_{\mu}}{\sigma}\right)\cos\theta\right]\right] + \left(\frac{2}{\pi}\right)^{\frac{1}{2}}\left(\frac{F_{\mu}}{\sigma}\right)\cos\theta\right\},$$
(Eq. 16)

and the marginal density function for off-axis angle corresponding to the bi-Gaussian distribution is just

$$p_{g_2}\left(\theta|(\sigma/F_{\mu})^2\right) = \frac{1}{2}\sin\theta\exp\left[-\frac{1}{2}\left(\frac{F_{\mu}}{\sigma}\right)^2\sin^2\theta\right] \\ \times \left[1 + \left(\frac{F_{\mu}}{\sigma}\right)^2\cos^2\theta\right].$$
(Eq. 17)

For the limiting case where  $\sigma/F_{\mu} \ll 1$ , the unimodal off-axis angular probability-density function (16) is approximately

$$p_f\left(\theta|(F_{\mu}/\sigma)^2\right) \propto \sin\theta \exp\left[\left(\frac{F_{\mu}}{\sigma}\right)^2\cos\theta\right],$$
 (Eq. 18)

this corresponding to the Fisher distribution so often used by the paleomagnetic community for unimodal directional. For the bi-Gaussian off-axis angular probability-density function (16), and in the same limit, the off-axis angular density function is approximately

$$p_b\left(\theta|(F_{\mu}/\sigma)^2\right) \propto \sin\theta \exp\left[\frac{1}{2}\left(\frac{F_{\mu}}{\sigma}\right)^2 \cos^2\theta\right],$$
 (Eq. 19)

**Figure S46** Examples of the marginal probability-density functions  $p_{g_1}$  for the Gaussian distribution (7). (a) Intensity *F*, with vectorial-mean intensity  $F_{\mu}$ , and with vectorial dispersions  $\sigma$  of 7.5, 15, 30, and 60  $\mu$ T, shown, respectively, by solid, long-dashed, short-dashed, and dotted lines. (b) Inclination *I*, (c) declination *D*, and (d) off-axis angle  $\theta$  with vectorial mean direction  $(I_{\mu}, D_{\mu}) = (45^{\circ}, 0^{\circ})$ , and with relative vectorial dispersions  $\sigma/F_{\mu}$  of 0.25, 0.5, 1, and 2, shown, respectively, by solid, long-dashed, short-dashed, and dotted lines. Examples (e-h) are for different mean inclinations, but only the (f) inclination and (g) declination density functions are affected; for vectorial-mean values of  $(F_{\mu}, D_{\mu}, \sigma) = (30 \ \mu T, 0^{\circ}, 7.5 \ \mu T)$  the solid, long-dashed, short-dashed, and dotted lines are for vectorial-mean inclinations  $I_{\mu}$  of 0°, 30°, 60°, and 90°, respectively.

**Figure S47** Comparison of maximum-likelihood fits of the 3D bi-Gaussian distribution to the (positive, top) Hawaiian data and (negative, bottom) Réunion data covering the past 5 Ma. Both the probability-density functions and the histograms of the data are shown for (a) intensity, (b) inclination, (c) declination, and (d) off-axis angle. Note that the Réunion data, particularly the declination and off-axis angle data, are fitted better than the Hawaiian data, also note the sizable difference in mean inclination between these two sites.

this corresponding to the Bingham distribution so often used by the paleomagnetic community for bimodal directional analysis. As with our comment about intensity distributions, because they are directly linked to the 3D Gaussian distributions, and because they apply to the complete range of possible vectorial dispersions, (16) and (17) are suitable for most paleodirection studies.

#### Maximum-likelihood estimation

In fitting paleomagnetic data to a particular Gaussian distribution, thereby yielding a measure of mean and variance, a convenient method is that of maximum-likelihood; for a general review see Stuart *et al.* 

(1999). With this formalism, the likelihood function is constructed from the joint probability-density function for the existing dataset. In our case we use the Gaussian density functions and/or their appropriate marginalizations to construct the likelihood, which, in its most general form, for all normally encountered types of data groups, is just

$$L = \prod_{j=1}^{N_{FD}} p_g(F_j, I_j, D_j) \prod_{k=1}^{N_{D}} p_g(I_k, D_k) \times \prod_{l=1}^{N_{FI}} p_g(F_l, I_l)$$
$$\prod_{m=1}^{N_F} p_g(F_m) \prod_{n=1}^{N_I} p_g(I_n).$$
(Eq. 20)

926

Here,  $N_{FID}$  is the number of intensity-inclination-declination triplets;  $N_{ID}$  is the number of inclination-declination pairs, etc. Maximizing *L* is accomplished numerically (Press *et al.*, 1992), an exercise yielding a particular paleomagnetic vectorial mean and variance. Insofar as the Gaussian distribution is an appropriate description of the paleovector field, then in the limit of large number of data, the maximum-like-lihood method yields unbiased estimates of the vectorial mean intensity and the vectorial mean direction (Love and Constable, 2003), which is not usually the case with the traditional method of making separate numerical averages of intensity data and unit directional vectors (Creer, 1983).

# **Application example**

In Figure S47 we show the results (after Love and Constable, 2003) of a maximum-likelihood analysis using the 3D bi-Gaussian distribution and fitting paleomagnetic data covering the past 5 Ma from both Hawaii and Réunion. Comparison of data from these two sites is of interest since they are on almost opposite latitudes, and therefore the asymmetry seen in the data, most prominently in inclination, is indicative of mean-field ingredients other than a simple geocentric axial dipole. The Réunion data are fitted much better than the Hawaiian data by the bi-Gaussian distribution with scalar variance, and we can say, therefore, that the Réunion data are relatively "isotropic" in their vectorial variance, while the Hawaiian data display an "anisotropy" in vectorial variance. Better fits to the Hawaiian data would require the introduction of covariance into the underlying Gaussian distribution functions; nonetheless this comparative analysis is enlightening. Software for fitting the 3D Gaussian distributions to paleomagnetic data can be obtained at http://geomag.usgs.gov.

# STORMS AND SUBSTORMS, MAGNETIC

#### Introduction

Magnetic storms were first defined in the mid-19th century when large variations in the horizontal intensity of the magnetic field were measured at a variety of locations on the surface of the Earth. Although much work was subsequently initiated on this topic, it has been the space age that has led to a more detailed understanding of the phenomena involved in magnetic storms. It is now established that magnetic storms are an element of the interaction between processes that occur on the Sun, the coupling between the solar wind and the Earth's magnetosphere, and the subsequent energization of particles within the Earth's magnetosphere (Tsurutani *et al.*, 1997). Furthermore, it is clear that storms occur as a result of abnormal conditions at the Sun and in the solar wind. As a result, the effects during magnetic storms on the space environment surrounding the Earth can be serious in terms of human activities in space and on the ground.

The term "magnetospheric substorm" is used to describe a range of associated phenomena that occur in the magnetosphere. The word substorm was initially used in the early part of the 1960s to portray rapid, repeatable variations of the polar magnetic field during magnetic storms. In order to characterize the overall phenomenology of auroral disturbances, the term was modified to the auroral substorm (Akasofu, 1964), before becoming more widely incorporated as the magnetospheric substorm in the 1970s. Substorms can be considered to be part of the normal solar wind magnetosphere interaction.

#### Magnetic storms

Magnetic storms are most easily observed in equatorial or low-latitude magnetograms as a depression in the magnetic field. In order to produce a simple means of identifying a magnetic storm, the Dst index was derived, which is based on the change in the horizontal component of the magnetic field measured at a number of low-latitude stations, which are separated in longitude. A schematic representation of the Dst index for an individual storm is given in Figure S48, which illustrates the three specific intervals or phases of a storm, each of which has different timescales.

The initial phase, often but not always, follows a rapid enhancement in the Dst index, over a timescale of a few minutes, which is referred to as a storm sudden commencement (SSC) and is caused by a rapid increase in the solar wind pressure incident on the Earth's magnetosphere.

**Figure S48** A schematic representation of the Dst index during a typical magnetic storm.

The initial phase lasts up to a few hours and is the period during which the Dst remains at a high level following the SSC. The second phase is the main phase of the storm, which is the time frame over which the Dst index reduces to its minimum value and represents the period of the main energy transfer and storage into the Earth's magnetosphere. The main phase of the storm typically lasts for 5-10 h. The final phase of the storm is the recovery phase, during which the Dst returns to its prestorm values and this phase lasts for about 10-15 h. Thus, the timescale for the whole storm is typically 24-30 h. Minimum values of Dst which can be reached are typically several hundred nanoteslas.

The Dst index, however, is just a means to identify the storm. The cause of these changes in the magnetic field is in the magnetosphere and is referred to as the ring current. This current flows in a westward direction in the equatorial plane of the magnetosphere and during storms ultimately surrounds the whole Earth at a distance between about 2 and  $7R_e$  from the center of the Earth (where  $R_e$  is the radius of the Earth and is approximately 6380 km). The ring current is carried by ions in the energy range 20–200 keV and the main phase of the storm is the time during which the ring current increases in intensity while during the recovery phase the ring current decays.

The initiators of magnetic storms are solar phenomena such as coronal mass ejections, solar flares, and coronal holes. These phenomena result in unusual conditions in the solar wind, for example, high values of the solar wind density and velocity (and hence pressure) and the interplanetary magnetic field (IMF). The orientation of the IMF is central to the energy transfer from the solar wind to the magnetosphere such that when the IMF has a southward component, the energy transfer is most efficient and occurs through the process of magnetic reconnection between the IMF and the geomagnetic field.

#### Magnetospheric substorms

A magnetospheric substorm comprises three separate phases: the growth, expansion, and recovery phases (e.g., Baker *et al.*, 1996). The growth phase is the interval during which energy transfer from the solar wind is the main process and this results in storage of that energy in the tail of the magnetosphere together with a small amount of dissipation in the ionosphere. The expansion phase is the interval during which the energy that has been stored in the tail is explosively released, with some energy appearing in the ionosphere, some in the ring current, and some being lost to the solar wind. Finally, the recovery phase is an interval when the magnetosphere-ionosphere system relaxes back to a quiescent state. The overall timescale of a magnetospheric substorm is typically 2-4 h.

The growth phase of the magnetospheric substorm begins with the onset of a period of southward IMF at the dayside magnetopause, which leads to magnetic reconnection between the IMF and the geomagnetic field, thereby creating open magnetic flux, which is connected at one end to the Earth and the other to the solar wind plasma. This newly opened magnetic flux is transported by the motion of the solar wind into the magnetotail where it is added to the lobes. In this way, magnetic energy,  $B^2/2\mu_0$  per volume, is stored in the tail as the lobe magnetic flux to the tail lobes is the reorientation of the magnetic field in the near-Earth tail, for example at geostationary orbit, where the field becomes less dipolar-like and more like the stretched mid- and far-tail field. This reorientation results from the formation and subsequent intensification of a thin current sheet in the inner magnetosphere termed "crosstail current."

The expansion phase of the magnetospheric substorm is normally accepted as starting with the brightening of the equatorward most auroral arc in the nightside ionosphere. This brightening begins in a localized region near midnight and propagates along the length of the arc both westward and eastward at phase velocities of up to  $10 \text{ km s}^{-1}$ . This is then followed by a poleward expansion of the auroral luminosity at speeds of typically a few hundred m s<sup>-1</sup>. This is known as the auroral breakup because of the rapid deformation of

the original quiet arc. Accompanying the auroral breakup is a host of phenomena of which the most important with regard to expansion phase onset identification are the Pi2 pulsation and the westward electrojet, both observed in the magnetic field. Pi2 pulsations are MHD waves with periods between 40 and 200 s, which are impulsive and last for a few cycles. The westward electrojet is the current that flows in the ionosphere primarily in the enhanced conductivity region associated with the auroral activity. This electrojet is sensed on the ground by magnetometers and has characteristic spatial variations in the horizontal and vertical intensities of the magnetic field. In the near-Earth tail, the enhanced crosstail current decreases, resulting in a change in the orientation of the field back to more dipolar like. The cause of this change in the crosstail current remains uncertain and is the source of much controversy. The energy stored in the tail is released in a bursty fashion, with the trigger for the release as yet unknown, and there may be more than one burst of energy release, resulting in secondary substorm intensifications after the expansion phase onset.

The recovery phase is the phase during which the system returns to a quiescent state. Overall, this results in the magnetic field becoming less disturbed and the auroral activity declining. Despite this, however, there are still dynamic variations in the field during the recovery phase, which illustrate that the process is by no means simple.

## **Outstanding questions**

Regarding magnetic storms, the outstanding questions concern the growth and decay of the ring current. The mechanisms by which particles can be energized to increase the ring current intensity remain unclear. Furthermore, once the ring current is formed, the mechanisms, which lead to the loss of particles from the ring current and the consequent decay of the ring current, are still debated. It is likely that waves over a range of frequencies play central roles in both these processes. Debate also continues over the solar cause of magnetic storms in terms of which phenomenon is the most important.

The outstanding questions regarding magnetospheric substorms center on the expansion phase onset. Several models exist for this and can be summarized thus. Reconnection at a near-Earth neutral line in the tail (approximately 20Re downstream from Earth) leads to a disruption of the enhanced tail current formed during the growth phase. This disruption propagates earthward, resulting in signatures in the ionosphere and at geosynchronous orbit (Baker et al., 1996). Alternatively, the current disruption could be caused nearer to the Earth (approximately 6-10R<sub>e</sub>) as a result of some instability, which is responsible for the signatures in the ionosphere and geosynchronous orbit, and then propagates tailward, causing the reconnection at a near-Earth neutral line (Lui, 1996). In addition, there is a question over what triggers the expansion phase onset (Lyons, 1996). It is unclear if a threshold has to be reached in the state of the tail or whether external triggers are sufficient to drive the process. Finally, the linkage between storms and substorms is more complex than previously thought and requires further attention (Kamide et al., 1998). These and many other questions concerning magnetic storms and substorms will be answered over the next decade of space research.

# SUPERCHRONS, CHANGES IN REVERSAL FREQUENCY\*

The geomagnetic reversal timescale appears to contain intervals of four distinct durations. They are called cryptochrons, subchrons, chrons, and superchrons, with durations of the order of thousands of years, tens of thousands, hundreds of thousands, and tens of millions. Cryptochrons are observed as excursions and are interpreted as aborted reversals; empirically they are said to differ from secular variation if the geomagnetic pole moves more than  $45^{\circ}$  from the geographic pole. Theoretically an excursion differs from a pair of reversals if the intermediate state fails to completely reverse, that is change from **B** to -B(Gubbins, 1999). There is probably no theoretical distinction between subchrons and chrons. Superchrons are distinct periods of one polarity lasting longer than any natural timescale for the geodynamo. Since this implies a cause related to some longer term evolution of the Earth, such as mantle convection or inner core growth, any theory aimed at explaining superchron behavior must also address long-term changes in the frequency of reversals, unless it invokes some sudden catastrophic change in the state of the Earth's core.

Theories for long-term changes in reversal rate can be listed under five categories:

- 1. Natural nonlinear behavior of the geodynamo
- 2. Growth and changes of the inner core
- 3. Changes in lower mantle electrical conductivity
- 4. Changes in total heat flow from the core
- 5. Changes in the geographical pattern of heat flow from the core

All theories are in a very rudimentary state as it has only recently become possible to test speculations against dynamo theory.

There are two clear periods in the past when the field remained the same polarity for a considerable length of time: from about 119 to 84 million years ago (Ma) the field was normal (the *Cretaceous Normal Superchron—CNS*) while from about 312 to 262 Ma the field was reversed (the *Permo-Carboniferous Superchron—PCRS*). The CNS is established beyond doubt because it is recorded on the ocean floors; any but the shortest of reversed intervals would have been discovered by now. The PCRS is older than the oceans and therefore normal intervals may remain to be discovered.

312 Myr still represents a small fraction of the age of the Earth and of the geomagnetic field. A number of authors have suggested the possible existence of another superchron during the Ordovician (see, e.g., Gallet *et al.* (1992)). Using a global paleomagnetic database, Johnson *et al.* (1995) derived a model of long-term reversal behavior for the

\*This article was left by Jack Jacobs in manuscript form and completed by the editor D. Gubbins, who takes responsibility for all errors and omissions in the final article. last 570 Myr. In addition to the two established superchrons (the CNS and PCRS), they found a long period of very low reversal rate in the Ordovician (502–470 Ma), which they suggested may be a previously unidentified superchron.

Johnson *et al.* (1995) also found a short period of anomalously low reversal rate around the Jurassic-Triassic boundary (212–185 Ma). However, Kent and Olsen (1999) in their analysis of cores from the Newark rift basin in North America found no evidence for an interval of low reversal rate around this time. They suspect Johnson *et al.*'s results may be an artifact of sampling bias. Algeo (1996) carried out a study of geomagnetic bias patterns through the Phanerozoic. In addition to the CNS and PCRS, he found four other first order polarity features—an interval of reversed polarity bias in the middle Cambrian-middle Ordovician and three intervals of normal polarity bias in the late Ordovician-late Silurian, in the early Jurassic, and in the middle Jurassic.

Gallet and Pavlov (1996), in an analysis of data from the Moyera river section of northwestern Siberia, found very few reversals, the field being dominantly reversed from the upper Cambrian to the middle Ordovician, and normal from the upper Ordovician to the lower Silurian. However only the Avenig (140 samples) has an acceptable time resolution (~100 Myr???) and they suggested the possibility of a single reversed interval lasting at least 15 Myr during this time. This is in agreement with the result from a composite sequence for the same period by Trench et al. (1991), but not with those of Piper (1978). In a later paper, Pavlov and Gallet (1998), using data from the Kulumbe river section in the same area suggested a 25-30 Ma-long period during the lower and middle Ordovician, dominated by reversed polarity with very few reversals. Algeo (1996) also found strong polarity bias during the first half of the Ordovician. Pavlov and Gallet (2001) later returned to the Kulumbe river section, sampling older rocks, and found a sequence of 28 magnetic polarity intervals, eight of which were defined by only one sample. Since the section had a duration of  $\sim$ 5 Myr, they proposed that the magnetic reversal frequency was high (~4-6 reversals per Myr) during part of the middle Cambrian, which is amongst the highest rates known within the Phanerozoic. This reversal frequency may also have existed during the lower Cambrian. They further suggested a drastic decrease in the reversal frequency between the lower-middle Cambrian and the end of the Tremodoc (Ordovician) when a superchron may have occurred.

The reversal record suggests a gradual increase in reversal frequency since the CNS, perhaps a result of slow changes on the timescale of mantle convection. McFadden and Merrill (1984) found an approximately linear trend in the mean rate of reversals, increasing from zero at 84 Ma at the end of the CNS to over four per Myr in recent times. Visual inspection of the reversal sequence suggests that, superimposed on this linear trend, there are oscillations with a period of  $\sim$ 30 Myr There has been much controversy over the reality of a 30 Ma periodicity (or 15 Myr proposed by some authors) but on the whole the claims of periodicities are not convincing (see Jacobs (1994) for a review of the debate). Merrill and McFadden (1990) later showed the pattern of reversals to have a linear decrease in reversal frequency from about 165 to 119 Ma, the commencement of the CNS. In a further paper, McFadden and Merrill (1997) showed that the reversal rate prior to the CNS is larger than the rate after the CNS.

Gallet and Courtillot (1995) adopted a different approach, plotting the successive lengths of polarity intervals as a function of their order of occurrence in the sequence. The longer duration polarity intervals become shorter, fewer and further part to indicate a change in behavior at 15–30 Ma. Flat "white noise" characterizes the behavior from this time to the present, while a quasiperiodic structure in magnetic interval lengths is observed between 85 and 25 Ma. Such behavior is similar to that proposed by Dubois and Pambrun (1990)—low-dimensional deterministic chaos from 85–30 Ma and a random process from 25 Ma to the present.

Gallet and Hulot (1997) offered an alternative interpretation to that of McFadden and Merrill (1997) for the evolution of the geomagnetic field over the last 160 Myr. They plotted the duration of individual polarity intervals as a function of their order of occurrence (as Gallet and Courtillot (1995) had done) and suggested that the geomagnetic polarity timescale could be split into three segments with different characteristics. For the time period 160–130 Ma, they proposed that the duration of magnetic polarity intervals was constant, i.e., during this period, the reversal process, unlike that of McFadden and Merrill was stationary. They suggested that at ~130 Ma, a change occurred leading to a discontinuous decrease in reversal frequency up to the CNS. The CNS is followed by a period of gradually increasing reversal frequency until 25 Ma, when the reversal process again became steady.

McFadden and Merrill (2000) derived a new statistic to distinguish between the two extreme alternatives of themselves (1997) and of Gallet and Hulot (1997). They showed that the data between 160 and 130 Ma require a linear trend towards longer polarity intervals, this trend continuing to the beginning of the CNS, i.e., a discontinuity at 130 Ma (as proposed by Gallet and Hulot) is neither required nor supported by the data. Moreover the trend towards shorter polarity intervals from 85 Ma continues to at least 12 Ma, there being no need for a change in the reversal process at 25 Ma as demanded by Gallet and Hulot (1997). Constable (2000) obtained a new estimate for the reversal rate as a function of time and was able to obtain confidence bounds on the temporal probability density function for geomagnetic reversals. For the period 0-158 Ma, she found that the derivative of the rate functions of reversals must have changed sign at least once. The timing of this sign change is constrained to be between 152 and 22 Ma at the 95% confidence level. Unfortunately she was unable to accept or reject either of the models of McFadden and Merrill and Gallet and Hulot.

Reversal frequency estimates for earlier times are hampered by the lack of precise dating. There are very few records showing a sequence of several reversals in rocks older than 1 Ga. Opdyke and Channel (1996) compiled a histogram of the lengths of polarity intervals from 330 Ma to the present. Apart from the CNS and PCRS, the majority of polarity intervals lie in the time range from 0.1 to 1 Myr, and there are very few with durations longer than 2 Myr.

A related question is the relationship (if any) between the strength of the Earth's magnetic field and the frequency of reversals—in particular with superchrons. Fuller and Weeks (1992) have given a summary of the two opposing views—either the field is strong, or it is weak during a superchron. Pick and Tauxe (1993) found extremely low average intensity for the CNS, and low values of the geomagnetic field during the PCRS were found by Prévot and Perrin (1992) from a list of paleointensity data determined from magmatic rocks up to 3.5 Ga, and by Harcombe-Smee *et al.* (1996) from lavas in S.W.

The latest contribution to this controversial question has been given by Tarduno et al. (2001), who found high geomagnetic intensities during the mid-Cretaceous. They used single crystals of plagioclase feldspar from eight independent lava flows that erupted at different times within 0.1-1 Ma from basalts of the Raymahal Traps of India (113-116 Ma). The average value from all the flows and the 56 crystals with reproducible data are taken to represent the true dipole field during the CNS. The averaging process removes possible sources of error in the magnitude of the virtual dipole moment from the highly variable (in space and time) nondipole components of the field, which vary on a timescale shorter than 10 kyr and hence cancel out unless data are averaged over 0.1-1 Myr. Their value of the mean intensity of the field is significantly higher than other values for the past 180 Myr, and the times of the mean paleointensity for the mean Cenozoic and early Cretaceous-late Jurassic when reversals were frequent. The question is still open.

Turning to theory, we must first ask whether the geodynamo could move spontaneously between reversing and nonreversing states, whether in fact no special external changes are required at all to produce superchrons. The longest natural mescale is the magnetic diffusion time (see *Geodynamo, dimensional analysis and timescales*), 25 kyr. If this Ordovician low reversal rate is substantiated, the 200 Ma spacing between the CNS, PCRS, and the Ordovician superchron would be a fundamental time constant for long-term geomagnetic field behavior, simulation for anything like this time, but studies of simpler systems suggest it is highly unlikely (Jones and Wallace, 1992). Barring some dramatic new findings, we can be fairly confident that some change is needed external to the liquid core.

The inner core is known to stabilize numerical dynamo simulations (Hollerbach and Jones, 1993). It is growing slowly as the Earth cools (see *Geodynamo, energy sources*), and was therefore smaller in the past. This may have made superchrons less likely in the distant past (Gubbins, 1999). Some dynamo calculations have more stable solutions without an inner core (Morrison and Fearn, 2000) because the two hemispheres are better connected, but this may be a special feature of this weakly driven model. For the inner core to account for the changes since the Ordovician superchron it would have to change size very significantly in 100 Myr, and repeatedly, with implied warming of the entire core. There is as yet no evidence for this, so the theory must remain a long shot.

This leaves changes in the lower mantle, which controls the boundary conditions for the geodynamo. The electrical conductivity of the lower mantle could have an effect if it were large enough, for example in substantial regions of entrained iron. This idea appears in theories of short-term core-mantle coupling (see Core-mantle coupling) and of reversal transition fields (Herrero-Bervera and Runcorn, 1997), but to affect the geodynamo seriously the highly conductive layer would have to be of 10–100 km thick, and this would affect the short term secular variation in a way that would surely have been observed by now.

This leaves thermal effects, which have received most attention to date. One idea is that a change in the style of mantle convection draws more heat from the core, as might follow for example from a major reorganization of the plate boundaries at the Earth's surface (it is interesting to note that Venus had a resurfacing event at 500 Ga and no longer has plate tectonics or magnetic field, but it may have had both in the past). Naïvely one might expect the geomagnetic field to be stronger and also to reverse in unstable fashion if the geodynamo is being driven hard, and weak and stable if the driving is weak. However, Pal and Roberts (1988) and Larson and Olson (1991) argued persuasively that the field is strong during a superchron, arguing that a thin D" layer at the bottom of the mantle would increase heat flow from the outer core (OC) to the mantle and so create more vigorous convection in the OC. The associated heat loss would lead to a strong, stable, nonreversing field (a superchron). Loper and McCartney (1986), McFadden and Merrill (1986) and Courtillot and Besse (1987), on the other hand, had argued earlier against a strong magnetic field during a superchron, which they claimed represents a low energy state with infrequent instabilities corresponding to inactive periods in the D" later when it is thick and heat transfer across the CMB relatively small. This view receives some support from dynamo studies (Jones and Wallace, 1992), which now include some sophisticated 3D numerical simulations (Kutzner and Christensen, 2002), although their reversing solutions do not resemble the geomagnetic field very much. Further support for low field strength during a superchron has been given by Hide (2000), who carried out a mathematical investigation of nonlinear processes in self-exciting dynamos. In his models the maximum strength of the magnetic field could be systematically higher when reversals are frequently than when they are infrequent. He suggested that a superchron is associated with a long quiescent period when convection in the lower mantle is comparatively feeble.

The second idea invokes changes not in the average heat flux from the core but the lateral variations in heat flux into the lower mantle (see *Core-mantle coupling, thermal*). These lateral variations almost certainly affect convection in the core, and there have been a number of geodynamo simulations that incorporate inhomogeneous thermal boundary conditions. A change in this pattern, which at present has high heat flow around the Pacific and low below Africa and the central Pacific, may change the style of convection from one that allows reversals to one that does not. There is some evidence for this in recent simulations (Glatzmaier *et al.*, 1999). The theory has the appeal of a 930

natural process of evolution of the Earth with the right timescale. This study also indicates correlations between the frequency of reversals, the direction, and the strength of the magnetic field. The most stable geodynamo (i.e., nonreversing, low SV) is the most efficient with the highest dipole moment. The near future will surely bring some exciting new insights into this problem.

# SUSCEPTIBILITY

What is magnetic susceptibility? This is a question I use to ask students, and I have got many different answers. One even said that it is the number on the display of instrument used. It is true that one can find several definitions of this physical parameter, more or less correct. For example, Encyclopedia Britannica gives quite nice description, saying that magnetic susceptibility is "quantitative measure of the extent to which a material may be magnetized in relation to a given applied magnetic field." Let us improve this definition, saying that magnetic susceptibility is a parameter characterizing the nature and intensity of response of material to external magnetic field.

Since magnetic properties of materials are mostly studied by applying a magnetic field  $(\mathbf{H})$  and measuring the magnetization  $(\mathbf{M})$  induced in these materials, magnetic susceptibility is defined by equation relating  $\mathbf{M}$  and  $\mathbf{H}$ :

$$\mathbf{M} = \chi_{\mathbf{v}} \mathbf{H},$$

which yields

 $\chi_{\rm v} = \mathbf{M}/\mathbf{H},$ 

where the subscript v denotes "volume." Thus,  $\chi_v$  is a material parameter—transfer function, linking induced magnetization and applied magnetic field.

Magnetization induced by the applied magnetic field is due to the effect of the field upon moving charged particles. Magnetism is characteristic of all materials containing charged particles. Since contribution of nucleons is very small and can be neglected, magnetism can be considered as practically entirely of electronic origin. Thus, magnetic susceptibility can be used to classify materials in terms of their response to external magnetic field as *diamagnetics*, *paramagnetics*, and a group of *ferrimagnetics* (for more details, reader is referred to, e.g., Dekker (1957) or Dunlop and Özdemir (1997)).

However, the above definition of magnetic susceptibility is only valid for linear behavior of induced magnetization in dependence of the applied magnetic field. In other words, it can only be applied to diamagnetic or paramagnetic materials, or ferrimagnetics in the range of magnetic saturation. In all other cases, and these are more common in natural rocks and minerals, more general definition applies

$$\chi_{v} = \frac{\partial \mathbf{M}}{\partial \mathbf{H}}\Big|_{\mathbf{H},\mathbf{M}} \quad \text{or } \chi_{v} = \lim_{\Delta H \to 0} \frac{\Delta \mathbf{M}}{\Delta \mathbf{H}}\Big|_{\mathbf{H},\mathbf{M}}$$

Mathematically speaking, it represents an angle between the tangent to the *magnetization curve*  $M(\mathbf{H})$  at given  $\mathbf{H}$  and the H axis, and in physics literature a term reversible susceptibility is sometimes used, or differential for  $\mathbf{H} = \mathbf{M} = 0$ . From this it is clear, that magnetic susceptibility depends not only on the material and the applied field, but also on the way it is measured.

Diamagnetic susceptibility rises from the distortion of electronic orbit due to applied magnetic field, forcing the electrons to additional precession motion. It is very small, negative, and independent of temperature and magnetic field

$$\chi_{\rm v} = -\frac{z\mu_0 \mathrm{e}^2 \overline{a^2} n}{6m_0},$$

where z is the number of electrons in atom, n is the number of atoms in unit volume,  $\overline{a^2}$  is the median of square of distances of electrons from the nucleus. The magnitude of diamagnetic susceptibility is very small, in the range of  $10^{-6}$  cgs Most organic compounds are diamagnetic only. Among minerals, diamagnetism is expressed in quartz, plagioclase, calcite, and apatite.

In paramagnetic substances, the constituent atoms have unpaired electrons, resulting in a net magnetic moment. At room temperature, the individual atomic moments are randomly oriented. If an external magnetic field is applied, they will tend to become aligned in a direction parallel to the external field. The resulting induced magnetization is called paramagnetic, and the corresponding susceptibility is defined by Curie law (first empirically derived by P. Curie in 1895):

$$\chi_{\rm v} = \frac{C}{T}$$

where 
$$C = \frac{M_{\infty}^2}{3n\mu_0 k}$$
 and  $M_{\infty} = nM$ , k being the Boltzman constant

The variation of the inverse susceptibility with temperature is linear, with slope 1/C, which is related to the number of unpaired electrons in the substance (*n*). The magnitude of paramagnetic susceptibility is in the range of  $10^{-3}-10^{-6}$  cgs and is temperature dependent (Figure S49).

Temperature (K)

Figure S50 Temperature dependence of inverse susceptibility for paramagnetics (left), ferrimagnetics (middle) and antiferromagnetics (right).

In nature, paramagnetic minerals may include clay minerals (chlorite, smectite, and glauconite), iron and manganese carbonates (siderite, rhodochrosite), ferromagnesian silicates (olivine, amphiboles, pyroxenes, etc.), as well as a variety of ferric-oxyhydroxide mineraloids.

In paramagnetic substances, individual atomic magnetic moments do not interact with each other. However, in many materials, interactions (of quantum-mechanic nature) between atomic moments result in spontaneous parallel (or antiparallel) alignment of atomic magnetic moments in the absence of external magnetic field, typical for a group of ferromagnetic, ferrimagnetic, and antiferromagnetic materials (all called herein as ferrimagnetics). In these materials, Curie's law is not obeyed and magnetization curve  $M(\mathbf{H})$  is not linear, but shows *hysteresis*, instead. In this case, magnetic susceptibility cannot be expressed on the basis of classical theory, as in the case of dia- or paramagnetism. However, above the transition *Curie* (*Néel*) *temperature*, material behaves paramagnetically, and the inverse value of magnetic susceptibility follows a linear line defined by Curie-Weiss law (Figure S50):

$$\chi_{\rm v}=\frac{C}{(T-T_P)},$$

where  $T_P$  is Weiss constant, often called paramagnetic Curie temperature. Note that mathematically  $T_P$  can be <0 K, which is physically impossible, but typical for antiferromagnetics. Typical ferrimagnetics are, for instance, magnetite and maghemite, while hematite is antiferromagnetic. There are no true ferromagnetic minerals in nature.

Magnetic response of ferrimagnetics becomes stronger as the number of unpaired electrons increases. Therefore, it is customary to measure magnetic susceptibility of a substance as a function of its weight, yielding mass-specific susceptibility. In order to distinguish the volume and mass-specific susceptibility, the former one is commonly denoted with  $\kappa$  (unlike most physics literature), while  $\chi$  is used for the latter one:

$$\chi = \frac{\kappa}{\rho},$$

where  $\kappa$  replaced  $\chi_v$  and  $\rho$  is density.

Mass-specific susceptibility is related to molar susceptibility  $\chi_M$  by

$$\chi_{\rm M} = \frac{\chi W_{\rm M}}{Z},$$

where  $W_{\rm M}$  is molar weight of the substance and Z is the number of moles. After some more calculations and simplifications, one can arrive at an expression for the effective magnetic moment of an ion:

$$\mu_{\rm eff} = 2.828 \left[ \chi_{\rm M} (T - T_P) \right]^{1/2}.$$

Regarding the fact that magnetization curve of ferrimagnetics is not linear, experimental determination of magnetic susceptibility depends also on the intensity of magnetic field (or point of the  $M(\mathbf{H})$  curve, at which it is measured), and on the way how it is measured. Therefore, in physics literature one can find terms initial, reversible, and differential magnetic susceptibility (Figure S51).

In terms of the applied magnetic field, frequency of the AC field has significant effect in case of presence of ultrafine super-paramagnetic

**Figure S51** Reversible and differential susceptibility as a function of the magnetic field at which the slope of magnetization curve is determined.  $\chi_P$  stands for initial susceptibility.

Figure S52 Schematic dependence of frequency-dependent magnetic susceptibility on grain size (after Dearing, 1994).

particles. At higher frequencies, energy of thermal excitations overcomes the alignment effect of the applied field and, consequently, magnetic moments of such particles are not aligned parallel to the applied field and do not contribute to magnetic susceptibility. Therefore, magnetic susceptibility measured at higher frequencies is always equal or lower than that measured at lower frequencies. Difference, expressed as percentage, is called frequency-dependent magnetic susceptibility (Figure S52),

$$\chi_{FD} = \frac{\chi_{LF} - \chi_{HF}}{\chi_{LF}}. \label{eq:constraint}$$

While  $\chi_{FD}$  depends strongly on grain size (e.g., Eyre, 1997; Dearing *et al.*, 1996), and is used as indicator of significance of SP particles, magnetic susceptibility itself depends mostly on mineralogy, and for a given mineral on its concentration.

# SUSCEPTIBILITY, MEASUREMENTS OF SOLIDS

#### Introduction

Magnetism is a property characteristic of all materials that contain electrically charged particles. A moving electrical charge (i.e., electric current) gives rise to a magnetic field in a material. The contribution of nucleons to the magnetic field in substances is small and requires special instrumentation to observe. For the purpose of this laboratory the effect from nucleons is neglected, thus magnetism may be considered to be entirely of electronic origin. In an atom, the magnetic field is due to the coupled orbital and spin magnetic moments associated with the motion of electrons. The orbital magnetic moment is due to the motion of electrons around the nucleus whereas the spin magnetic moment is due to the precession of the electrons about their own axes. The resultant of the orbital and spin magnetic moments of the constituent atoms of a material gives rise to the observed magnetic properties.

Knowledge about the magnetic properties of materials is an important aspect in the study and characterization of substances. Unlike many others, commonly employed analytical methods, magnetic property characterization is a nondestructive technique.

#### Theory

Often magnetic properties of materials are studied by applying a magnetic field and measuring the induced magnetization in these materials. The magnetic induction, B, that a substance experiences when placed in an applied external magnetic field, H, is given by the expression

$$B = H + 4\pi M, \tag{Eq. 1}$$

where M is the magnetic moment of the compound per unit volume or the Magnetization. The volume susceptibility of the compound,  $\chi_{\nu}$ , is defined as the ratio of the induced magnetic moment per unit volume to the applied field:

$$\chi_v = M/H. \tag{Eq. 2}$$

The two most important responses observed are characterized as diamagnetic and paramagnetic moment (Figure S53). As shown in this figure, the applied magnetic field remains unaffected in a vacuum but is attracted by a paramagnetic, and repelled by an ideal diamagnetic media.

In diamagnetic materials, all the electrons in the atoms are paired (e.g.,  $H_{2(g)}$ ,  $NaCl_{(s)}$ ) and the resultant magnetic moment is zero due to the absence of unpaired electrons. The external magnetic field induces a current whose associated magnetic field is directed opposite to the applied field. The induced magnetic moment associated with this field is called a diamagnetic moment and is negative relative to the applied magnetic field and independent of temperature. The magnitude of the diamagnetic susceptibility is usually small, in the range of  $10^{-6}$  cgs units. All inert gases and most organic compounds are examples of diamagnetic materials.

In paramagnetic materials, the constituent atoms have unpaired electrons resulting in a net magnetic moment. Generally at room temperature, the individual magnetic moments are randomly oriented as shown in Figure S54 above. If an external magnetic field is applied to these randomly oriented intrinsic magnetic moments, they will tend to become aligned in a direction parallel to the external magnetic field.

The magnetic moment induced in such materials by the application of an external magnetic field is called a paramagnetic moment. The magnitude of the susceptibility of paramagnetic substances is in the range of  $10^{-3}$ – $10^{-6}$  cgs units and is positive. Typical paramagnetic compounds include gaseous compounds like molecular oxygen (O<sub>2</sub>) and nitric oxide (NO), vapors of alkali metals and certain salts of transition and rare-earth metals.

The alignment of the magnetic moments of a paramagnetic substance under an applied magnetic field is opposed by the thermal motion of the magnetic ions which tends to randomize the moments. Hence the observed paramagnetic susceptibility of a substance increases with decreasing temperature since the effect of thermal

**Figure S53** Behavior of applied magnetic field in different media: (a) vacuum, (b) paramagnet, and (c) ideal diamagnet.

Applied field, H = 0

Figure S54 Random orientation of magnetic moments in paramagnetic material.

**Figure S55** (a) Magnetic susceptibility and (b) inverse magnetic susceptibility dependence on temperature of a paramagnetic material.

motion is minimized at lower temperatures (Figure S55). According to Curie's Law,

$$\chi_{\rm M} = \frac{C}{T} \tag{Eq. 3}$$

the susceptibility of a paramagnetic substance is inversely proportional to temperature where *C* is the Curie constant. The variation of the inverse magnetic susceptibility  $(\chi_M^{-1})$  with temperature is linear. The slope of this line is equal to 1/C. The value of *C* is related to the number of unpaired electrons present in the compound by the following expression

$$(8C)^{1/2} = g[S(S+1)]^{1/2} = [n(n+2)]^{1/2},$$
 (Eq. 4)

where Lande's factor  $g \approx 2.0$  for an electron or ion with no orbital contribution to the magnetic moment and *S* is the resultant spin quantum number (it is the total spin angular momentum of all the unpaired electrons in the system), and *n* is the number of unpaired electrons in the system (i.e., S = n/2). Equation (4) is generally valid for compounds of most of the first row transition metals, where the orbital contribution to the magnetic moment is completely quenched and only the spin contribution, *S* need be considered. This will be discussed in more detail subsequently.

Figure S55 shows the plot of  $\chi$  versus *T* and  $1/\chi$  versus *T* (*T* in absolute temperature, K) typical for a paramagnetic substance in which orbital contribution to the susceptibility is negligible.

Paramagnetic materials, besides having unpaired electrons, contain paired electrons in the inner (closed) shells of the constituent atoms.

**Figure S56** Types of magnetic ordering: (a) ferromagnetic, (b) antiferromagnetic, and (c) ferrimagnetic.

The presence of these paired electrons makes diamagnetism an inherent property of all materials. Thus the magnetic moment measured is in fact the sum of both paramagnetic (positive quantity) and the associated diamagnetic (negative quantity) moment. Since the presence of an intrinsic magnetic moment in a substance results in a large paramagnetic moment, the diamagnetic effects are often neglected in the calculations. However, if the paramagnetic and diamagnetic moments of the substance under investigation are of comparable magnitude, and where accurate measurements are desired, corrections due to the diamagnetic contributions are made to the measured magnetic moments.

So far we have considered paramagnetic substances in which there are no significant interactions between the magnetic moments of its atoms. However, magnetic moments of individual atoms in many substances do interact with each other in several different ways. In these materials, Curie's law is not obeyed; often, the magnetic behavior of these substances is best described by a Curie-Weiss law which takes into account the interactions among the individual magnetic moments

$$\chi_{\rm M} = \frac{C}{(T-\theta)},\tag{Eq. 5}$$

where  $\theta$  is the Weiss constant (or paramagnetic Curie temperature).

Interactions of magnetic moments in condensed systems (i.e., solids) will in most cases lead to different types of magnetic ordering, characteristic of the substance. This is shown in Figure S56 where the net spin on each atom is represented by an arrow aligned "with" or "against" the applied external magnetic field. The type of magnetic interactions present in a particular substance is primarily determined by the nature of the constituent ions and chemical bonds. The magnetic interactions between the individual magnetic moments result in a net stabilization energy. The two most common types of magnetic ordering or interactions are called ferromagnetism and antiferromagnetism. In ferromagnetic substances, the magnetic moments of adjacent atoms are aligned parallel to one another below a certain critical temperature (known as the Curie temperature,  $T_c$ ) as shown in Figure S56a. This type of magnetic ordering is characterized by a spontaneous magnetization of the substance below  $T_c$  even in the absence of an external magnetic field. Iron, nickel, and cobalt and some rare-earth metals, as well as some compounds and alloys of these elements are typical examples that show ferromagnetic ordering.

In antiferromagnetic substances, the individual magnetic moments are aligned antiparallel to one another below a certain critical temperature (known as Néel temperature,  $T_N$ ). This interaction gives no net magnetization when the neighboring atoms have magnetic moments of identical magnitude as shown in Figure S56b. Most compounds of the transition elements such as MnO, MnF<sub>2</sub>, FeCl<sub>2</sub>, and elements such as chromium,  $\alpha$ -manganese and some rare-earth metals such as cerium, praseodymium, neodymium, samarium, and europium display antiferromagnetic ordering. Compounds that exhibit ferromagnetic or antiferromagnetic type of magnetic ordering often obey the Curie-Weiss law (5) at temperatures well above the transition temperatures (ordering temperature,  $T_c$  or  $T_N$ ).

Ferrimagnetism is another prevalent type of ordering of the magnetic moments. In a ferrimagnetic substance, although the individual magnetic moments of adjacent atomic particles are aligned antiparallel, they are not of equal magnitude (i.e., when the type of interacting neighboring atoms are different), e.g.,  $Fe_3O_4(FeO \cdot Fe_2O_3)$ .

As expected, the magnetic response becomes stronger, as the number of unpaired electrons present increases. Hence it is customary to measure experimentally the magnetic susceptibility of a substance as a function of its weight,  $\chi_g$ 

$$\chi_{\rm g} = \chi_{\nu} / \rho, \tag{Eq. 6}$$

where  $\chi_g$ , the mass susceptibility of the compound, is the induced magnetic moment per unit mass per unit applied magnetic field, and  $\rho$  is the density of the material.

The mass susceptibility of the compound is related to the molar susceptibility,  $\chi_M$ 

$$\chi_{\rm M} = \chi_{\rm g} \cdot {\rm MW}/Z, \tag{Eq. 7}$$

where MW is the molecular weight of the compound and Z is the number of moles of magnetic ions per formula weight of the compound. The molar magnetic susceptibility of a compound having isolated magnetic ions with no magnetic interactions is given by (assuming total quenching of orbital moments)

$$\chi_{\rm M} = \frac{N_{\rm A} \beta^2 g^2 S(S+1)}{3k_{\rm B}T}.$$
 (Eq. 8a)

In the above expression,  $N_A$  is Avogadro's number,  $k_B$  is the Boltzmann constant, and  $\beta$  is a constant unit called the Bohr magneton (BM). Note that (8a) is similar to that shown by Curie's law which was derived from experimental observations, giving the Curie constant, *C* 

$$C = \frac{N_{\rm A}\beta^2 g^2 S(S+1)}{3k_{\rm B}}.$$
 (Eq. 8b)

As discussed above, in condensed systems, e.g., liquids and solids, generally there are some magnetic interactions between the magnetic ions such that a modified Curie's law known as the Curie-Weiss law is applied

$$\chi_{\rm M} = \frac{N_{\rm A} \beta^2 g^2 S(S+1)}{3k_{\rm B}(T-\theta)}.$$
 (Eq. 9)

In substances with interacting magnetic moments and where the orbital contribution to the magnetic moments is significant, the molar susceptibility is given by

$$\chi_{\rm M} = \frac{N_{\rm A} \beta^2 g^2 J(J+1)}{3k_{\rm B}(T-\theta)},$$
 (Eq. 10)

here the resultant total angular momentum, J, is given by

$$J(J+1) = L(L+1) + S(S+1),$$
 (Eq. 11)

and the value of g factor is given by Landé's equation:

$$g = 1 + \frac{S(S+1) - L(L+1) + J(J+1)}{2J(J+1)}.$$
 (Eq. 12)

The quantum number L is the resultant orbital angular momentum of all unpaired electrons present in the atom (i.e., L is zero for a completely filled orbital). However for most compounds of the first row

transition metal series, the orbital contribution to the magnetic moment is negligible, such that J = S and (10) is identical to (9). In these and other compounds of the transition metal series the metal ions are typically surrounded by strong ligands that quench the orbital contribution to the magnetic moment.

Equation (9) can be further simplified by defining  $\mu_{\text{eff}}^2$  as  $g^2 S(S+1)$  and combining all of the constants to give:

$$\chi_{\rm M} = \left(\frac{N_{\rm A}\beta^2}{3k_{\rm B}}\right) \frac{\mu_{\rm eff}^2}{(T-\theta)} \approx 0.125 \frac{\mu_{\rm eff}^2}{(T-\theta)}.$$
 (Eq. 13)

This equation allows us to calculate the effective magnetic moment of an ion,  $\mu_{\rm eff}$ , which can be rewritten as

$$\mu_{\rm eff} = 2.828 [\chi_{\rm M}(T-\theta)]^{1/2}, \qquad ({\rm Eq. 14})$$

where  $\chi_M$ , the molar susceptibility, is obtained from (7) and *T* is the temperature in Kelvin.

#### Instrumentation

In this experiment, the method to be used in the measurement of the magnetic susceptibility of substances is based on the principle of stationary sample but moving magnet. Here, the balance (i.e., Johnson Matthey Magnetic Susceptibility Balance, MSB), measures the force that the sample exerts on a suspended permanent magnet, unlike the Gouy balance which measures the equal and opposite force which a magnet exerts on the sample.

In the experiment that follows, the mass susceptibility of a compound,  $\chi_g$ , to be used in (7) is calculated from the quantities obtained using the MSB by the following formula

$$\chi_{\rm g} = \frac{LC_{\rm bal}(R - R_0)}{(m \times 10^9)},$$
 (Eq. 15)

where  $C_{\text{bal}}$  is the calibration constant of the balance, *L* is the length in centimeters (cm) of a well-packed sample in the tube, *m* is sample mass in grams (g), *R* is the reading obtained for the tube plus sample,  $R_0$  is the empty tube reading (normally a negative value, i.e., diamagnetic).

The MSB must be calibrated with the standard compound, HgCo(SCN)<sub>4</sub> which has a  $\chi_g = 16.44 \times 10^{-6}$  cgs at 20°C. This first measurement is required for the calculation of the calibration constant of the balance,  $C_{\text{bal}}$ , in (15).

#### **Experimental procedure**

- 1. Turn the *Range* Knob to  $\times 1$  scale and let the MSB warm up for.
- 2. Adjust the MSB to read 000 using the Zero knob when no tube is inside the tube guide.

Many of the following steps may not be required if we supply preprepared samples.

- 3. Place the empty tube into the tube guide of MSB, and record the reading,  $R_0$  (normally a negative value, i.e., diamagnetic).
- 4. Remove the empty tube from the MSB and weigh it carefully on a balance to the nearest milligram; record the mass of the empty tube in grams,  $m_{\rm t}$ .
- 5. Prepare your sample for measurement by grinding (if not already in a powdered form). Sample must be ground to a fine powder in a mortar and pestle.
- 6. Introduce your sample into the preweighed empty tube and tap (the sample tubes are expensive, made of brittle quartz materials; so tap them gently to avoid breakage) on a wooden bench several times to achieve densely packed (i.e., minimum empty space

between grains) sample. The length of the well packed sample in the tube should be between 2.5 and 3.5 cm (or a length appropriate to the diameter of the tube being used, as suggested by the manufacturer of the MSB).

- 7. Place the packed tube into the tube guide in the MSB, wait for stable reading before recording this first reading,  $R_1$ . If the reading is off-scale, remove the packed tube, set the *Range* Knob to  $\times 10$  scale and then *rezero* the MSB before putting back the packed sample. Record your reading, but remember to multiply this reading by 10.
- 8. Remove the packed tube from the MSB and tap it several times to further compress the solid in the tube and remove any trapped air.
- 9. Place the packed tube back into the tube guide in the MSB, and record a second reading,  $R_2$ . If this second reading ( $R_2$ ) is not the same as the first reading ( $R_1$ ), then repeat further the tapping/measuring sequence until *two* successive readings are the same. Even packing gives constant reading hence tap the sample tube gently till a constant reading is indicated.
- 10. Take the temperature reading, *T*, of the area around the MSB; remove the packed tube from the MSB and measure the sample length in the tube in centimeters, *L*.
- 11. Immediately, measure the mass of the packed tube on a balance and record its mass in grams,  $m_{t,s}$ , find the actual mass of the sample (*m*) in the packed tube in grams by subtracting the mass of the empty tube ( $m_t$ ) from this value; i.e.,

 $m = m_{\mathrm{t,s}} - m_{\mathrm{t}}$ .

- 12. Do another measurement of the same sample by repacking the same tube and following the procedures above. (Note: data for the same empty tube, i.e.,  $R_0$  and  $m_t$  should remain the same.)
- 13. Clean the tube by tapping out the powder, followed by several washings with a squirt bottle filled with soapy water. Finally rinse and dry with acetone.

#### Calculations and worked examples

- 1. Calculation of the calibration constant,  $C_{\text{bal}}$ :
  - (a) HgCo(SCN)<sub>4</sub> has a  $\chi_g = 16.44 \times 10^{-6}$  cgs at 20°C

$$\chi_{\rm g}$$
 at  $T \,^{\circ}{\rm C} = \frac{4\,981}{(283+T)} \times 10^{-6}\,{\rm cgs}$ 

then at  $T = 21.0 \,^{\circ}\text{C}, \chi_{\text{g}}$  is

$$\chi_{\rm g} = \frac{4981}{(283+21)} \times 10^{-6} \, {\rm cgs} = 16.38 \times 10^{-6} \, {\rm cgs}.$$

(b) Refer to Table S3, data No. 1 for HgCo(SCN)<sub>4</sub>;

$$\chi_{\rm g} = \frac{LC_{\rm bal}(R-R_0)}{(m\times 10^9)},$$

on rearranging;

 $C_{\rm bal} = \frac{\chi_{\rm g}(m \times 10^9)}{L(R - R_0)}.$ 

Hence for  $T = 21.0 \,^{\circ}\text{C}$ ,  $C_{\text{bal}}$  becomes;

$$C_{\text{bal}} = \frac{16.38 \times 10^{-6} (0.5082 \times 10^9)}{3.25(2\,120 - (-31))} = 1.19076.$$

(c)  $\chi_g$  for Ni(en)<sub>3</sub>S<sub>2</sub>O<sub>3</sub> refer to Table S3, data No. 2;

$$\chi_{\rm g} = \frac{LC_{\rm bal}(R-R_0)}{(m\times10^9)} = \frac{3.30\times1.19076(750-(-31))}{(0.2787\times10^9)},$$

Table S3 The list of chemicals to be used in this experiment

No.	Chemical	MW (g mole $^{-1}$ )
Standard	HgCo(SCN)4	491.85816
1	MnSO <sub>4</sub> ·2H <sub>2</sub> O	187.03221
2	MnO <sub>2</sub>	86.93685
3	Cu(HCOO) <sub>2</sub> ·H <sub>2</sub> O	171.59676
4	Mn <sub>2</sub> O <sub>3</sub>	157.8743
5	$Ni(en)_3S_2O_3$	351.1206
6	KMnO <sub>4</sub>	158.03395
7	$K_4Fe(CN)_6\cdot 3H_2O$	422.39248
8	$Co(NH_4)_2(SO_4)_2 \cdot 6H_2O$	395.22908
9	$Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$	392.14288
10	$K_2Cr_2O_7$	294.18476

i.e.,  $\chi_{\rm g} = 11.01 \times 10^{-6} \, {\rm cgs}$  at  $T = 21.0 \, {}^{\circ}{\rm C}$ .

Compare this value of  $\chi_g$  for Ni(en)<sub>3</sub>S<sub>2</sub>O<sub>3</sub> with the value given in literature, i.e.,  $\chi_g$  at 20.0 °C = 11.04 × 10<sup>-6</sup> cgs and since

$$\chi_{\rm g}$$
 at  $T^{\circ}C = \frac{2759}{(230+T)} \times 10^{-6}$  cgs;

then

$$\chi_{\rm g}$$
 at 21.0 °C =  $\frac{2759}{(230+21)} \times 10^{-6}$  cgs = 10.99 × 10<sup>-6</sup> cgs.

2. Worked examples: refer to Table S3, data for  $\alpha$ -MnS (data No. 4)

$$\chi_{\rm g} = \frac{LC_{\rm bal}(R-R_0)}{(m \times 10^9)} = \frac{3.15 \times 1.19076(8\,840 - (-27))}{(0.5358 \times 10^9)}$$

i.e., 
$$\chi_g = 62.07 \times 10^{-6}$$
 cgs at  $T = 23.0$  °C.  
Hence  $\chi_M$  for this compound can be calculated using (7),  
i.e.,  $\chi_M = \chi_g \times MW/Z = 62.07 \times 10^{-6} \times 87.002$  g mol<sup>-1</sup>, since  
 $Z = 1$  for  $\alpha$ -MnS,  
therefore,  $\chi_M = 5.40 \times 10^{-3}$  emu mol<sup>-1</sup>.

To calculate the effective magnetic moment,  $\mu_{\text{eff}}$ , we make use of (14), i.e.,

$$\begin{aligned} \mu_{\rm eff} &= 2.828 (\rm emu\,mol^{-1}\,K)^{-1/2} [\chi_{\rm M}(T-\theta)]^{1/2} \\ &= 2.828 (\rm emu\,mol^{-1}\,K)^{-1/2} [5.40\times10^{-3}\,\rm emu\,mol^{-1} \\ &\quad (296-(-490)\,K]^{1/2} \\ &= 5.83\,\rm BM. \end{aligned}$$

The students will study a series of first row transition metal compounds to determine the oxidation state of the ion in each compound and the number of unpaired electrons, from the measurement of the magnetic susceptibility. The compounds will include various transition metal complexes varying in different number of *d*-electrons. The students will directly measure the mass susceptibility of each compound using a Magnetic Susceptibility Balance (MSB, Johnson Matthey model). Given the values of Curie constant ( $\theta$ ) for each compound, the students will be able to find the effective magnetic moment of the manganese ion from the measured values of the molar susceptibility of each compound using (14), hence will be able to calculate the number of unpaired electrons.

# SUSCEPTIBILITY, PARAMETERS, ANISOTROPY

One of the main interests in the determination of the low field anisotropy of magnetic susceptibility (AMS) is its value as a petrofabric indicator. An important part of the interpretation of AMS measurements in this context involves the orientation of the principal susceptibilities. Several methods of calculating mean directions of the principal susceptibilities, and associated regions of confidence have been devised, but the tensor-averaging technique will provide a better estimate in most circumstances (Ernst and Pearce, 1989). Also, different methods have been proposed to estimate regions of confidence around the mean principal susceptibilities. When the individual measurements are not very different from the calculated mean (in which case it is said that the uncertainty is not large), the regions of confidence calculated with different methods are similar to each other and exert a small influence in the interpretation of results. When the uncertainty in the mean susceptibility is large, however, the regions of confidence found with different methods can be very different (Tauxe, 1998). Nevertheless, instead of entering in a pointless discussion concerning which statistical method is better suited for every specific case, when a large scatter of directions of principal susceptibilities is found it is more significant to check whether the individual data used for the calculation of the average directions of susceptibility might include systematic variations of principal susceptibilities with a well-defined physical meaning. The identification of different statistical populations made in this form not only provides a more meaningful interpretation of AMS results than an interpretation based in a very rigorous statistical treatment that does not acknowledge physical controls on the mineral fabric, but also leads to situations in which the uncertainty associated with the average of each AMS population is relatively small. Consequently, by adequately identifying systematic fluctuations in the AMS of a rock unit and associating them with changes in the physical conditions controlling the magnetic fabric (like for example at opposite sides of a tabular intrusive where shear direction is expected to be different in orientation), it turns out that the method used in the calculation of the associated regions of confidence is relatively unimportant.

On the other hand, sometimes is necessary to concentrate our attention in the numeric components of the susceptibility tensor. This part of the analysis may be somewhat problematic not only because of the large number of AMS parameters that have been proposed over time (Tables S4 and S5), but also because the parameters used in a particular analysis generally are selected based more on previous use than on some objective criteria. Historically, five classes of AMS parameters have been defined: Bulk susceptibility, foliation, lineation, shape, and degree of anisotropy. Among these, the bulk susceptibility is the only one that has a well-defined physical meaning. Whether it is calculated as the arithmetic or the geometric average of the three principal susceptibilities, the bulk susceptibility is one of the three invariants associated with any second rank tensor, and consequently it is a measure of susceptibility independent of the coordinate system used as a reference frame.

In contrast, the physical meaning of all the other AMS parameters is less clear, and even it may be controversial. For instance, the lineation parameters were proposed to supposedly yield a measure of the intensity of alignment of elongated particles as detected through AMS

Table S4 Shape parameters

	Parameters	Name	Range	Group	Source
1.	$(k_1 - k_2)/(k_2 - k_3)$	Prolateness	0 to		(Khan, 1962)
2.	$(k_2 - k_3)/(k_1 - k_2)$	Oblateness	0 to		(Khan, 1962)
3.	$a \sin\{(k_2 - k_3)/(k_1 - k_3)\}^{1/2}$	Angle V	0 to 90		(Graham, 1966)
4.	$(2k_2 - k_1 - k_3)/(k_1 - k_3)$	Difference shape factor	-1 to 1		(Jelinek, 1981)
5.	$(k_1 - k_2)/\{(k_1 + k_2)/2 - k_3\}$	q factor	0 to 2	S1	(Granar, 1957)
6.	$(k_2(k_1-k_2))/(k_1(k_2-k_3))$	-	0 to		(Janak and Hrouda, 1969)
7.	$(k_3(k_1-k_2))/(k_1(k_2-k_3))$	Shape indicator	0 to		(Stacey et al., 1960)
8.	$(k_2/k_3 - 1)/(k_1/k_2 - 1)$	D factor	0 to		(Hrouda, 1976)
9.	$(2n_2 - n_1 - n_3)/(n_1 - n_3)$	Shape parameter $T$	-1 to 1		(Jelinek, 1981)
10.	$k_1/k_2$	Lineation	1 to	S2a	(Balsey and Buddington, 1960)
11.	$(k_1 - k_2)/k_m$	Magnetic lineation	0 to 3		(Khan, 1962)
12.	$(k_2 - k_3)/k_m$	Magnetic foliation	0-1.5		(Khan, 1962)
13.	$k_2/k_3$	Foliation	1 to	S2b	(Stacey et al., 1960)
14.	$1 - (k_3/k_2)$	Foliation	0 to 1		(Porath, 1971)
15.	$k_1 k_3 / k_2^2$		0 to		(Stacey et al., 1960)
16.	$k_2^2/k_1k_3$	E factor		S2	(Hrouda et al., 1971)
17.	$k_3/k_1 - 2k_2/k_1 + 1$	<i>B</i> parameter	-1 to $1$		(Cañón-Tapia, 1992)

 $n_i = \ln(k_i), i = 1, 2, 3, \text{ and } k_m = (k_1 + k_2 + k_3)/3.$ 

	Parameters	Name	Range	Group	Source
1.	$k_1/k_3$	Anisotropy degree P	1		(Nagata, 1961)
2.	$100(k_1 - k_3)/k_1$	Percentage anisotropy	0-100		(Graham, 1966)
3.	$(k_1 - k_3)/k_{\rm m}$	Total anisotropy $H$	0-3	A1	(Owens, 1974)
4.	$(k_1 - k_3)/2k_{\rm m}$	Percentage anisotropy	0-1.5		(Khan, 1962)
5.	$(k_1 - k_3)/k_2$	Absolute anisotropy	0–		(Rees, 1966)
6.	$(k_1 + k_2)/2k_3$	Foliation	1–	A2	(Balsey and Buddington, 1960)
7.	$((k_1 - k_2)/2) - k_3$	Magnetic excess	$0-1 (\times k_1)$		(Granar, 1957)
8.	$\exp\{(2[(a_1)^2 + (a_2)^2 + (a_3)^2]\}^{1/2}$	Corrected anisotropy degree $(P')$	1	A3	(Jelinek, 1981)
9.	$k_{1/}(k_{3}k_{2})^{1/2}$	Emplacement factor	1–		(Ellwood, 1975)
10.	$2k_1/(k_3+k_2)$	Lineation degree	1	A4	(Hrouda et al., 1971)
11.	$100(1-k_3/2k_1-k_2/2k_1)$	A parameter	0-100		(Cañón-Tapia, 1992)

Table S5 Parameters quantifying the degree of anisotropy

 $a_i = \ln(k_i/k_m')$ , i = 1,2,3, and  $k_m = (k_1 + k_2 + k_3)/3$ ,  $k_m' = (k_1k_2k_3)^{1/3}$ .

measurements. This interpretation is only correct if the AMS is controlled by elongated objects of similar (and previously known) aspect ratios and for which the AMS bears a direct relation with the shape of the object (normal shape-effect), but it becomes misleading under other conditions. In particular, if the AMS is controlled by minerals in which the physical dimensions of the grain are inversely related to the intensity of susceptibility (inverse shape-effect Rochette et al., 1991), the lineation becomes a measure of the grouping of particles over one plane rather than reflecting the degree of clustering of the largest dimensions of the minerals. Alternatively, if the AMS of two rocks is controlled by minerals with a normal shape-effect but different average aspect ratios, the magnetic lineation of those two rocks will be different even when the degree of clustering of the minerals is the same. In an extreme case, a rock formed by very elongated minerals that are not perfectly aligned might yield a larger lineation than a second rock formed by a perfect alignment of not so elongated minerals, therefore potentially leading to erroneous petrofabric interpretations.

These problems are not exclusive of the lineation parameter, as ambiguities are found when the physical meaning of all the other types of AMS parameters is examined in detail. Until now, there have been two different approaches to alleviate this situation, both of which have been unsuccessful in finding a general agreement within the scientific community. The first attempt in suggesting criteria for the selection of AMS parameters was made by Ellwood et al. (1988). They pointed out that some methods of measurement favor the use of parameters that include the differences of the principal susceptibilities while others call for the use of their ratios (see also Hrouda and Jelinek, 1990). Undoubtedly, this distinction has some merit within an instrumental basis, but it overlooks the fact that most of the available parameters use both ratios and differences of the principal susceptibilities in their definitions. Furthermore, this approach has the problem that actual calculation of different parameters often reduces in practice to a simple arithmetical combination of the principal susceptibilities regardless of the method used for the measurement of the susceptibility tensor (Ellwood et al., 1988; Tarling and Hrouda, 1993). The second attempt to devise useful criteria to guide the selection of AMS parameters was made by Cañón-Tapia (1994). He used a mathematically oriented point of view to compare the most important parameters proposed until that time, and to estimate the influence that such parameters could have in the final interpretation of results. Based on a theoretical comparison in which individual parameters could be conveniently expressed as families of lines, it was shown that many of the parameters proposed in the literature are equivalent to each other and that the only difference between two apparently independent parameters can be reduced to a difference in a numeric range. In particular, using this approach it was shown that the foliation and lineation parameters are special cases of the shape parameters, and therefore little is gained with their use as separate categories. In contrast with the experimentally derived

criteria, the geometrically based comparison is applicable to any parameter defined as a combination of two or three of the principal susceptibilities. Consequently, this set of criteria can be used in a general context to guide the selection of AMS parameters in a more ordered form than possible with other criteria available until now. Unfortunately, costume derived from continual use of a particular type of AMS parameters seems to be the dominant criteria in some cases. Consequently, foliation and lineation parameters have continued to be used as independent types and, in some instances, these two parameters are reported together with a third shape parameter in the same work.

Although lacking an objective criteria behind their usage, in practice it is found that the two most commonly used parameters are those called P' and T (Tables S4 and S5, respectively). Another pair of parameters that has been used with increasing frequency, especially because of its use in studies of lava flows, is formed by the A and Bparameters. These two pairs of AMS parameters yield different numeric ranges in the analysis of AMS measurements (hence requiring caution when comparing different works). Qualitatively, however, these two pairs of AMS parameters yield equivalent results and therefore the main aspects in the interpretation will remain unaltered irrespective of which pair of parameters was used (Cañón-Tapia, 1994).

In summary, despite the various methods available for the calculation of average orientations of principal susceptibilities and associated regions of confidence, when attention is given to the physical factors controlling the acquisition of the AMS of a rock, the differences between alternative methods of calculation becomes negligible for the interpretation of results. In contrast, little agreement has been reached concerning the selection of AMS parameters. More details concerning the physical value of individual AMS parameters will be required before reaching a clearly satisfactory set of criteria that can be used as a general guide for their selection.

# TAYLOR'S CONDITION

#### Taylor's condition

Taylor's condition, first derived by J.B. Taylor in 1963, is a statement about the electromagnetic torque within the Earth's core, namely that it must vanish when integrated over cylindrical shells parallel to the axis of rotation. It is one of the most important results in geodynamo theory.

#### **Basic equations**

The two equations we will need are the induction equation:

$$\frac{\partial \mathbf{B}}{\partial t} = \nabla \times (\mathbf{U} \times \mathbf{B}) + \nabla^2 \mathbf{B}, \qquad (\text{Eq. 1})$$

governing the evolution of the magnetic field **B** in the core, and the Navier-Stokes equation (in its simplest, Boussinesq form):

$$Ro\left[\frac{\partial}{\partial t} + \mathbf{U} \cdot \nabla\right] \mathbf{U} + 2\hat{\mathbf{e}}_{z} \times \mathbf{U} = -\nabla p + E \nabla^{2} \mathbf{U} + (\nabla \times \mathbf{B})$$
$$\times \mathbf{B} + \mathbf{F}_{\mathrm{T}}, \qquad (\mathrm{Eq. 2})$$

governing the fluid flow U. In general there would also be an equation for the thermal and/or compositional buoyancy that ultimately drives the whole system, but for our discussion here we can take the buoyancy force  $\mathbf{F}_{T}$  to be prescribed. The only feature that will matter is that it is purely radial.

In these equations, length has been scaled by  $r_0$ , time by  $r_0^2/\eta$ , **U** by  $\eta/r_0$ , and **B** by  $\sqrt{\Omega\rho\mu_0\eta}$ , where  $r_0$  is the outer core radius,  $\eta$  the magnetic diffusivity,  $\Omega$  the Earth's rotation rate,  $\rho$  the density, and  $\mu_0$  the magnetic permeability. The two nondimensional parameters then appearing in (2) are the Rossby and Ekman numbers  $Ro = \eta/\Omega r_0^2$  and  $E = \nu/\Omega r_0^2$ , where  $\nu$  is the viscosity. Inserting the numbers, we find that  $Ro = O(10^{-9})$  and  $E = O(10^{-15})$ , indicating the extreme dominance of rotation over inertia and viscosity.

One very basic question then is where does the Lorentz force fit into this balance? Is it dominant, like the Coriolis force, or very small, like inertia and viscosity? Formally it is certainly comparable to the Coriolis force in (2), but that merely reflects our scalings for **B** and **U**. So the question is, are these the right scalings, that is, do **B** and **U** come out to be O(1) when measured in these  $\sqrt{\Omega\rho\mu_0\eta}$  and  $\eta/r_0$  units? As we will see, Taylor's condition touches upon precisely this point, and suggests that **B** (and possibly **U** as well, see *dynamo, model-Z*) may not necessarily come out to be O(1), but may scale as some power of *E* instead.

#### Taylor's analysis

If Ro and E are so small, we might try to simplify the Navier-Stokes equation by dropping the inertial and viscous terms entirely, yielding

$$2\hat{\mathbf{e}}_z \times \mathbf{U} = -\nabla p + (\nabla \times \mathbf{B}) \times \mathbf{B} + \mathbf{F}_{\mathrm{T}}.$$
 (Eq. 3)

Taking the curl (and using also  $\nabla \cdot \mathbf{U} = 0$ ) yields

$$-2\frac{\partial}{\partial z}\mathbf{U} = \nabla \times [(\nabla \times \mathbf{B}) \times \mathbf{B} + \mathbf{F}_{\mathrm{T}}], \qquad (\text{Eq. 4})$$

where  $(z, s, \phi)$  are standard cylindrical coordinates. One might suppose then that the solution is simply  $\mathbf{U} = \mathbf{U}_{M} + \mathbf{U}_{T}$ , with the so-called magnetic and thermal winds given by

$$\mathbf{U}_{\mathrm{M}} = -\frac{1}{2} \int \nabla \times [(\nabla \times \mathbf{B}) \times \mathbf{B}] \mathrm{d}z, \quad \mathbf{U}_{\mathrm{T}} = -\frac{1}{2} \int \nabla \times \mathbf{F}_{\mathrm{T}} \, \mathrm{d}z.$$
(Eq. 5)

Instead, it turns out that in general (3) has no solution at all. To see why, consider its  $\phi$ -component:

$$2\mathbf{U} \cdot \hat{\mathbf{e}}_{s} = -\frac{1}{s} \frac{\partial p}{\partial \phi} + \left[ (\nabla \times \mathbf{B}) \times \mathbf{B} \right] \cdot \hat{\mathbf{e}}_{\phi}$$
(Eq. 6)

(it is at this stage that we use the fact that  $\mathbf{F}_{T}$  has no  $\phi$ -component). Next, integrate (6) over the so-called geostrophic surfaces C(s) shown in Figure T1, consisting of concentric cylindrical shells parallel to the *z*-axis. The pressure-gradient term then vanishes, since

$$\oint \frac{\partial p}{\partial \phi} d\phi = 0.$$
 (Eq. 7)

The Coriolis term also vanishes, since  $\int U \cdot \hat{e}_s dS$  is the net flux across C(s), which must be zero if the fluid is incompressible, as in the Boussinesq approximation here. We are thus left with Taylor's celebrated result, stating that **B** must satisfy

**Figure T1** The geostrophic surfaces C(s) over which (8) is to be integrated. Note also how these surfaces change abruptly across the so-called tangent cylinder, the particular surface (indicated by the dotted lines) just touching the inner core.

$$\int_{C(s)} [(\nabla \times \mathbf{B}) \times \mathbf{B}] \cdot \hat{\mathbf{e}}_{\phi} \, dS = 0.$$
 (Eq. 8)

That is, when considered pointwise, all four forces contribute to (3), but when the corresponding torques are integrated over these particular surfaces C(s), the buoyancy, pressure-gradient and Coriolis terms all drop out, so the only remaining term must then also be zero. We see therefore that unless **B** satisfies (8), and on *each* such surface C(s), (3) simply has no solution at all.

Now suppose that **B** does satisfy (8), so a solution exists. There is then the additional complication that this solution is not unique, since one can add to it an arbitrary geostrophic flow  $U_g(s)\hat{\mathbf{e}}_{\phi}$ , which after all satisfies  $\partial \mathbf{U}/\partial z = 0$ ,  $\nabla \cdot \mathbf{U} = 0$ , and the no normal flow boundary conditions. Equation (3) thus has the awkward feature that it has either no solution at all if (8) is not satisfied, or else an infinite number of solutions if it is.

This arbitrariness in the geostrophic flow can fortunately be removed, by requiring that **B** should not only satisfy (8) at some particular instant, but that it should evolve in time in such a way that (8) continues to be satisfied. That is, we want not only (8), but also d/dt(8), or

$$\int_{C(s)} \left[ (\nabla \times \mathbf{B}) \times \frac{\partial \mathbf{B}}{\partial t} + \left( \nabla \times \frac{\partial \mathbf{B}}{\partial t} \right) \times \mathbf{B} \right] \cdot \hat{\mathbf{e}}_{\phi} \, \mathrm{d}S = 0. \quad \text{(Eq. 9)}$$

To see how this determines  $U_{g}$ , we recall first (1), giving  $\partial \mathbf{B}/\partial t$  in terms of **B** and **U**. We remember further that except for  $U_{g}$ , the rest of **U** is known, from (5). If we therefore write

$$\mathbf{U} = U_{\mathrm{g}}(s)\hat{\mathbf{e}}_{\phi} + \mathbf{U}_{\mathrm{M}} + \mathbf{U}_{\mathrm{T}},\tag{Eq. 10}$$

then inserting (10) into (1), and then (1) into (9), we end up with an (horribly complicated) equation in which the only unknown quantity is  $U_{g}$ . In this way (3) has a unique solution after all, and in the process (8) continues to be satisfied into the future. Taylor therefore envisioned the geodynamo evolving through such a sequence of states.

# Alternatives to Taylor's analysis

Unfortunately, no one has ever succeeded in evolving a numerical geodynamo model according to Taylor's prescription. Instead, most workers have proceeded more cautiously, not setting *Ro* and *E* identically to zero. If one restores viscosity, at least in the Ekman boundary layers, then an asymptotic analysis (Tough and Roberts 1968) of these layers yields:

$$\int_{C(s)} [(\nabla \times \mathbf{B}) \times \mathbf{B}] \cdot \hat{\mathbf{e}}_{\phi} \, \mathrm{d}S = E^{1/2} \frac{4\pi s}{(1-s^2)^{1/4}} U_{\mathrm{g}}(s), \quad \text{(Eq. 11)}$$

indicating that the integrated electromagnetic torque does not have to vanish identically, but can instead be balanced by this small but nonzero viscous torque. (One might suppose that  $U_M$  and  $U_T$  would have associated viscous torques as well. However, the constants of integration in (5) can be chosen such that their contributions vanish.)

Equation (11) can then be solved for  $U_g$  in terms of **B**. According to this prescription therefore, the field evolves according to (1), and at each instant in time the flow is still given by (10), but with  $U_g$  now given by (11) rather than Taylor's more complicated formula. The advantage of this approach is that it is not only easier to implement numerically (although still nontrivial), it is also more general than Taylor's approach. In particular, by postulating an expansion of the form

$$\mathbf{B} = \mathbf{B}_0 + E^{1/2} \mathbf{B}_1 + E \mathbf{B}_2 + \cdots, \qquad (\text{Eq. 12})$$

and assuming that  $\mathbf{B}_0$  satisfies (8), we can recover Taylor's solution (and in the process also obtain the higher-order viscous corrections to it). This is not the only possibility though. We can also postulate an expansion of the form

$$\mathbf{B} = E^{1/4} \mathbf{B}_0 + E^{3/4} \mathbf{B}_1 + E^{5/4} \mathbf{B}_2 + \cdots,$$
(Eq. 13)

where now **B**<sub>0</sub> does *not* satisfy (8). In doing so, we obtain the so-called Ekman states, which do not exist at all in Taylor's analysis, because there  $E \equiv 0$ . Malkus and Proctor (1975) then conjectured that in general the field would start out in the Ekman regime, but would undergo a transition to the Taylor regime for sufficiently strong forcing. That such a transition can indeed occur was demonstrated numerically by Hollerbach and Ierley (1991).

There are also additional possibilities beyond these two states; for example, Hollerbach (1997) showed that an intermediate state can perhaps exist in which the leading order field scales as  $E^{1/8}$ . If one allows the existence of boundary layers other than the Ekman layers implicitly contained in (11), one can also obtain the so-called model-Z states (see *dynamo, model-Z*).

The geophysical significance of this plethora of possible states is that it is believed that the geodynamo is not necessarily in a single state throughout its entire evolution. Most of the time it is probably in a Taylor state (or possibly a model-Z state), since those are the only two states in which  $\mathbf{B} = O(1)$ , as we would like it to be. During reversals or excursions though, it could conceivably be in one of the weaker states. Indeed, what triggers these events may well be a breakdown of the previously existing Taylor state.

Finally, we note that fully three-dimensional numerical simulations are unfortunately not yet in a parameter regime where one could test these various ideas; numerically accessible Ekman numbers are so large that one cannot clearly distinguish between these different states. It is only in mean-field models such as that of Hollerbach and Ierley (1991) that one can reduce E sufficiently to obtain clear distinctions between different states. Because Taylor's condition is inherently axisymmetric though, these results should carry over to the fully three-dimensional models, if only we could reduce E further there as well.

# Introduction

Émile Thellier (Figure T2), a pioneer in rock magnetism and archeomagnetism, was born February 11, 1904 at Mont-en-Ternois (Pas-de-Calais), France and died May 11, 1987 in Paris. Following studies at the École Normale Supérieure de Saint-Cloud (1924–1926), he taught at the École Primaire Supérieure de Bourges (1927–1930). In spite of a heavy teaching load, 21 h per week, he successfully completed the Licence èssciences physiques of the Faculté des Sciences de Paris, where he would spend the remainder of his career. His outstanding performance led his

Figure T2 Thellier, Émile (1904–1987).

professors to urge him to embark on research. At the Sorbonne in the laboratory of Prof. Charles Maurain, he completed a Diplôme d'Études Supérieures (1931), studying the magnetism of baked clay, and the Agrégation de Sciences physiques (1932).

It had been known since at least the time of Brunhes (1906) that the thermoremanent magnetization (TRM) acquired by baked clays and volcanic rocks paralleled the direction of the geomagnetic field acting when they cooled and survived later reversals of the field. Maurain proposed to Thellier the idea of using the TRM of ancient pottery to deduce not only the direction but also the strength of the Earth's field at the time of firing. This program Thellier later carried out brilliantly during a long career, but his first desire was to reproduce TRM in the laboratory and understand its properties. His success in this undertaking makes him the true "discoverer of magnetic memory," in the words of his great confrere, Louis Néel. Working with clays from the famed Sèvres pottery factories, and later with volcanic rocks, Thellier minutely and exhaustively determined how TRM forms, producing a remarkable Docteur ès-Sciences thesis (Thellier, 1938).

This landmark paper, which has lost none of its immediacy today, launched his academic career at the Institut de Physique du Globe de Paris, where he became successively Physicien-adjoint (1943), Maître de Conférences (1945), Professeur (1948) and Director (1954–1966). From 1967, he moved his research to the Observatoire du Parc Saint-Maur, in the suburbs of Paris, where he established a CNRS Laboratoire de Géomagnétisme, which he molded into one of the world's leading rock magnetic and paleomagnetic research centers. Thellier received many honors in his lifetime. He was named an Officer of the Legion of Honour (1957), elected to the Académie des Sciences (1967), and awarded four prizes by the academy and one by the Université de Paris. His first love, to the end of his life, remained his research and the laboratory he had created.

#### Thellier's laws of thermoremanent magnetization

Thellier worked exclusively with samples containing very fine particles of minerals like magnetite (Fe<sub>3</sub>O<sub>4</sub>) and hematite ( $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>) which we now know contain only one magnetic domain (single-domain particles) or at most a very few domains. For such particles he established a series of universal properties (Thellier, 1938, 1941; Thellier and Thellier, 1941). A master experimentalist, he perfected astatic, translation, and rotating-sample magnetometers of unprecedented sensitivity. Without such instruments, it would have been impossible to satisfy himself or others of the universality of laws such as the additivity of partial TRMs because the clays he used in his earliest work and the hematites used by his student Roquet (Roquet and Thellier, 1946; Roquet, 1954) were weakly magnetic compared to the volcanic rocks favored by others (Koenigsberger, 1938; Nagata, 1943).

The Thellier "laws" are most clearly stated in Thellier (1946), a masterpiece of mature reflection about results obtained in the preceding one and a half decades and their implications for theories of magnetism. [For alternative statements, see Roquet (1954, p. 21–23) and Aubouin and Coulomb (1987).] Quoting Thellier (translated from the French original), we have the following general properties.

- 1. TRM (intensity) is proportional to field (strength) for weak fields.
- 2. All partial TRMs are parallel to the field *H* in which they were acquired.
- 3. A partial TRM acquired by cooling in H through the temperature interval  $(T_2, T_1)$  and in zero field through all other temperature intervals is unaffected by reheating in zero field to a temperature  $\leq T_1$  and completely disappears after reheating to  $T_2$ .
- 4. A partial TRM  $(T_2, T_1, H)$  is independent of other partial TRMs acquired in temperature intervals outside  $(T_2, T_1)$ , which may be due to fields differing from H in strength and direction.
- All these partial TRMs add geometrically but each of them retains true autonomy and an exact memory of the temperatures and field in which they were acquired.

The first two properties were known or assumed before Thellier's time (e.g., Folgerhaiter, 1899). The latter three are entirely novel and are usually referred to as Thellier's laws. Thellier's statements recognize the vectorial nature of partial TRM additivity and independence, and form the basis for using thermal demagnetization to separate natural remanent magnetization (NRM) vectors of different ages in paleomagnetism. These statements go well beyond the usual scalar laws given in textbooks (e.g., Dunlop and Özdemir, 1997). Collectively, the five laws form a firm fundamental justification for determining the direction and strength of the paleomagnetic field from the NRM of rocks and baked materials, provided the NRM fraction utilized was produced originally as one or more partial TRMs carried by single-domain or nearly single-domain size grains. Number 3 is the basis for magnetic paleothermometry (e.g., Pullaiah *et al.*, 1975).

# Thellier and the theory of thermoremanent magnetization

Louis Néel was intrigued by the apparent generality of the Thellier laws, clearly related to the fine size of the magnetic carriers and not to their chemistry. In 1949, he published his celebrated theory of thermal relaxation of single-domain grains, which very elegantly and completely explained Thellier's observations. Partial TRM was seen to be acquired sharply at a blocking temperature  $T_{\rm B}$  during cooling, as a grain passed from a superparamagnetic to a thermally blocked state, and demagnetized ("unblocked") at the identical temperature  $T_{\rm B}$  during reheating. From this single property flow the three Thellier laws of reciprocity (blocking and unblocking as reciprocal processes), independence and additivity. This powerful and far-reaching theoretical picture remains the foundation of magnetic theory today, in both geophysics and magnetic recording.

What is not generally recognized is that Thellier himself anticipated Néel's ideas, albeit in qualitative rather than quantitative form, three years earlier. Again quoting from Thellier (1946): "These facts, which do not as yet seem to have attracted the attention of theoreticians, seem to me to demand a mechanism of immobilization of elementary magnetic moments below a temperature  $\theta$ , this temperature having a strong variation from point to point within a body. One can imagine the body to be constituted of elementary domains, perhaps very tiny, each with spontaneous magnetization. Above  $\theta$ , their moments will be free (rotation, wall displacement or reversal) and the magnetic state of the body will establish itself by the combined action of the field and of thermal agitation (a sort of paramagnetism). Below  $\theta$ , the elementary moments will be bound to equilibrium positions from which they undergo only reversible displacements in weak fields. The temperature  $\theta$  will vary at each point in the body, perhaps with the dimensions and the shape of the crystalline grains, and will be broadly distributed between the Curie point and room temperature. One can thus explain thermoremanence by the progressive fixing, in the course of cooling, of moments, which find themselves held fast when they pass through their individual temperature  $\theta$ . One can also account for the shape of thermomagnetic curves, in particular the strong increase in susceptibility below the Curie point."

In this remarkable paragraph are all the essential ingredients of Néel's picture: blocking temperature  $\theta$ ; unblocked or superparamagnetic state above  $\theta$  in which thermal agitation establishes an equilibrium; freezing in of the equilibrium in cooling with only reversible changes possible below  $\theta$ ; and distribution of  $\theta$  values due to variable sizes and shapes of grains, explaining the spectrum of partial TRMs comprising the total TRM of the body. Thellier even anticipates the explanation of the Hopkinson peak in susceptibility at high temperature. Although Thellier's ideas were not crystallized into a quantitative theory, his intuition was correct in every essential.

Néel did not directly acknowledge these early theoretical ideas but his appreciation of Thellier's enormous experimental contributions is clear in his commentary on a paper summarizing all of Thellier's results (Thellier, 1951, p. 217; translated from French): "Among the phenomena demonstrated in the magnetization of baked clays and lavas, we should distinguish carefully (total) TRM on the one hand and the independent magnetizations acquired in nonoverlapping temperature intervals (i.e., partial TRMs) on the other... The second is a much more remarkable phenomenon and it is to Thellier that we owe our experimental knowledge of it."

# Anhysteretic magnetization and AF demagnetization

Thellier's earliest scientific achievements were made in collaboration with three remarkable women, whose contributions tend to be overlooked. First was his wife Odette Thellier, who participated in experiments showing that thermal demagnetization of TRM to a temperature  $T_1$  resulted in precisely the same intensity as suppressing the field at  $T_1$ during initial cooling from the Curie point  $T_C$  (i.e., pTRM ( $T_C, T_1, H$ ) (Thellier and Thellier, 1941). From these experiments evolved the pTRM reciprocity law. Odette Thellier was also her husband's full partner in archeomagnetic research on both paleodirections and paleointensities throughout the 1940s and 1950s, culminating in their famous paper, Thellier and Thellier (1959) (see following section).

Thellier's second collaborator, Juliette Roquet, extended investigations to synthetic minerals of both fine and coarse grain sizes and natural materials containing different size fractions. Her thesis (Roquet, 1954) is the first systematic rock magnetic study of grain-size trends in isothermal and thermal properties of partial TRM and other remanences. It set a standard that has yet to be surpassed, thanks to her dedication and the exacting standards set by her mentor.

Third was Francine Rimbert, who constructed one of the first AF demagnetizers and used it to demonstrate that anhysteretic remanent magnetization (ARM) is almost as strong and resistant to alternating fields as TRM (Thellier and Rimbert, 1954). They pointed out the need to scrupulously eliminate any extraneous fields during AF demagnetization, including the ambient geomagnetic field, to avoid contaminating NRM by unwanted ARMs. This was the pioneering study in AF demagnetization, which was then developing as a standard paleomagnetic cleaning method.

Rimbert's thesis (Rimbert, 1959), another monumental piece of work testifying to her ability and her supervisor's stringent expectations, is a complete experimental and theoretical study of ARM, partial ARMs, and AF demagnetization. It is the ultimate justification of AF bias methods for encoding magnetic information, for example in analog audio and video recording, and of AF cleaning of successive generations of primary and secondary NRMs in rocks. Laws analogous to those of Thellier for partial TRM have since been verified for finegrained magnetic oxides (Dunlop and West, 1969) and ferromagnetic thin films (Papusoi and Apostol, 1979), ARM playing the role of TRM and AF substituting for temperature.

# Archeomagnetism and the Thellier-Thellier paleointensity method

Archeomagnetism is the study of the direction and intensity of the geomagnetic field during historical times. Directional work is on the face of it more straightforward than determining paleointensity because loss of part of the primary NRM does not affect the direction of the remainder. Loss of NRM intensity, on the other hand, translates directly into a diminished estimate of paleointensity; a problem the Thellier-Thellier method was designed to overcome.

In spite of the comparative ease of directional measurements and the early beginning made by Émile and Odette Thellier, they published during the 1940s and 1950s only sporadic determinations of inclination I (for pots and bricks for which only paleohorizontal at the time of firing was known) or both I and declination D (for fixed objects such as the kilns in which firing took place). This was not for want of experimental work but because of the Thelliers desire to have a complete and trustworthy picture of the variations of D and I through time before publishing a master curve that would certainly be widely

used by archeologists as a dating tool. Thus it was only after investigations were complete for about 100 sites in France, Turkey, Cambodia, and North Africa that Émile Thellier revealed in a presentation at the 1971 IUGG assembly in Moscow the fruits of all their labors, curves of secular variation of the field throughout the past 2000 years.

The Thelliers moved more quickly to establish the historical record of field intensity. For paleodirectional work, Émile Thellier had perfected a sensitive spinner magnetometer on a grand scale, still in use today, capable of measuring the NRMs of intact pots with dimensions as large as 50cm without the need to subsample these priceless archeological treasures. Paleointensity work required a methodological invention of equal ingenuity, the Thellier-Thellier protocol, still the standard method used today.

The Thellier-Thellier method compares NRM, produced thermally in an unknown ancient field  $H_A$ , with a TRM produced in a known laboratory field  $H_L$ . This basic idea had been put forward earlier by Folgerhaiter (1899) and Koenigsberger (1938) but no trustworthy results emerged. Folgerhaiter, quoted by Thellier (1938, 287), says (translated from French) "One could also arrive at some conclusion about the intensity of the terrestrial field by reheating ancient vases and comparing the ancient and presently acquired intensities of magnetization; but measurements made on vases heated and reheated in repeated experiments have shown me that this method leads to too uncertain results." The reason for the uncertainty is alteration of the chemistry and physical state of the magnetic minerals resulting from heating, demonstrated very clearly by Koenigsberger's progressive heating experiments on igneous rocks.

The novelty of the Thelliers' procedure is in the interweaving of pairs of heating-cooling steps to successively higher temperatures, instead of a single heating-cooling to  $T_{\rm C}$ . In their original version (Thellier and Thellier, 1959), both heatings to a particular temperature  $T_i$  were carried out in the presence of a laboratory field (the ambient Earth's field in their experiments) but the sample was rotated 180° between heatings. In the currently most used version (Coe, 1967), the first heating-cooling is in zero field and the second in  $H_{\rm L}$ . In the Coe version, the first heating serves to demagnetize that part of the NRM with  $T_{\rm B} \leq T_{\rm i}$ , while the second heating replaces this loss with a partial TRM  $(T_i, T_o, H_L)$ . The NRM and partial TRM are not generally in the same direction, so that they must be obtained by vector subtraction of the results of the two heatings. In the original version, equal partial TRMs in opposite directions are acquired in the two heatings, but the vector subtractions are still straightforward. Although the modified version gives a neater segregation between NRM loss and partial TRM gain, the original version has some bonuses: the two heatings have perfect symmetry and no null field is needed.

The Thellier-Thellier method is firmly rooted in Thellier's three laws of partial TRM. This protocol has three tremendous advantages, not matched by other techniques:

- There is a built-in test of the TRM origin of the NRM, namely constancy of the ratio of NRM lost/partial TRM gained over successive heating steps.
- 2. Portions of the NRM that are unreliable can be recognized and discarded. A common contaminant at low  $T_i$  is viscous remanent magnetization (VRM) produced by the present Earth's field. Alteration of mineral microstructure or chemistry tends to occur at high  $T_i$ .
- 3. Linear least-squares fitting to the set of acceptable NRM and partial TRM data can be used to obtain the mean paleointensity ratio  $H_A/H_L$  and its associated error. This procedure, the Arai plot, was introduced later, by Nagata *et al.* (1963) but it is a natural consequence of the linear replications in the Thellier-Thellier method.

The name of Koenigsberger has been associated by some with this method and given precedence over the Thelliers themselves (so-called KTT method). This misrepresents the facts. In four of Koenigsberger's papers published in German journals between 1930 and 1936 and in his summary work in English (Koenigsberger, 1938), there is no

indication that he was aware of partial TRMs or their properties. The only paper by Thellier he cites is on determining directions. He did carry out stepwise heatings with  $H_L$  parallel or antiparallel to NRM but these were separate, not interwoven, experiments, and there was no attempt to use the results to estimate field strength. Most of his samples altered so much in the first set of heatings that there was no symmetry between  $+H_L$  and  $-H_L$  curves.

Koenigsberger espoused the idea that NRM spontaneously decayed with time (what we would nowadays call viscous decay) so that the ratio  $Q_n = NRM/kH$  would be systematically lower than  $Q_t = TRM/k'H$ for rocks of increasing age. Here k, k' are susceptibilities measured before and after TRM acquisition and H is the local present Earth's field. He viewed this as an age determination, not a paleointensity, method. Thellier (1938, p. 293) correctly ascribed the differences between  $Q_n$ and  $Q_t$  to increased susceptibility resulting from alteration during heating and not to spontaneous decay of NRM. Thellier went on to suggest that the ratio  $Q_n/Q_t = (NRM/TRM) (k'/k)$  might serve as a rough estimate of the paleointensity ratio  $H_A/H_L$ . This is a slight improvement on Folgerhaiter's prescription,  $H_A/H_L = NRM/TRM$ , in that it takes some account of alteration of a sample through the ratio k'/k, but it is far from being an earlier incarnation of the powerful and sophisticated Thelliers' method.

Viewing the considerable alteration evidenced by the differences between k' and k in Koenigsberger's igneous samples, Thellier soon came to the reasonable conclusion that the suggested correction procedure was unjustified, particularly since the quantitative relation between remanence and susceptibility depends strongly on mineralogy and grain size. He says (Thellier, 1938, p. 293) "The susceptibility has changed markedly as a result of heating for many of these rocks; they should be rejected for the purpose of studying the intensity of the terrestrial field." Since then, many intricate and ingenious schemes have been proposed for "undoing" the effects of alteration during heating but none in the final analysis gives results that the most paleomagnetists would trust. There is really no substitute for the Thellier-Thellier method (under which we include microwave heating methods that heat the magnetic minerals but not the rock matrix), nor for the uncompromising standards set by Émile Thellier.

# THERMAL WIND

The term *thermal wind* refers to steady or slowly time-varying shear flow, driven by buoyancy forces due to lateral gradients in density and modified by planetary rotation through the Coriolis acceleration. Thermal winds in the Earth's fluid outer core are important in the geodynamo. These flows generate toroidal magnetic field in the outer core, drive anomalous rotation of the solid inner core, and contribute to the observed secular variation of the geomagnetic field, particularly the westward drift. Thermal winds may also play a key role in geomagnetic polarity reversals. This article reviews the basic properties of thermal winds in the core and describes how these flows affect the geomagnetic field.

# Examples of thermal wind flows

Examples of thermal wind flows abound in Nature. The general circulation of Earth's atmosphere is a thermal wind to a first approximation, and is driven by lateral variations in density associated with the pole-toequator zonal temperature gradient. Some major ocean current systems such as the Gulf Stream are driven partly by lateral density gradients and qualify as thermal wind flows, the density gradients associated with these currents arising from both temperature and salinity variations. Lateral density variations are certainly present in the outer core, due to the combined effects of thermal and compositional variations. Because rotation influences fluid motion in the core as much as it does in the ocean and atmosphere, thermal winds are likely to be important parts of core flow. However, since the outer core is a much deeper fluid and is affected by convection and the forces associated with Earth's magnetic field, thermal winds in the core are expected to differ from their atmospheric and oceanic counterparts in certain respects.

### The thermal wind equation

A thermal wind equation appropriate for Earth's outer core can be obtained from the vorticity conservation equation in the limit where the fluid inertia and the viscous force are negligible in comparison with effects of the Coriolis acceleration, density gradients, and the Lorentz force due to Earth's magnetic field. Here the focus is on the zonal (the longitude-averaged) component of motion in the longitude (east-west) direction, which is usually the largest part of the thermal wind. Assuming a Boussinesq fluid, the equation for this component of motion near the surface of the core is (Davidson, 2001)

$$2\Omega \frac{\partial u_{\phi}}{\partial z} = -\frac{g}{\rho R} \frac{\partial \rho}{\partial \theta} - \left(\nabla \times \frac{\vec{J} \times \vec{B}}{\rho}\right)_{\phi},$$

where  $u_{\phi}$  is the zonal velocity in the  $\phi$ -direction (measured eastward),  $\rho$  is fluid density,  $\theta$  is co-latitude,  $\Omega$  is the angular velocity of rotation in the z-direction,  $\vec{J}$  and  $\vec{B}$  are electric current density and magnetic field intensity, respectively, and g is the acceleration of gravity at the core's outer radius R. The thermal wind equation is written here in terms of density, but as its name suggests, it is often applied to fluids where the density is a function of temperature only. In these cases

$$\frac{\partial \rho}{\partial \theta} = -\alpha \rho \, \frac{\partial T}{\partial \theta},$$

where *T* is temperature and  $\alpha$  is the thermal expansion coefficient of the fluid.

Before describing thermal winds in the core, it is useful to consider a rotating fluid in which lateral density gradients and electric currents are negligible. In this case the thermal wind equation reduces to the Proudman-Taylor constraint:

$$\frac{\partial u_{\phi}}{\partial z} = 0.$$

Fluid motions satisfying this constraint are sometimes called columnar, because they have zero shear in the axial direction, parallel to the rotation axis. In a rotating fluid with strong lateral density gradients or strong Lorentz forces, the Proudman-Taylor constraint does not hold. The above equation dictates that the flow contains axial shear in proportion to these effects. Other terminology is sometimes used for these flows. In Meteorology and Oceanography, the term thermal wind usually refers specifically to the shear, not the flow itself (Cushman-Roisin, 1994). In rotating, electrically conducting fluids, Lorentz force-driven shear flows are sometimes called *magnetic winds*.

# Thermal wind in the core

The general pattern of zonal flow we expect in the outer core is illustrated in Figure T3, which shows cross sections of the time-averaged zonal temperature, fluid motion, and magnetic field structure from a numerical dynamo model. This dynamo is driven by thermal convection and the lateral density variations are proportional to the lateral temperature variations. The model is a highly idealized (and probably over-simplified) representation of the geodynamo, but it illustrates the basic structure of thermal winds in a rotating, convecting dynamo. Although some of the input parameters are not accurately scaled (in particular, the rate of rotation is far too slow for the Earth and the fluid has higher electrical conductivity than the outer core) the model gives realistic results for several important properties. For example, its external magnetic field is dipole-dominant, like the geomagnetic field, and it tends toward axial symmetry when averaged over long periods of time. At any instant, however, both the flow and the magnetic field are not as symmetric, as shown in Figure T3. The magnetic secular variation in this model exhibits a preference for westward drift,

**Figure T3** Cross-sections of time- and azimuthally averaged structure of a numerical dynamo model driven by thermal convection in a rotating, electrically conducting spherical fluid shell. The parameters of this model are the same as the thermal convection benchmark dynamo of Christensen *et al.* (2001), but with twice the rotation and heating rates. (a) Contours of temperature; (b) streamlines of meridional circulation with flow direction arrows; (c) contours of zonal velocity showing the thermal wind; (d) contours of toroidal magnetic field intensity; (e) poloidal magnetic field lines with direction arrows. Contour shading is proportional to magnitude; solid and dashed lines indicate positive and negative values, respectively. Zonal velocity and toroidal magnetic field intensity are positive eastward. Magnetic polarity in this model is normal relative to present-day geomagnetic polarity; this has no effect on the flow.

especially near the poles, which is also Earth-like. These general similarities with observed geomagnetic field behavior result from fundamental constraints on convection in a rotating spherical shell, and are not particular to this model. It is therefore reasonable to assume that the pattern of zonal flow in the model may approximate the time-averaged pattern of zonal flow within the Earth's core.

The large amount of axial shear in Figure T3c and its spatial relationship to the lateral temperature variations in Figure T3a and the meridional circulation in Figure T3b indicate the time-averaged zonal velocity is mostly thermal wind. In contrast, there is very little columnar motion in the time-averaged flow in this dynamo. In the Earth's core, there is evidence from the geomagnetic secular variation for time-varying zonal columnar flow with periodicity of order one century. Oscillating columnar core flow is thought to be important in the exchange of momentum between the core and the mantle associated with decade time-scale fluctuations in the length of the day. But the existence of columnar flow in the core over longer periods of time has yet to be established.

The time-average zonal temperature shows a basic octupole pattern. Elevated temperatures occur near the equatorial plane in Figure T3a, a consequence of efficient heat transport by small-scale convection, which is suppressed by the zonal averaging and is not evident in the velocity fields in Figure T3b and T3c. The thermal wind is particularly strong within the axial cylinder containing the inner core, the inner core tangent cylinder (q.v.). Here it is closely related to the axisymmetric meridional circulation, which consists of a polar plume with return flow along the tangent cylinder. Zonal flow inside the tangent cylinder is directed westward near the core-mantle boundary, but reverses direction with depth and becomes eastward near the inner core boundary. The high-latitude westward motion near the coremantle boundary in both hemispheres are polar vortices, analogs to the ozone-trapping polar vortices in the stratosphere. The eastward motion of the thermal wind deep in the outer core results in viscous and electromagnetic stresses on the inner core boundary. The drag produced by these stresses tends to make the inner core super-rotate, that is, spin slightly faster than the mantle. This offers an explanation for the anomalous rotation of the inner core inferred by some seismic studies. Figure T3c shows that the belts of eastward motion responsible for inner core super-rotation extend out to the core-mantle boundary at midlatitudes. At lower latitudes, the thermal wind flow immediately below the core-mantle boundary is weak, but at greater depth there is a submerged westward jet centered on the equator, an equatorial undercurrent.

The combination of the westward undercurrent and the eastward flow near the inner core boundary generates much of the toroidal component of the magnetic field shown in Figure T3d. The shear contained in these flows stretches the poloidal magnetic field lines shown in Figure T3e, winding them into pairs of toroidal field coils with opposite polarity in each hemisphere. This is an example of toroidal field induction by the so-called  $\omega$ -dynamo effect, and is considered to be a critical part of the geodynamo process in the core. The thermal wind also influences the poloidal magnetic field, although in a different way. Comparison of Figure T3e and T3c shows that the poloidal field lines tend to align with the contours of the thermal wind velocity, a configuration that allows the field to nearly co-rotate with the thermal wind. The tendency of poloidal field lines to align with the thermal wind is an example of Ferraro's (1937) law of co-rotation, a general magnetohydrodynamic principle that has been used to infer planetary rotation rates from magnetic variations.

In rotating fluids where the lateral density variations are produced by convection, the amplitude of the thermal wind obeys the following relationship:

$$U \approx \left(\frac{F}{\Omega}\right)^{1/2}$$

where U is the r.m.s. thermal wind amplitude and F is the flux of buoyancy associated with the convection. The same formula has been

found to hold in convection-driven dynamos with relatively strong magnetic fields, another consequence of Ferraro's law of corotation (Aubert, 2005). According to this relationship, a thermal wind velocity of  $U = 10^{-3} \text{ m s}^{-1}$  in the core, which is consistent with the observed geomagnetic secular variation, is associated with a convective buoyancy flux of about  $F = 7 \times 10^{-11} \text{ m}^2 \text{ s}^{-3}$ . This is within the range of the buoyancy flux estimates based on the core's present-day energy budget (Aurnou *et al.*, 2003). A scaling analysis of the thermal wind equation reveals that the lateral density variations needed to maintain a thermal wind flow with this amplitude in the core are less than one part in a million (Jackson and Bloxham, 1991), too small, unfortunately, to be observed in the gravity field or by seismic methods.

The high degree of symmetry in Figure T3 is a consequence of time and azimuthal averaging. Significant departures from axial symmetry are present in the thermal wind and the other variables at any instant, because of transient chaotic fluctuations in the model. In the core, similar transient chaotic fluctuations are also likely, and these might account for the hemispheric asymmetry observed in the geomagnetic field during historical times, and may be the cause of dipole excursions and polarity reversals. Even longer-lasting deviations from symmetry are also possible in the geodynamo, due to interaction of core flow with heterogeneity in the lower mantle. It is well established that spatial heterogeneity in boundary heat flow can produce localized thermal winds in a rotating fluid (Sumita and Olson, 1999), and it has been proposed that thermal winds in the core are tied to lower mantle heterogeneity by this mechanism. It has also been proposed that slow changes in the core flow, responding to changes in the structure of the lower mantle heterogeneity, can causes the long-term variations observed in magnetic reversal frequency record (Gubbins, 1987).

In summary, multiple lines of evidence indicate thermal winds are present in the core and affect the geodynamo in a variety of ways. Much remains to be learned about the nature of these flows and their relationship to the other parts of the Earth.

# TIME-AVERAGED PALEOMAGNETIC FIELD

The geocentric axial dipole hypothesis (q.v.), or GAD, is a central tenet of paleomagnetism: the geomagnetic field is assumed to average over time to a simple dipolar form aligned with the Earth's rotation axis. This enables measurement of past plate motion, continental drift, and regional geological deformation. The dipole assumption allows any magnetic direction determined at a site to be transformed to a virtual geomagnetic pole (VGP), defining the axis of the assumed dipole. Many VGPs determined within a single rock unit are found to cluster about a center, called the paleomagnetic pole. The paleomagnetic pole is treated as an estimate of the location of the geographic pole at the time of formation of the rock unit; the scatter of VGPs is supposed to be caused by geomagnetic secular variation. The latitude of the rock unit at the time of its formation, and the angle through which the rock unit has rotated since its formation, can be obtained from the paleomagnetic pole position. The scatter of VGPs around the paleomagnetic pole provides an estimate of the error on the paleomagnetic pole and hence the errors on the latitude and rotation of the rock unit.

Merrill and McElhinny (1996) discuss the establishment of the GAD in detail. Simple clustering of the VGPs is not enough to demonstrate dipolar structure: a definitive determination requires similar paleomagnetic pole positions for a range of contemporary locations. This is possible in the recent geological past when plate motions are negligible or are well determined by other means; for the more distant past it is possible to compare latitudes determined paleomagnetically with those determined by paleoclimate. Statistical distributions of paleomagnetic inclination can also be used to establish the dipole structure. Adequate time sampling of the rock unit is also essential in determining an accurate paleomagnetic pole, which must be long enough to average out the secular variation. In practice the VGP cluster can give confidence of adequate time sampling but dating of individual samples often fails to define the time interval.

Theory has had little or no input into the development of the GAD because dynamo theory has only very recently been developed to the point where it can be used to explore the nature of the time average. There are three separate issues. The first is the time span required to make an average. This must exceed the advection time, or time for fluid to traverse the core, which is about a thousand years. It probably needs to exceed the diffusion time, or time for the magnetic field to decay in the absence of dynamo action, which is about twenty-five thousand years. The magnetic field is quite chaotic—excursions are now known to occur every few tens of thousands of years, at least in the Brunhes—which suggests an even longer time span. Some paleo-magnetists advocate much longer times of millions of years, and the issue is not resolved.

The second is the dipolar structure, which requires the inclination to vary with distance from the pole according to the dipole formula, and the vertical field to vary as  $\cos\theta$ , where  $\theta$  is co-latitude. The dipole form falls off more slowly than any other configuration with distance from the source, and is therefore favored by our great distance from the Earth's core. It is very unlikely to result from dynamo action, and we now suspect preferred generation of magnetic field just outside the *tangent cylinder* as occurs in many geodynamo models and is seen in the modern field. Paleomagnetic data has been modeled by a variety of axisymmetric configurations limited to low degree axisymmetric spherical harmonics without any consensus. A review is given in Merrill and McElhinny (1996).
The third is whether the time-average contains any departures from axial symmetry. The simplest dynamo model would have the magnetic field rotating freely with respect to the solid mantle, leaving an axisymmetric time-average. Any departure from axial symmetry would therefore be evidence of the influence on core convection of anomalies in the solid mantle. Lateral variations in heat flux, topography, and electrical conductivity have all been suggested, but only heat flux has been investigated quantitatively (see Core-mantle coupling, thermal). Some numerical geodynamo models have laterally varying heat flux or temperature on the outer boundary defined by the shear wave velocity in the lowermost mantle, and some of these exhibit nonaxisymmetric time averages bearing some resemblance to the modern field (Bloxham, 2000). Paleodeclination, which is zero for all axisymmetric field configurations, is best for detecting departures from axial symmetry. Unfortunately it is a difficult measurement to make with confidence because the rock may have rotated. Geological mapping is capable of detecting tilt, or rotation about a horizontal axis, but cannot directly detect rotation about a vertical axis. Some authors therefore reject paleodeclination information altogether, while others claim that only an axisymmetric time-average can be estimated (McElhinny et al., 1996). However, when paleomagnetic data are subjected to the same analysis as is used in making models of the modern field (see Main field modeling) they produce departures from axial symmetry that resemble, at least in the northern hemisphere, those of the modern field (Gubbins and Kelly, 1993; Johnson and Constable, 1995), as expected from recent geodynamo simulations.

In summary, the time-averaged field encompasses both the oldest and the best-established hypothesis of paleomagnetism, the GAD, and the newest and most controversial meeting point between paleomagnetism and dynamo modeling, the question of whether the solid mantle influences the core. Current research programs into both the geodynamo and the paleomagnetic time average will undoubtedly answer some of the remaining questions in the near future.

# TIME-DEPENDENT MODELS OF THE GEOMAGNETIC FIELD

In this article we will review a selection of the different time-dependent models of the magnetic field that have been produced. We generally restrict attention to models that have been produced specifically as time-dependent models, typically using a dataset spanning a wide range in time; only a little reference is made to models designed to describe either the static magnetic field or its rate of change (secular variation) at a particular point in time. Useful descriptions of these types of model can be found in Barraclough (1978) or Langel (1987).

Our description centers then on models of the magnetic field **B** which are simultaneously models of its spatial  $((r, \theta, \phi)$  in spherical coordinates) dependence and the temporal dependence (*t* denotes time). The standard technique which is common to all the analyses we will describe is to employ the *spherical harmonic* (q.v.) expansion of the field in terms of Gauss coefficients  $\{g_l^m; h_l^m\}$  for the internal field; some of the most recent models also incorporate coefficients representing the external field. All the models will employ the Schmidt quasinormalization common in geomagnetism.

A time dependent model of the field necessarily must be built using a dataset spanning a period of time, denoted herein  $[t_s, t_e]$ . In order that a spherical harmonic analysis can be performed a parametrization is required for the temporal variation of the field. The unifying idea, common to all analyses, is to use an expansion for the Gauss coefficients of the form:

$$g_l^m(t) = \sum_i {}^i g_l^m \phi_i(t), \qquad (\text{Eq. 1})$$

where  $\phi_i$  are a set of basis functions and the  ${}^ig_l^m$  are a set of unknown coefficients. (A similar expansion is of course used for  $h_l^m$ .) The different models that have been produced over the last few decades differ in their choice of the  $\phi_i(t)$ . With an expansion of the form (1) the unknown coefficients  $\{{}^ig_l^m, {}^ih_l^m\}$  are denoted as a model vector **m**, and when linear data such as the elements (X, Y, Z) are required to be synthesized (denoted by vector **d**) the resulting forward problem is linear and of the form:

$$\mathbf{d} = A\mathbf{m},\tag{Eq. 2}$$

where A is often termed the equations of condition or design matrix. It is generally the case that the inverse problem of finding the coefficients **m** is solved using the method of least squares (see Main field modeling).

It is straightforward to treat single observations of the field (such as made by surveys or satellites) as being independent measurements that can be fitted simultaneously in a least-squares process. Some words are in order regarding the treatment of observatory data in time-dependent field modeling. Observatories obviously supply critical data on the secular variation, and indeed the accuracy of many of the modern field models rests on the observatory time series. A problem that must be recognized, however, is the fact that the observatories are subject to a (quasi-) constant field associated with the magnetization of the crust in the region that they are located. If observatory data are mixed with other types of data (survey, satellite data), this so-called observatory bias must be recognized, otherwise it will bias the solution for the main field because an observatory time-series essentially records it many times. Two approaches have developed for dealing with this. The first, developed by Langel *et al.* (1982), is to solve for the observatory biases (three per observatory in the *X*, *Y*, and *Z* directions) as unknowns at the same time as solving for the magnetic field. This technique continues to be adopted in the comprehensive series of field models (see below), and works very effectively. The second approach is to desensitize the observatory data to the presence of the bias. An effective way of doing this is to work with the rate-of-change of the field from the observatory, and hence first differences of observatory data are used in the ufm and gufm series of models (see below). There appears to be very little difference in the results of the two approaches.

### Taylor series models

The earliest analyses simply used a Taylor expansion for the Gauss coefficients of the form:

$$g_l^m(t) = g_l^m(t_0) + \dot{g}_m^m(t_0)(t-t_0) + \ddot{g}_l^m(t_0)\frac{(t-t_0)^2}{2!} + \cdots \quad \text{(Eq. 3)}$$

about some central epoch here denoted  $t_0$ . This expansion is of the form (1), with the identification  $\phi_i(t) = (t - t_0)^n / n!$  and  ${}^i g_l^m = (\partial_t)^n g_l^m(t_0)$ , the *n*th time derivative at the central epoch.

In the case of the Taylor expansion A is a dense matrix. The first models to be produced this way were those of Cain *et al.* (1965, 1967), who produced models GSFC(4/64) and GSFC(12/66) with temporal expansions truncated at first derivative and second derivative terms, respectively. The truncation level was subsequently raised to third derivative terms in the model GSFC(9/80) of Langel *et al.* (1982).

When it is desired to produce a model of the field spanning a long time period, it is clear that a large number of terms will be required in (3), and it no longer remains an attractive method because of numerical instabilities and lack of flexibility of the parametrization. It is known that in the case of an equidimensional inverse problem (the same number of data as unknowns) with perfect data, the inner-product matrix associated with the problem becomes the classically ill-conditioned Hilbert matrix. As a result the expansion (3) becomes unsuitable as a temporal expansion with many parameters.

#### Two-step models

A variety of models have been made by a two-step process of first making a series of spatial models at particular epochs, followed by some form of interpolation. For example, the international geomagnetic reference fields and definitive geomagnetic reference fields are strictly snapshot models of the field for particular epochs, but they can be used to calculate the magnetic field at times intermediate between two epochs by linear interpolation between the models. As a result it is possible to evaluate the DGRFs at any point in time between 1900 and the present day, though from a purist point of view they are not strictly time-dependent models of the magnetic field.

Finally, the idea of using splines as a temporal expansion was first employed in the two-step approach by Langel *et al.* (1986), an idea that proved influential on subsequent authors.

### Models of SV over century timescales

Beginning in the mid-1980s, more flexible representations of the time dependency were introduced. Beginning with Bloxham (1987), who used Legendre polynomials, a variety of functions have been usedsee Table T1. The methods have gradually moved toward the use of splines as basis functions, beginning with the work of Bloxham and Jackson (1992), very much in the pioneering spirit of Langel et al. (1986). There are two reasons for this change. Firstly, when global basis functions such as Legendre or Chebychev expansions are used, the design matrix remains dense and requires considerable memory for its storage, whereas a B-spline basis is a local basis, meaning that the basis functions are zero outside a small range (see Figure T4). This fact leads to a design matrix which is sparse (in fact it is banded), and its storage is minimized. Secondly, the B-splines provide a flexible basis for smoothly varying descriptions of data. In fact one can show that of all the interpolators passing through a time-series of points (say  $f(t_i), i = 1, N$ ), an expansion in cubic B-spline of order 4 (f(t)) say) is the unique interpolator which minimizes a particular measure of roughness

$$\int_{t_s}^{t_e} \left[ \frac{\partial^2 \hat{f}(t)}{\partial t^2} \right]^2 \mathrm{d}t. \tag{Eq. 4}$$

950

The idea of attempting to construct a smooth representation in time is an application of "Occam's Razor," that there should be no extra detail in the representation than that truly demanded by the data. This idea of "regularization" has been employed in the models of Table T1 from

Figure T4 B-splines of order 4.

that of Bloxham (1987) onward. All the models minimize a combination of norms on the core-mantle boundary (CMB) of the form:

$$\int_{t_s}^{t_e} \left[ \nabla_h^{(n_1)} \partial_t^{(n_2)} B_{\mathbf{r}} \right]^2 \mathrm{d}\Omega \,\mathrm{d}t, \tag{Eq. 5}$$

where  $B_r$  is the radial field on the CMB. The models produced by Bloxham, Jackson and coworkers use  $n_1 = 0$  and  $n_2 = 2$  in one norm, and  $n_1 = 1$  and  $n_2 = 0$  (approximately) in a second norm; this is slightly different to that of the comprehensive models (see below).

The ufm1/ufm2 and gufm1 field models share a common aim, namely to model the long-term secular variation at the core surface as accurately as possible. They were built using the B-spline basis with knots every 2.5 years, and from the largest datasets possible at the time: ufm1/ufm2 used over 250000 data originating from old ships' logs, survey data, observatories and satellite missions; a description of the oldest data can be found in Bloxham (1986) and Bloxham *et al.* (1989). The gufm1 model was built from similar data from the 20th century, but a vastly expanded historical dataset, described in Jonkers *et al.* (2003)—the model contains over 365000 data and 36512 parameters. No account is explicitly taken of external fields in these models.

### The comprehensive models

An effort began in the early 1990s to build a comprehensive series of field models which took account of many effects which are recorded in geomagnetic data in addition to the core secular variation. The first model was reported by Sabaka and Baldwin (1993). We will specifically report on the latest model CM4 (Sabaka *et al.*, 2004). In general terms the model includes representations of the main field, its secular variation, and both local-time (Sun-synchronous) and seasonal modes of the magnetospheric and ionospheric fields, as well as describing

**Figure T5** Comparison of secular variation models and annual means at (a) Chambon-la-Forêt, France, (b) Alibag, India. Because the post-1990 data were not used in the creation of *gufm1*, there is a small mismatch at the end of the data series—this shows the difficulty in predicting the secular variation.

ring-current variations through the *D*st index and internal fields induced by time-varying external fields. The data used in creating the model consists of POGO, Magsat, Ørsted, and CHAMP satellite data (totaling over 1.6 million observations) and over 500000 observatory data; the latter consist of either a 1.00 a.m. observation (actually an hourly mean) on the quietest day of the month during the 1960–2002.5 period, plus observations every 2 h on quiet days during the POGO and Magsat missions.

**Figure T6** Comparison of one month (April 1990) of hourly mean data (X, Y, and Z components) from selected observatories and predictions from CM4. (a) Charters Towers, (b) Kakioka, (c) Scott Base, (d) The *D*st index for April. Note the commencement of a magnetic storm on the tenth day. The *D*st index is used in the synthesis of predictions at individual observatories.

The comprehensive model takes into account not only the timevarying core magnetic field (out to degree 13) but also the static crustal field from degree 14 to degree 65. Because a model of the lithospheric field to this degree captures only a small proportion of the total lithospheric signal, it is necessary to also solve for 1635 observatory biases, generally three components at each observatory. The novel features of the model arise in its very sophisticated treatment of the external magnetic fields, and we will discuss these in some detail.

The ionospheric field is modeled as currents flowing in a thin shell at an altitude of 110 km. This leads to magnetic fields which are derived from potentials below and above this layer, which influence the observatory and satellite data, respectively (since all the satellites fly above this layer). In quasidipole coordinates, the currents are allowed to vary with 24, 12, 8, and 6 h periods, as well as annually and semiannually. Induced fields are accounted for by assuming that the conductivity distribution of the Earth varies only in radius, which means that an external spherical harmonic can only excite its corresponding internal spherical harmonic. The magnetospheric field is also parameterized in a similar way, with both daily and seasonal periodicities, but also a modulation is allowed based on the *D*st index.

In order to take into account the poloidal *F*-region currents through which the satellites fly, a parametrization is made in terms of a toroidal magnetic field, which also has periodic time variations.

The model is estimated by an iteratively reweighted least-squares method, using Huber weights, and the core contribution is regularized as in (5) using  $n_1 = 2$  and  $n_2 = 1$  in one norm and  $n_1 = 0$  and  $n_2 = 2$  in another. This difference from the ufm1/gufm1 method simply

represents a different approach; the fundamental quantity in the comprehensive models is the secular variation  $\partial_t B_r$ , which has an expansion in B-splines, and the main field  $B_r$  is found as the integral of this using the 1980 value as the offset or integration constant. All the other parameters are regularized in a similar way, by smoothing on spheres at different altitudes, representing the physical locations of the sources. In total CM4 consists of 25243 free parameters.

# Discussion

To illustrate the fidelity with which the various field models are able to model observatory data, we show in Figure T5 a comparison of model *gufm1*'s predictions with some observatory annual mean datasets. To show CM4's performance on very short timescales, Figure T6 compares the model to hourly mean values for the month of April 1990,

**Table T2** Comparison of r.m.s differences between observatory annual means and predictions from the models gufm1 and CM3, the latter with or without its external contributions

Component	No. of data	gufm1	CM3 (all)	CM3 (no external)
X	4047	17.71	17.48	18.09
Y Z	4047 4047	21.27 24.55	21.45 24.49	21.47 24.53

**Figure T7** Comparison of model values for first six Gauss coefficients. (a) 1590–1990, (b) 1960–2002.5. Solid is gufm1, dashed is CM4 and the triangles are DGRFs. In (a)  $g_1^0$  has been fixed to decrease at a rate of 15 nT yr<sup>-1</sup> prior to 1840; in the absence of intensity data it is necessary to fix the amplitude of the solutions.

data that were not used in deriving the model. It is clear that the model is capable of predicting variations rather well, though with more difficulty at the Antarctic station SBA (Scott Base). Table T2 compares the performance of models gufm1 and CM3 against observatory data, showing almost identical performance. This comes about principally because of the large intrinsic variance of the data at some observatories, which neither field model is able to capture. Figure T7 shows a comparison of the model predictions for the variation in the first six Gauss coefficients over century and decade timescales. Although small differences exist, particularly in estimates of the instantaneous secular variation, it is apparent that modeling has reached a stage where there is considerable consensus between the models.

# **TRANSFER FUNCTIONS**

### Introduction

Transfer functions are used in *magnetotellurics* and *geomagnetic depth sounding* to determine subsurface electrical conductivity from surface measurements of natural electric and magnetic fields (Simpson and Bahr, 2005). A transfer function describes the mathematical relationship between surface measurements of variations of electric and magnetic fields.

# Magnetotelluric transfer functions

Magnetotellurics uses natural electromagnetic field variations to image subsurface electrical resistivity structure through electromagnetic induction. The surface electric and magnetic fields at each frequency are related through

$$\begin{bmatrix} E_x \\ E_y \end{bmatrix} = \begin{bmatrix} Z_{xx} & Z_{xy} \\ Z_{yx} & Z_{yy} \end{bmatrix} \begin{bmatrix} H_x \\ H_y \end{bmatrix}$$

where Z is defined as the magnetotelluric impedance, a transfer function. The components  $E_x$  and  $E_y$  are orthogonal components of the electric field and  $H_x$  and  $H_y$  are orthogonal components of the magnetic field. These electromagnetic fields are nonstationary and the transfer functions are computed as the average of many measurements. Robust statistical methods are used to reliably estimate the transfer functions (Jones *et al.*, 1989; Larsen *et al.*, 1996; Egbert, 1997) and remotereference processing should always be used (Gamble *et al.*, 1979).

### Magneto-variational studies

The vertical and horizontal magnetic fields are related through a magnetic field transfer function **T** defined as

$$[H_z] = \begin{bmatrix} T_{xz} & T_{yz} \end{bmatrix} \cdot \begin{bmatrix} H_x \\ H_y \end{bmatrix}.$$

In the simple 2D geometry shown in Figure T8, the electric currents flow along a conductivity anomaly and generate vertical magnetic fields that are oriented upward on one side and downward on the other. The magnetic field transfer function is often called the tipper. The transfer function T can also be displayed as induction arrows which are horizontal vectors with north and east components  $T_{zx}$  and  $T_{zy}$ , respectively. Each component of the induction arrow is a complex number with a real (in-phase) and imaginary (out-of-phase) part. In the convention of Parkinson (1962), the real induction arrows point toward a conductor (see Dudley Parkinson) as shown in Figure T8. In the Wiese convention the arrows point away from conductors (Wiese, 1962). The direction of the induction arrows is further discussed by Lilley and Arora (1982). Induction arrows exhibit a reversal above a conductivity anomaly as illustrated in Figure T8. The ocean is the largest conductor on the surface of the Earth. Thus in surveys in coastal areas, the real Parkinson arrows will point at the ocean and the seawater must be included in conductivity models (see Coast effect of induced currents). Edward Bullard is alleged to have commented that "geomagnetic induction was a good way to find coastlines, but there are easier ones." Large-scale magneto-variational studies generate

**Figure T8** The geometry of the vertical magnetic fields associated with naturally induced electric currents flowing in a buried conductor. In the Parkinson convention the real induction arrows point at the conductor, become stronger as the conductor is approached, and then reverse direction above the conductor.

maps of induction arrows over a wide range of frequencies and have been used to map the structure of the lithosphere on a number of continents (Gough, 1989).

### Interstation transfer functions

If magnetotelluric data are recorded simultaneously at an array of stations, then interstation transfer functions can be defined. If a magnetic field  $H_x^1(\omega)$ , is measured at one station and  $H_x^2(\omega)$ , is measured at another station, then the interstation transfer function can be written as

$$I_{21}(\omega) = \frac{H_x^2(\omega)}{H_x^1(\omega)}$$

at a frequency  $\omega$ . All stations in an array are related to the same base station. One of the first applications of this method was described by Schmucker (1970) in a study of the southwestern United States. Interstation magnetic field transfer functions can be inverted in a similar way to apparent resistivity and phase to produce a resistivity model of the Earth.

# TRANSIENT EM INDUCTION

Geophysicists measure the electrical conductivity of subsurface materials for a variety of purposes including geological mapping, mining investigation, groundwater resource evaluation and environmental assessment (Meju, 2002). One of the methods used for mapping subsurface conductivity distributions is the transient electromagnetic (TEM) method that employs artificially controlled source fields. The TEM method is sensitive to electrical conductivity averaged over the volume of ground in which induced electric currents are caused to flow.

# Transient electromagnetic induction

The TEM method is founded on Maxwell's equations that govern electromagnetic phenomena. Combining Ohm, Ampere, and Faraday laws (Wangsness, 1986; Jackson, 1998) results in the damped wave equation

$$\frac{\partial^2 B}{\partial t^2} - \mu_0 \sigma \frac{\partial B}{\partial t} - \mu_0 \epsilon \frac{\partial^2 B}{\partial t^2} = \mu_0 \nabla \times J_{\rm S}, \tag{Eq. 1}$$

where *B* is magnetic field,  $\mu_0$  is magnetic permeability,  $\sigma$  is electrical conductivity,  $\varepsilon$  is dielectric permittivity,  $J_S$  is the source current distribution, and *t* is time. For most geophysical applications of TEM, the earth is generally considered to be nonmagnetic, such that  $\mu_0 = 4\pi \times 10^{-7} \text{ Hm}^{-1}$ , the magnetic permeability of free space. The third term on the left-hand side of (1) is the energy storage term describing wave propagation. The second term on the left-hand side of (1) is the energy dissipation term describing electromagnetic diffusion. In the TEM method,  $\partial^2 B/\partial t^2$  is relatively insignificant compared to  $\partial B/\partial t$ , so that the wave propagation term is safely ignored. TEM induction is thus a diffusive phenomenon.

A physical understanding of this phenomenon can be obtained by recognizing that the induction process is equivalent to the diffusion of an image of the transmitter (TX) loop into a conducting medium. The similarity of the equations governing electromagnetic induction and hydrodynamic vortex motion, first noticed by Helmholtz, leads directly to the association of the image current with a smoke ring (Lamb, 1945, p. 210). The latter is not "blown," as commonly thought, but instead moves by self-induction with a velocity that is generated by the smoke ring's own vorticity and described by the familiar

Biot-Savart law (Arms and Hama, 1965). An electromagnetic smoke ring dissipates in a conducting medium much as the strength of a hydrodynamic eddy is attenuated by the viscosity of its host fluid (Taylor, 1958, pp. 96–101). The medium property that dissipates the electromagnetic smoke ring is electrical conductivity.

An inductively coupled TEM system is shown in Figure T9a. A typical TX current waveform I(t) is a slow rise to a steady-on value  $I_0$  followed by a rapid shut-off, as exemplified by the linear ramp in Figure T9b (top plot). Passing a disturbance through the TX loop generates a primary magnetic field that is in-phase with, or proportional to, the TX current. According to Faraday's law of induction, an electromotive force (emf) that scales with the time rate of change of the primary magnetic field is also generated. The emf drives electromagnetic eddy currents in the conductive earth, notably in this case during the ramp-off interval, as shown in Figure T9b (middle plot). After the ramp is terminated, the emf vanishes and the eddy currents start to decay via Ohmic dissipation of heat. A weak, secondary magnetic field is produced in proportion to the waning strength of the eddy currents. The receiver (RX) coil voltage measures the time rate of change of the decaying secondary magnetic field as depicted in Figure T9b (bottom plot). In typical TEM systems, the RX voltage measurements are made during the TX off-time when the primary field is absent. The advantage of measuring during TX off-time is that the relatively weak secondary signal is not swamped by the much stronger primary signal.

During the ramp-off, the induced current assumes the shape of the horizontal projection of the TX loop onto the surface of the conducting ground. The sense of the circulating induced currents is such that the secondary magnetic field they create tends to maintain the total magnetic field at its original steady-on value prior to the TX ramp-off. Thus, the induced currents flow in the same direction as the TX current, i.e., opposing the TX current decrease that served as the emf source. The image current then diffuses downward and outward while diminishing in amplitude. A mathematical treatment of the electromagnetic smoke ring phenomenon appears in Nabighian (1979).

### Transient electromagnetic forward modeling

Calculation of the TEM field generated by a magnetic or electric dipole source situated on, above or within a layered conducting medium is a well-known boundary value problem of classical physics. One standard solution technique is to calculate the mutual impedance, Z between the transmitter and receiver loops as a function of measurement (or delay) times t. For a TX loop of radius a and RX loop of radius b that are co-axial and located on the ground's surface, we have that (Knight and Raiche, 1982)

$$Z(t) = -\pi\mu_0 ab \int_0^\infty L_p^{-1} \{I(p) p A_0(\mathbf{m}, p, \lambda)\} J_1(\lambda a) J_1(\lambda b) d\lambda.$$

In the above equation,  $A_0(\mathbf{m}, p, \lambda)$  is the layered-earth impedance function, **m** represents the parameters of the hypothetical earth-model (namely electrical conductivities,  $\sigma_j$  and thicknesses,  $h_j$  of the layers), p is the Laplace transform variable corresponding to  $-i\omega$  where  $\omega$  is the angular frequency, "i" is the imaginary unit,  $\lambda$  is the integration variable for the inverse Hankel transform, I(p) represents the Laplace transform of the normalized current waveform and is equal to  $-p^{-1}$  for step function turn-off of TX current,  $J_1$  is the Bessel function of order 1, and  $L_p^{-1}$  is the inverse Laplace transform operator with respect to p.

Similar analytic solutions are available for other TX-RX configurations and a variety of special-purpose algorithms are available for evaluating such Hankel transforms or integrals over Bessel functions. Note that the manner in which the TX current is switched off influences the TEM response and needs to be accounted for in the forward models (Raiche, 1984).

The TEM response of 3D subsurface conductivity distributions requires the application of numerical methods for solving the governing Maxwell partial differential equations (see Hohmann, 1987). Full 3D numerical simulations involve a complete description of the physics of electromagnetic induction including galvanic and vortex contributions. The galvanic term appears when induced currents encounter spatial gradients in electrical conductivity. Electric charges accumulate across interfaces in electrical conductivity. In 1D layered media excited by a purely inductive electromagnetic source such as a loop, induced currents flow horizontally and do not cross layer boundaries. In that case, only the vortex contribution is present.

# Transient electromagnetic method of geophysical prospecting

In TEM surveying, a primary field is generated by a rectangular or square TX loop, with dimensions of ten to a few hundred meters (Figure T10). A long straight wire grounded at both ends can also serve as the transmitter. For shallow depth probes, a 20 m-sided TX loop could suffice for imaging about 60-100 m depth depending on ground conditions (Meju *et al.*, 2000). The primary field is not continuous but consists of a series of pulses between which the

**Figure T9** (a) TX loop lying on the surface of an isotropic uniform half-space of electrical conductivity,  $\sigma$ . A disturbance *l*(*t*) in the source current immediately generates an electromagnetic eddy current in the ground just beneath the TX loop. An RX coil measures the induced voltage *V*(*t*), which is a measure of the time-derivative of the magnetic flux generated by the diffusing eddy current. (b) Typical TX current waveform *l*(*t*) with slow rise time and fast ramp-off; induced emf *V*(*t*), proportional to the time rate of change of the primary magnetic field; decaying secondary magnetic field *H*(*t*) due to the dissipation of currents induced in the ground (Everett and Meju, 2005).

**Figure T10** Basic set-up for TEM surveying. The ground is inductively energized using a grounded wire or transmitter loop. The electric or magnetic fields induced in a subsurface conductor ( $\sigma(r)$ ) are systematically measured along survey lines using a suitable detector coil.

primary field is switched off and measurements made. The rapid termination of the primary field in the TX causes Eddy currents to be produced in the subsurface, and the associated secondary field is measured on the surface using a detector (RX) coil (Figure T10). RX may be a small multiturn coil (about 1 m diameter) or a relatively large loop. The decaying transient signal is sampled at various time gates to yield a sounding curve. The transient signal can last from a few microseconds to several hundreds of millisecond, and an observational bandwidth of about 0.005-30 ms is desirable for near-surface investigations (10-400 m). The character of the transient signal is a function of the subsurface resistivity structure, with the shallow structure influencing the TEM response at early times soon after TX turn-off and measurement at increasing times allowing the deeper electrical structure to be interpreted. For shallow structure, TEM systems use high base-frequencies (i.e., pulse repetition rates), small transmitter loops (5-50 m), need only low power source (12 V battery), but in particular requires a very rapid primary field turn-off (currently  $\leq 1.5 \ \mu$ s). The accuracy of the narrow early sampling times is also an important factor. For deeper structure, larger transmitter loops, higher power and of course longer transient measuring times at the receiver are required.

There are a number of different configurations as regards the position of the receiver relative to the transmitter (Figure T10). The receiver can be located in the center of the TX loop (in-loop or central-loop technique) or outside it (separated-loop or offset-loop arrangements). In the single-loop or coincident-loop configuration, the TX loop serves as the RX during transmitter-off times or both the TX and RX loops are separate but coincident.

# **TRUE POLAR WANDER**

# Definitions and early views

The idea that polar wander (PW) must have occurred dates back to the 19th century. Geologists, paleontologists, and paleoclimatologists suggested that the Earth's equator must have been located far from its present position in the distant geological past, at least viewed from certain continents, given the present day locations of climatological belts derived from certain types of rocks or fossil assemblages. Darwin (1877) made the first attempt at quantitative modeling but this suffered from several errors (see Steinberger and O'Connell, 2002, for an analysis). In the early 1950s, paleomagnetists provided quantitative evidence that the geographical latitudes of individual continents had indeed changed with time, hence that the instantaneous geographic or rotation pole had moved with respect to most continents. The paths followed by the poles in the geological past were termed "apparent" polar wander paths (or APWPs), because it was not clear whether it was the pole or the continent that had moved. It would soon become apparent that continents (more accurately tectonic plates) had moved with respect to each other and that a significant part of APW was actually due to these relative motions. The question was: is there a remaining fraction in polar wander, which would be a characteristic of "Earth as a whole," and which would not be accounted for by plate tectonics. This fraction is what is generally called "true" polar wander (TPW).

TPW refers to the large scale motions of the Earth's rotation axis with respect to the "bulk silicate Earth" or "solid Earth" through geological time (rather than "Earth as a whole," indeed, much of the core is a fluid with small viscosity and the parts which will be important to us in this article are the solid though slowly deforming mantle and crust, i.e., the silicate earth; see below). External forces driving shorterterm changes, such as precession, are not considered here. TPW could result from centrifugal forces acting on mass anomalies distributed on or inside the Earth: excess mass, for instance, will lead to slow deformation of the Earth and change its rotation axis, causing the mass to move towards the equator without being displaced with respect to the solid Earth. The problem is to define precisely which part wanders with respect to which reference frame in a deformable Earth. We seek to identify the axis of rotation of a reference frame RF which is relevant to the solid Earth relative to an inertial (or absolute astronomical) frame of reference IFR (i.e., determined by the angular momentum vector of Earth; see f.i. Steinberger and O'Connell, 2002). The reference frame RF can be selected as the one which has zero net rotation when motions are integrated over the entire mantle, called the "mean mantle" reference frame. Or one can define a "mean lithosphere" frame, in which the lithospheric plates have no net rotation. Because of lateral variations in viscosity of the deformable Earth layers, these frames in general do not coincide (Ricard *et al.*, 1991; O'Connell *et al.*, 1991). Although the "mean mantle" frame can be computed in numerical simulations in which the density distribution is given in the entire mantle, when attempting to constrain it with actual (paleomagnetic) observations, we will have to assume that the "mean mantle" frame is identical to some frame based on observations: the "hotspot reference frame" will most often be the one involved. Steinberger and O'Connell (2000) calculate that the approximation is good even if hotspots move in the convecting mantle (see also Davies, 1988; Steinberger, 2000). This is discussed further later in this article.

Is the concept of Earth as a whole meaningful? If the Earth were perfectly rigid, there would be no polar wander. Of course we now know that the Earth is not rigid, and that its crust and mantle actually deform actively at the typical velocities of plate tectonics ( $\sim 10-100 \text{ mm yr}^{-1}$ ). Thus, PW involves (relative) motions of the rotation axis with respect to the Earth's mantle. Lambeck (1980) points out that from the time of Kelvin, in 1863, up to the work published by Gold in 1955, a number of qualified physicists believed that polar wander was not only possible, but even inevitable if the long-term rheology of the planet was inelastic.

However, in a landmark treatise on the rotation of the Earth, Munk and Macdonald (1960) were led to question both the observational and theoretical bases for large-scale polar wandering. They considered that evidence from either paleomagnetism or paleontology available at that time was at best tenuous, and proposed that the "excess" bulge (the present bulge is indeed larger than what would be expected if the Earth behaved as a fluid, called the hydrostatic bulge) was a fossil remainder from a time when the Earth rotated faster.

A decade later, plate tectonics and continental drift had basically been established. Another landmark paper by Goldreich and Toomre (1969) reflected the new view of the Earth. They hypothesized that (large scale) polar wandering and continental drift shared a common explanation through mantle convection and resulting redistribution of masses within the mantle. Goldreich and Toomre (1969) started their analysis of the motions of the rotation axis of a quasirigid (slowly deforming) Earth with the now classical figure (inspired by Gold, 1955) where a colony of beetles (the continents or other mass anomalies) move slowly at the surface of a rigid rotating sphere (Figure T11a). They used this to demonstrate that, once set spinning about the axis with the greatest nonhydrostatic moment of inertia, a slowly deforming body would always continue to spin almost exactly about the same principal axis, as that axis moved through it. Viewed from space, the rotation and principal axes are fixed with respect to the stars, and the crust and mantle move relative to it (again, the shorter-term effects of precession are neglected here). The speed of motion is  $N^{1/2}$  times the average speed of the *N* beetles of mass *m*; hence if *N* (and *m*) is large, large polar wandering is possible. In a numerical experiment, Goldreich and Toomre (1969) simulated very large polar wander, with particularly intense and rapid swings.

The physics of TPW can be explained in a (hopefully) simple way (e.g., Ricard et al., 1993a; Steinberger and O'Connell, 2002). TPW is seen as the result of conservation of angular momentum of a rotating, deformable body (i.e., whose inertia tensor slowly changes with time). In simple terms, the inertia tensor comprises three components (1) the inertia of a spherical Earth, (2) the hydrostatic equilibrium part, that is the inertia of its equatorial bulge (which, as mentioned above, is slightly larger than what it would be if the planet were a fluid), and (3) the remainder, the "total" nonhydrostatic contribution to the inertia tensor, which itself comprises a contribution "imposed" by mantle convection (linked to subducting slabs, upwelling plumes, and more generally thermal and chemical mass heterogeneities resulting from the long history of mantle convection) and one caused by the change of the rotation axis and the immediate elastic and delayed viscoelastic adjustment to the new equilibrium shape. Each of the three terms is very small compared to the previous one. Changing the rotation of a spherical object (term 1) does not require energy on geological time scales; the bulge (term 2), itself a function of rotation, results in a viscous drag which controls only the speed at which rotation can

**Figure T11** (a) Diagram illustrating polar wander on a quasirigid planet (after Goldreich and Toomre, 1969; Gordon, 1987). The beetles represent mass anomalies which change with time (drifting plates or mantle heterogeneities), inducing changes in the principal nonhydrostatic moments of inertia. The coordinate system attached to the (slowly deforming) solid planet moves with respect to the rotation (or spin) axis. (b) Example of interplay between deformation and change of the rotation axis of the Earth in the hypothetical case when four mass changes (two positive or excess, two negative or deficit) are imposed such that the center of mass does not change and only one nondiagonal inertia tensor element changes (from Steinberger and O'Connell, 2002). In an absolute astronomical reference frame the direction of the rotation axis is fixed; positive masses drift to the equator (and negative ones away). Therefore the relative position of the rotation axis changes with respect to the mass distribution, the change in rotation axis causes the Earth to deform, the change in shape causes the axis to move further, until a new equilibrium is asymptotically approached.

958

change; as a result, the direction of rotation is fixed by the smallest term (term 3), i.e., the nonhydrostatic component. The rotation axis tracks the maximum eigenvector of the nonhydrostatic inertia tensor as fast as adjustment of the hydrostatic bulge allows (Figure T11b illustrates this for a simple case): the hydrostatic bulge is a response to the current rotation axis, and it will move in accord with the motion of that rotation axis, which is determined by the nonhydrostatic inertia tensor. Seen from an observation point on the surface of the Earth, TPW appears as the wave-like propagation of the bulge. Ultimately, the viscosity of the mantle will control the rate of this motion (Ricard *et al.*, 1993a,b; for a recent synthesis and numerical results showing the time scales involved, see Steinberger and O'Connell, 2002).

With estimates of degree 2 components of the geopotential derived from satellite data, Goldreich and Toomre (1969) showed that the nonhydrostatic part of the earth's inertia ellipsoid is triaxial, the present rotation axis coinciding with the largest of the nonhydrostatic moments of inertia. Therefore, there was no need to resort to the idea of a fossil bulge: the nonhydrostatic Earth simply departs from perfect sphericity. Goldreich and Toomre's (1969) Earth had no bulge to control the rotation speed (on a rotating planet, the faster the beetles the more random their paths and the less the viscous bulge has time to flow, impeding TPW); also isostatic compensation implies that only objects far from interfaces (such as subductions and upwellings, not surface plates or beetles...) which are not isostatically compensated can act (e.g., Ricard *et al.*, 1993b). But their presentation had a goal of pedagogical efficiency and in that sense was quite successful.

### How is TPW measured (on short time scales)?

Now, how can we obtain measures of the position of the rotation axis of the Earth? This depends on the time scale. On the short side of the scale, astronomers and geodesists are the appropriate experts. According to these scientists, polar wandering is occurring at present. One of the most recent determinations uses the star catalogue established from the Hipparcos astrometric satellite (determinations of the positions, proper motions, and parallaxes of 100000 stars). Optical astrometric measurements of star positions made during the past century have been rereduced using that catalogue by Gross and Vondrak (1999), producing the longest available homogeneous series of polar motion. The annual, Chandler, and Markowitz wobbles (all periodic or quasiperiodic with annual to decadal periods) have been separated from the longer-term trend of the mean pole (which is of interest to us). The result (see arrow in Figure T12) is a mean drift of the Earth's rotation pole over the period 1900–1992 of 3.5 milliarcsec yr<sup>-1</sup> (or ~107 mm a<sup>-1</sup> or 107 km Ma<sup>-1</sup> for later comparison with geological values), along the direction of the 79°W meridian (uncertainties on absolute values are a few per mil). Data reduction involves modeling of tectonic plate motions, tidal variations and ocean loading and this estimate of present-day TPW is considered as the best unbiased one. This is actually not far from earlier determinations, for instance by Markowitz (1970) (3.5 milliarcsec yr<sup>-1</sup> towards 65°W longitude).

It has been proposed since the late 1970s that this long-term polar wander is largely due to postglacial rebound, i.e., lithospheric and mantle response to melting of ice (e.g., Sabadini and Peltier, 1981; Mitrovica and Milne, 1998), which has mainly a vertical expression at the surface. The pole is moving toward Hudson Bay, where a large ice mass melted and the lithosphere is currently rising. Possibly contributing sources include mantle convection (Steinberger and O'Connell, 1997), and secular change in ice sheet mass and sea-level (e.g., James and Ivins, 1997). McCarthy and Luzum (1996) compare theoretical estimates and conclude that snow loading, changes in Antarctic ice and Pleistocene deglaciation all provide estimates in reasonable agreement with observations. Melting of glaciers or changes in major hydrological reservoirs are at least a factor of 10 less efficient. Overall, the hydrostatic bulge adjusts to changes in the position of the Earth's rotation axis in about 10<sup>4</sup> years, which is the characteristic time for upper mantle deformation (glacio-isostatic rebound).

### How is TPW measured (long time scales)?

How long have the recent rate and direction been maintained, and what values applied in the geological past? On these longer time scales, say longer than  $10^6$  years, paleomagnetism has become the primary source of information. Although interesting information comes from geological field observations (reconstruction of paleoclimate belts based on occurrences of fossils or certain rock types, or wind

**Figure T12** (a) True polar wander paths deduced from the hotspot model of Müller *et al.* (1993) going from the Present back to 130 Ma, and that of Morgan (1983) going from 130 back to 200Ma, with associated 95% confidence ellipses (shaded light gray); 20 Ma sliding window. Ages are in Ma and correspond to the actual mean age of the data in the corresponding window, which is why they are not regularly distributed when the original time windows were. Note that the external circle is at 50° latitude. (b) A simplified outline of the TPW path of (a) outlining successive episodes and standstills. The long arrow shows the mean direction of pole motion between 1900 and 1990 (79°W with a large uncertainty); modulus is ~107 mm a (see text, section "How is TPW measured (on short time scales)?"). (After Besse and Courtillot, 2002).

directions), the key source of quantitative information on polar wander originated from the first paleomagnetic works in the 1950s (with the seminal paper of Creer *et al.*, 1954), and paleomagnetism has remained the main provider of such data. Although clearly doubtful, Munk and MacDonald (1960) already spent a first long chapter on paleomagnetic evidence of polar wander, noting the importance of early syntheses by Runcorn (1956) and several others who demonstrated that continents could not have remained in the same relative positions throughout geological time. A recent review of paleomagnetism is given by McElhinny and McFadden (2000).

The apparent polar wander paths from all the major plates are being defined with increasing accuracy, and their differences reflect continental drift and plate tectonics. This demonstration of the reality of "apparent" polar wander seen from any plate has led some to propose that the concept of "true" polar wandering might be irrelevant or unnecessary (see review in Gordon, 1987). McKenzie (1972) noted that the concept of PW could be useful if the motion of the pole relative to any one plate was much larger than the motion between pairs of plates (Figure T13). The most often accepted view is that the concept is worthwhile if a reference frame external to the plates themselves can be defined, in which there was significant motion of the pole. Various attempts, namely the "vector-sum" and "mean-lithosphere frame" methods, have been reviewed for instance by Jurdy (1981) and Gordon (1987). The "mean-lithosphere frame," first proposed by Jurdy and Van der Voo (1974, 1975), minimizes the difference between a displacement (vector) field and a rigid rotation of the entire Earth's surface. Jurdy and Van der Voo found no significant change in the Cenozoic and Jurdy (1981) concluded in favor of hotspot motion, not TPW. Hargraves and Duncan (1973) had earlier proposed the idea of "mantle roll" in which the nonlithospheric mantle "rolls" beneath the mean lithosphere to which the rotation axis is fixed. McElhinny and McFadden (2000, p. 328) repeated some of these calculations with updated kinematic and paleomagnetic data and concluded that TPW was not discernible from zero over the past 50 myr, as had been found by Jurdy and Van der Voo (1974, 1975).

However, most studies performed in the last two decades follow an alternate approach, based on the possibility, originally suggested by Morgan (1972, 1981), that hotspots could provide a valid reference frame for the mantle. The meaning and existence of that reference frame has been the subject of continued debate, up to this day.

### Apparent and TPW, and the hotspot reference frame

We recall that hotspots are active volcanoes, apparently unrelated to (and often but not always far from) plate boundaries, which have been active for tens of millions of years. Hotspots are supposed to be the surface manifestation of plumes, which have left traces in the form

of (quasi-) linear chains of extinct volcanoes on the plate(s), which passed over them. Morgan (1972, 1981) proposed that these plumes have a "deep" mantle origin: these convective instabilities may be anchored at least down to the transition zone and possibly all the way down to the core-mantle boundary (yet another topic of heated debate). As a plate moves over such a plume, the relative motion can be described by a rotation about a pole, which is often called the Euler pole: if the rotation axis remains unchanged, the trace of the plume (the hotspot track) will form a small circle about the Euler pole, as do transform faults about the relative rotation axis of two plates (Figure T14). If the traces can be identified and the extinct volcanoes dated, one can define a "hotspot apparent polar wander" (Gordon, 1987) in the same way one defines the apparent polar wander path of any plate. If hotspots are indeed fixed with respect to each other and are fixed within the mantle (we will return to these essential assumptions), then hotspot apparent polar wander describes the wander of the Earth's rotation axis with respect to the hotpots (or vice versa). It is this motion of the pole with respect to the hotspots, assumed to act as a reference frame for the mantle, which has been taken as an estimate of TPW. Motion of plates with respect to the hotspots is sometimes (improperly) called "absolute motion." Note that "APW" (corresponding to a rotation operator  $\Omega_1$ ), i.e., the rotation of the Earth's rotation axis with respect to a given plate, "HS" or "absolute motion" (corresponding to a rotation operator  $\Omega_2$ ), i.e., the rotation of the plate with respect to the hotspot reference frame, and "TPW" (corresponding to a rotation operator  $\Omega_3$ ), i.e., the rotation of the Earth's rotation axis with respect to the hotspot reference frame are linked through the simple equation:  $\Omega_1 = \Omega_2 \times \Omega_3$  (i.e., as soon as two of them are given the third can be derived, see, e.g., Besse and Courtillot, 2002).

Determining TPW in that sense requires the best possible knowledge of APWPs of all plates (i.e., the best possible data base of paleomagnetic poles to determine the paleolatitudes and orientations of plates with respect to the rotation axis), of their relative motions (e.g., kinematics from oceanic data such as marine magnetic anomalies and azimuths of transform faults), and positions and ages of individual volcanoes along hotspot tracks on as many plates and for as many hotspots as possible. Paleolatitudes of these seamounts are used for comparison to test model predictions. Note that (except in the final part of this article) we will restrict ourselves to the last 200 million years (i.e., the time for which some ocean kinematic information is preserved).

APWPs and kinematic models were developed from the 1960s to the 1980s under the key assumption that, when averaged over a sufficient amount of time, in excess of a few thousand years, the Earth's magnetic field could be described accurately by a geocentric axial dipole (so-called GAD hypothesis). Following early attempts by Livermore *et al.* (1984) and Andrews (1985), Besse and Courtillot (1988, 1991) proposed to blend the two data sets (i.e., the paleomagnetic poles used

**Figure T13** True polar wander in the mean lithosphere reference frame. Each thin solid line with arrow represents motion of the north pole (NP)  $_{n}V_{NP}$  with respect to a plate *n* (or vice versa). The thick vector  $V_m$  links NP with the center of gravity of the end-points of all individual velocity vectors (weighed by the fractional area occupied by each plate). True polar wander is considered useful when the modulus (scalar magnitude) of  $V_m$  is large compared to those of the dashed vectors representing velocities with respect to the center of gravity,  $_{n}V_{NP}-V_m$ . (after McKenzie, 1972; McElhinny and McFadden, 2000).

**Figure T14** Relationship between hotspot tracks and segments of APW paths if the spin axis has been fixed with respect to the hotspots. Plate F is fixed relative to the hotspots, while plate M rotates about the Euler pole relative to plate F, the hotspots and the paleomagnetic axis (assumed to coincide with the spin axis). The hotspot trace on plate M, the transform faults on the plate boundaries between F and M, and the segment of the APW path all lie on small circles centered on the Euler pole (Gordon, 1987).

to derive the APWPs and the oceanic data used to derive plate kinematic models). They used then available paleomagnetic data (from North America, Africa, Eurasia and India) and kinematic models (from the Indian, Central Atlantic, and North Atlantic oceans) and produced a "synthetic" APWP, which was defined with respect to South Africa and then transferred to all other plates. Motion of hotspots with respect to the plates was then integrated to derive an estimate of TPW. As a consequence of publication of a Global Paleomagnetic computerized Database and of much improved reconstructions of past plate motions, this work was updated recently (Besse and Courtillot, 2002).

### A recent TPW curve for the last 200 million years

The resulting TPW curve, based on 242 independent data from the African, Antarctic, Australian, European, Greenland, Indian, and North and South American plates, is shown in Figure T12a with a 20 myr time resolution. Points are shown with their 95% confidence circles (radii  $A_{95}$ ) every 10 myr and every other point is statistically independent (estimates at 5 myr intervals are also available in that study). We recall that the 95% confidence intervals depend on many parameters linked to paleomagnetic data collection and laboratory treatment (see, e.g., McElhinny and McFadden, 2000, p. 91), but fail to explicitly include uncertainties on plate motions: they are supposed to be our best estimate of the cone within which the "true" direction is expected to lie. In other terms, there is a remaining 5% chance that our determination is more than  $A_{95}$  away from the true direction.

The first points, corresponding to the period 8-59 Ma, are all in the same quadrant, between  $3.3^{\circ}$  and  $5.9^{\circ}$  away from the present rotation pole, with 95% uncertainties ranging from  $2.0^{\circ}$  to  $3.8^{\circ}$ . They are not statistically distinct from each other and therefore could correspond

to a standstill. A mean position can be calculated from all (102) data points in that time window: it is found to lie at 85.1°N, 153.3°E  $(A_{05} = 1.5^{\circ})$ , significantly displaced from the pole. The youngest mean pole at  $\sim$ 5 Ma (mean age 3.0  $\pm$  2.4 Ma) is at 86.4°N, 166.8°E  $(A_{95} = 2.5^{\circ})$ , also significantly displaced from the pole but not statistically different from the 8-59 Ma overall mean. It seems that TPW may have been negligible for an extended period of about 50 myr, but accelerated a few myr ago, with a velocity on the order of 100 km myr<sup>-1</sup>. The path displays a succession of a standstill at 160-130 Ma, a quasicircular track from 130 to 70 Ma, then the standstill at 50-10 Ma and the faster motion up to the present (Figure T12b). The TPW rate between 130 and 70 Ma averages 30 km my<sup>-1</sup>. This would confirm earlier findings (e.g., Andrews, 1985; Besse and Courtillot, 1991) that TPW appears episodic in nature, with periods of (quasi-) standstill alternating with periods of faster TPW. The typical duration of these standstill periods is on the order of a few tens of millions of years (50 myr). Because of all the uncertainties in models of hotspot kinematics prior to  $\sim$ 130 Ma, it is not safe to place too much weight on behavior prior to that time. The major event since then is therefore the end of the 130-60 Ma period of relatively fast polar wander, with the standstill (i.e., no or little TPW) from 60 Ma (actually because of larger 95% confidence circles, possibly 80 Ma) to 10 Ma. Marcano et al. (1999) find TPW rates on the order of or less than 40 km myr<sup>-1</sup> in the Permotriassic, i.e., typical of times since then, extending the period of moderate TPW back to more than 250 myr.

However uncertain, evidence for the fact that Earth emerged from a long standstill to enter a new period of faster polar wander in a different direction 10 Ma ago (~5 Ma at the higher resolution) is particularly interesting. That period would then still be going on. The youngest pole at ~5 Ma, taken at face value, would imply a TPW rate of 130 km myr<sup>-1</sup> in the direction ~15°W (with a large azimuthal uncertainty from 10°E to 40°W, due to proximity of the 5 Ma pole to the present rotation axis). The first-order agreement with recent astronomical determinations (107 km myr<sup>-1</sup> in the direction 79°W, with a possible range from 65°W to 85°W; see section "How is TPW measured (on short time scales)?") has reinforced the idea that this might be a valid estimate and that TPW might have been rather uniform over the last few millions of years, corresponding to significant, large scale changes in ice cover. Ice is not considered to have played a significant role before, and it was absent prior to ~30 Ma.

### Does super fast TPW occur?

Prévot et al. (2000) argue for an episode of super fast TPW between 114 and 118 Ma (in excess of 500 km myr<sup>-1</sup>). Besse and Courtillot (2002; see also Cottrell and Tarduno (2000), and Tarduno and Smirnov, 2001, 2002) critically discuss this and other suggestions at other epochs (e.g., Petronotis and Gordon (1999) at 80-70 Ma; Sager and Koppers (2000) at about 84 Ma). They conclude that none of the several suggested super fast events (with velocities of hundreds of  $km myr^{-1}$ ) is based on sufficiently robust sets of observations. For instance, Cottrell and Tarduno (2000) tested the hypothesis of Sager and Koppers (2000) using data from Italian sections and found that it failed the test. On the other hand, Besse and Courtillot (2002) and Tarduno and Smirnov (2002) showed that the episode found by Prévot et al. (2000; see also Camps et al., 2002) was not statistically robust due to the use of too short time windows. Gordon et al. (2004) recently conclude in favor of a super fast episode seen on the Pacific plate between 88 and 81 Ma (see below). However, it remains reasonable (in the author's view) to assume that many of these features correspond to erroneous individual data or other sources of error. Only the recent phase of TPW since 5 Ma may prompt us to accept that TPW velocities up to 100 km myr<sup>-1</sup> can be maintained over periods of millions of years (Figure T12).

Two of the nagging questions which must be fully addressed before the concept of global TPW and the velocities mentioned above can be accepted are geometry of the mean geomagnetic field and hotspot fixity.

### Is the mean field sufficiently close to an axial dipole?

Slight departures from a purely centered ancient dipole field have been noted as early as 1970, when Wilson argued for a far-sided and right-handed distribution of virtual geomagnetic poles during the Cenozoic: average paleomagnetic poles tend to fall beyond the geographical pole and to the east of it, seen from the site where the data have been obtained. A number of analyses concluded that, when averaged over the last few million years, an axial quadrupole component is detectable, with an amplitude on the order of 3-6% of the axial dipole (e.g., Constable and Parker, 1988; Schneider and Kent, 1990b; Quidelleur et al., 1994; Carlut and Courtillot, 1998). Livermore et al. (1983, 1984) tried to extract such a quadrupolar term in a worldwide paleomagnetic database going back 200 myr<sup>-1</sup>. More recently, Besse and Courtillot (2002) find moderately far-sided poles, consistent with a persistent quadrupole moment (on the order of  $3 \pm 2\%$  of the dipole over the last 200 myr), but its amplitude can be neglected for many applications. The GAD hypothesis has recently been further challenged by suggestions that significant long-term octupolar contributions of between 6 and 25% of the GAD may have existed for Precambrian through early Tertiary time (Kent and Smethurst, 1998; Van der Voo and Torsvik, 2001; Si and Van der Voo, 2001; Torsvik et al., 2002). For instance, Si and Van der Voo (2001) propose that a value of 6% would account for the low inclinations observed in central Asia in the Cretaceous and early Tertiary. A symposium in honor of Neil Opdyke has reviewed the pros and cons of octupolar contributions to the long-term mean field (the reader is referred to the corresponding AGU monograph and to other articles in this encyclopedia). Courtillot and Besse (2004) attempt to find evidence for octupolar contributions in the 0-200 myr period. In that new analysis, data from sites believed to have possibly undergone a tectonic rotation about a local vertical axis are included, contributing 174 out of 465 data. The positions of mean poles are analyzed in 20 myr windows in common-site longitude, respectively, for the northern mid-latitudes, equatorial and southern mid-latitudes, searching for the distinctive antisymmetrical pattern expected for a dipole plus octupole field. They next analyze the distribution of "latitude anomaly" (derived from the inclination anomaly, i.e., observed minus expected in case of a pure dipole) versus dipole latitude. Based on these various data manipulations, they find no robust evidence for an octupole and estimate that values on the order of 5% are unlikely to have been exceeded in the last 200 myr. A preliminary 200 myr overall mean field has an octupole of  $3 \pm 8\%$  (i.e., not significant; note that the present day value is on the order of 4%, but this is an "instantaneous value" with large secular variation, which in large part could average out). Thus field geometry is unlikely to severely alter TPW estimates, for which it is not the main source of "noise."

### Is the estimate of TPW truly global?

A legitimate concern regarding the above conclusions is due to the fact that the analysis is not truly global, in that it fails to encompass the Pacific plate. Petronotis and Gordon (1999) have compiled an APW path (nine poles from 125 to 26 Ma) for the Pacific plate, with four poles based on the analysis of skewness of ocean crust magnetic anomalies, three on seamount magnetic anomaly modeling (Sager and Pringle, 1988) and two undetermined. Using the Pacific plate versus hotspot kinematic model of Engebretson *et al.* (1985), based on dating of volcanoes which are part of hotspot tracks such as Hawaii, Louisville, or MacDonald (see, e.g., Figure T15 in the case of Hawaii), Besse and Courtillot (2002) have determined a corresponding 125–26 Ma "Pacific hotspot only" TPW curve. The "Pacific" and "Indo-Atlantic" TPW curves are compared in Figure T16. This comparison is interesting because the data sets they are based on are

**Figure T15** The Hawaii-Emperor seamount chain in the Pacific (ETOPO5 bathymetry image). The track with diamonds, which closely follows the observed one, is for the best-fit Pacific plate motion. Two reconstructed tracks of Pacific-hotspot motion in the Indo-Atlantic reference frame are also shown with quantitative plate reconstruction error ellipses. The reconstructed track, which is closer to the observed one, includes East-West Antarctic motion. Chrons and ages (in Ma) are shown (after Raymond *et al.*, 2000).

**Figure T16** Comparison between the "Indo-Atlantic" (open dots and dashed line) and "Pacific" (squares and solid line) TPW paths (after Besse and Courtillot, 2002).

entirely different and independent. Despite some significant differences to which we return shortly, it is worth emphasizing that the two curves are altogether similar in shape (tracks, amplitudes, azimuths), particularly the 300° longitude trending track from 130 to 70 Ma, though the two are offset (in the same general direction) by about 7°. More precisely, the confidence intervals intersect (though points are not in the intersection) near 125, 90, 60, 40 and 30 Ma. The main differences occur between 80 and 70 Ma: the 82 and 65-72 poles derived from Petronotis and Gordon (1999) and the 77 and 67 Ma poles derived by Besse and Courtillot (2002) are clearly distinct. In as yet unpublished work, Gordon et al. (2004 and R. Gordon, personal communication March 2004) have updated the APW path of the Pacific plate. It is now defined by 11 paleomagnetic poles from nonoverlapping age windows going back to 125 Ma. Nine of these poles (32-81 Ma) are determined from skewness analysis. Comparing their APWP to Pacific hotspot motion with respect to the spin axis, Gordon et al. (2004) find a TPW curve which agrees fairly well with their previous analysis, except for a significant change in the 32-40 Ma pole. The new curve implies rather small motion between 81 and 32 Ma, with larger swings before and after. The most recent shift, during the past 30 myr, is about 10° (or 35 km myr<sup>-1</sup> on average). A bigger shift by about 20° would have occurred between 88 and 81 Ma (i.e., more than 300 km  $myr^{-1}$ , an episode of super fast motion which in our view remains to be demonstrated). Comparing the new Pacific TPW curve to the Indo-Atlantic one derived by Besse and Courtillot (2002), Gordon et al. (2004) conclude that there is no significant net motion between Pacific and Indo-Atlantic hotspots in the past 125 myr<sup>-1</sup> (see section "Are hotspots fixed with respect to each other?"). This conclusion depends both on data quality and on the validity of the plate motion models.

There are ongoing debates on the validity of the data used by Gordon and collaborators to construct their Pacific APWP, whether the uncertainty regions they use are realistic, and also on the question of fixity of Pacific hotspots with respect to each other and to the "Indo-Atlantic" hotspots (see below). For instance, Tarduno and Cottrell (1997; see also Tarduno *et al.*, 2003) have determined the paleolatitude (based on inclination-only data from cores) of the 81 Ma old Detroit Seamount, which is part of the Emperor chain, not far from its northern termination in the Kuril Trench. The paleolatitude (36.2 +  $6.9/-7.2^{\circ}$ ) is distinct from that based on the 81 Ma pole of the Pacific APWP (Sager and Pringle, 1988) which is on the order of 20°N, based on seamount anomaly poles. Tarduno and Cottrell (1997) exclude the possibilities of inadequate sampling of secular variation, bias due to unremoved overprints or off-vertical drilling. They point out the uncertainties encountered when building an APWP for an oceanic plate, such as the Pacific, solely from inversions of magnetic surveys over seamounts and/or analysis of skewness of marine magnetic profiles. Following several authors (e.g., Parker, 1991), Di Venere and Kent (1999) and Cottrell and Tarduno (2000) argue that the reliability of the Pacific paleopoles based on either modeling of seamount magnetic anomalies or determination of skewness of marine magnetic anomalies should be considered suspect. Both are prone to numerous biases and could yield errors in excess of 10° in the position of the mean poles derived from them. Seamounts suffer from induced and viscous magnetizations, and potential unresolved multiple polarities of magnetization. Skewness suffers from anomalous skewness as recognized by all users of such data. If one uses only the highest resolution, standard paleomagnetic data from the Pacific, much of Mesozoic TPW for that plate is seen as motion between hotspot groups (e.g., Tarduno and Gee, 1995).

### Are hotspots fixed with respect to each other?

We must therefore now review briefly the question of hotspot fixity. Norton (1995) has suggested that the famous 43 Ma Hawaiian bend in the Hawaiian-Emperor hotspot track (see Figure T15) was actually a "nonevent," i.e., indicated a change in motion of the Hawaiian hotspot with respect to the mantle rather than a change in Pacific plate motion. Koppers et al. (2001) have tested the fixed hotspot hypothesis for Pacific seamount trails. They use seamount locations to first determine stage Euler poles, which they then test against observed  $^{40}$ Ar/ $^{39}$ Ar age progressions. The main stages tested are 0–43, 43–80, and 80-100 Ma. Koppers et al. find that the 0-43 Ma Hawaiian and Foundation seamount trail pair is the only one compatible with the fixed hotspot hypothesis. Most other trail pairs would require relative motions of order (or in excess) of 10 km myr<sup>-1</sup>. The 43-80 Ma Emperor/Line pair shows particularly large discrepancies, requiring motions of at least 30 km myr<sup>-1</sup>. Based on careful analysis of 14 Pacific seamount tracks, using updated age determinations and bathymetry, Clouard and Bonneville (2001) show that Pacific seamounts are actually created by different processes, many being short-lived. They conclude that only the Hawaii and Louisville chains qualify as long-lived hotspots that can robustly be tested for fixity.

Di Venere and Kent (1999) have addressed the problem of relative motion between the Pacific and Indo-Atlantic groups of hotspots, using paleomagnetic results from Marie Byrd Land in West Antarctica. Though they demonstrate that some motion must have taken place since 100 Ma between West (Marie Byrd Land) and East Antarctica, they conclude that this motion cannot account for more than 20%, and possibly as little as 4% of the 14.5° offset between the observed and predicted positions of the 65 Ma Suiko seamount on the Emperor continuation of the Hawaiian hotspot track (Figure T15). They also discuss the integrity of the Pacific plate and the role of missing plate boundaries and errors in kinematic plate circuits, and find that they play a small role. Di Venere and Kent (1999) conclude that most of the apparent motion between the two main groups of hotspots is real, with an average drift of about 25 km myr<sup>-1</sup> since 65 Ma. Torsvik *et al.* (2002) summarize paleomagnetic tests, which in their view raise increasing doubts on the fixity of hotspots. Though Indo-Atlantic hotspots appear to have remained stable, the Pacific hotspots, most notably Hawaii, appear to have drifted southward with respect to the spin axis in the 65-45 Ma period. Torsvik et al. (2002) conclude that global analyses fail to support TPW since the late Cretaceous, and suggest controversial, slow TPW in the early Cretaceous. Their preferred explanation for this is southward drift of Atlantic hotspots prior to ~95 Ma.

**Figure T17** A schematic cross section of the dynamic Earth going through its rotation axis, outlining the possible sources of three types of plumes/hotspots: "primary," deeper plumes possibly coming from the lowermost mantle boundary layer; "secondary" plumes possibly coming from the top of domes near the depth of the transition zone at the locations of the superswells; "tertiary" hotpots may have a superficial origin (after Courtillot *et al.*, 2003).

Courtillot et al. (2003) recently reanalyzed the characteristics of the world catalogue of some 50 hotspots. Based on geophysical (buoyancy, tomography), geochemical (He isotope ratio) and geological (presence of a seamount track, of a flood basalt) criteria, Courtillot et al. (2003) suggest that surface hotspots on Earth may have three distinct origins (Figure T17): at least seven "primary" hotspots (Hawaii, Easter, Louisville, Iceland, Afar, Reunion, and Tristan da Cunha) would originate from the deepest part of the lower mantle, possibly anchored on chemical heterogeneities deposited in the D" layer. Some  $\sim$ 20 "secondary" hotspots might originate from the bottom of the transition zone in relation with the large transient domes that correspond to the two antipodal superswells under the central Pacific and Africa. And the remainder ( $\sim$ 20) could be upper mantle features, as suggested for instance by Anderson (e.g., 2000). Very recently, Montelli et al. (2004) have traced the deep roots of some primary plumes into the lowermost mantle, based on a new type of "finite-frequency" tomography. The list of their primary plumes is similar to though not identical with that of Courtillot et al. (2003).

Restraining themselves to potential primary hotspots, Courtillot *et al.* (2003) find no evidence for inter-hotspot motion significantly larger than 5 km myr<sup>-1</sup> either within the Pacific hemisphere or the Indo-Atlantic hemisphere hotspots (however, in very recent work, Steinberger *et al.* (2004) and Koppers *et al.* (2004) do evidence some motion between Hawaii and Louisville). Such rms velocities of 5 km myr<sup>-1</sup> or less, i.e., an order of magnitude less than rms plate velocities are to first order "small." So, some primary hotspots indeed seem to provide a quasifixed frame in each hemisphere over the last 80–100 myr. Was there then any motion between the two hotspot ensembles? This raises the well-known difficulty of establishing a reliable kinematic connection between the two hemispheres through Antarctica. This has recently been addressed by Raymond *et al.* 

(2000). Based on updated kinematics, these authors predict the location of the Hawaiian hotspot back in time, under the hypothesis that Reunion and Hawaii have remained fixed with respect to each other; for this, they use the dated tracks left on the African and Indian plates by the Reunion hotspot since it started as the Deccan traps 65 Ma ago. The plot of misfit between the predicted and observed positions for Hawaii as a function of time (Figure T15) indicates that the two hotspots have actually drifted slowly (Figure T18a), at  $\sim 10$  km myr<sup>-1</sup>, for the last 45 myr, but at a much faster rate ( $\sim$ 50 km myr<sup>-1</sup>) prior to that (assuming that there is no missing plate boundary or unaccounted for motion between E and W Antarctica), vindicating earlier conclusions reached by Tarduno and Cottrell (1997). Courtillot et al. (2003) conclude that the primary hotspots may form two distinct subsets in each one of the two geodynamically distinct hemispheres. Each subset would deform an order of magnitude slower than typical plate velocities. The two subsets would have been in slow motion for the last 45 myr, but in faster motion prior to that.

Figure T18b,c displays paleomagnetically derived paleolatitudes for the Hawaii and Reunion hotspots, which can be taken as the best documented representatives from each hemisphere. However sparse, the data are compatible with the same simple two-phase history, in which there was little latitudinal motion in the last 45 myr, but significant equatorward motion prior to this, at about 50 km myr<sup>-1</sup> for Hawaii and 30 km myr<sup>-1</sup> for Reunion. There is an uncertainty of a few myr (up to 5) on the timing of the change from one phase to the next at 40–50 Ma. The ~45 Ma date is most accurately fixed by the age of the bend of the Hawaiian-Emperor chain, if this is indeed the common time of change of all processes described in Figure T18, which we assume to be the case to a first approximation. Tarduno *et al.* (2003) report new data from the Emperor seamounts that confirm an ageprogressive paleolatitude trend. The southward drift rate is about

**Figure T18** Time variations of four significant kinematic, geographic or dynamic indicators of hotspot motion (all on the same time scale in million years B.P.). All display a steplike change in velocity at  $\sim$ 40–50 Ma. Velocity patterns are shown as full or black lines, depending on whether the change happened at 40 or 50 Ma. (a) Distance between observed and predicted positions for the Hawaiian hotspot. (b) and (c) Latitudinal evolution of the Hawaiian and Reunion hotspots. (d) Along track TPW velocity at 10Ma intervals (after Courtillot *et al.*, 2003; Tarduno *et al.*, 2003).

 $40 \text{ km myr}^{-1}$  between 81 and 47 Ma. Tarduno *et al.* (2003) also conclude that TPW was smaller than suggested in earlier studies.

The recently re-evaluated estimate of TPW over the last 200 myr (Figure T12) is uncertain, as recalled above, being based only on hotspots from the Indo-Atlantic hemisphere. The TPW curve estimated using Pacific-only data is similar to the Indo-Atlantic TPW, seemingly validating to first order the concept that TPW is a global phenomenon (Figure T16). We have seen that Gordon *et al.* (2004) believe that motion between the two subsets of primary hotspots is small enough that the hotspot reference frame remains useful for estimating TPW over the past 125 myr On the other hand, Besse and Courtillot (2002) suggest that TPW pole positions for the two hemispheres are significantly displaced between ~50 and ~90 Ma (Figure T16).

Due to the high viscosity of the bulk of the lower mantle (see e.g., Lambeck and Johnston, 1998; Steinberger and O'Connell, 2000), the primary (and probably also the secondary) plumes follow the large-scale motion of the lower mantle. The two groups of primary hotspots might indicate that the two separate mega-cells of quadrupolar convection, centered on the Pacific and African super-upwellings, have moved little (~10 km myr<sup>-1</sup>) in the last ~40–50 myr with respect to each other, but underwent some significant (~50 km myr<sup>-1</sup>), rather

uniform, relative motion in the previous tens of millions of years. This motion would have already been going on prior to the oldest preserved trace of the Hawaiian hotspot (e.g., prior to 80 Ma). Hotspot tracks become fewer and more uncertain as one goes back in the past and pre-100 Ma TPW estimates should be regarded with caution. However, there are indications (Besse and Courtillot, 2002) that the phase of TPW which ended around 50 Ma may have started  $\sim 130$  Ma ago (Figure T12). What could have triggered it? The geometry of density anomalies associated with upwellings (notably with the two superswells) may not have a large enough effect on the principal axes of inertia of the Earth and hence on TPW (Richards et al., 1999). However, because they are antipodal, the direction of maximum principal axis of inertia is very sensitive to time variations in superswell structure and some TPW should occur on the same time scale as the superswells (with alternating quiet and more rapid episodes) and with an amplitude which could be similar to that due to subducting slabs (Greff-Lefftz, 2004). Indeed, cold subducted material may have a larger effect on TPW (e.g., Ricard et al., 1993a,b). It has been proposed that this material may accumulate along the great circle of dominant downwelling in the lower mantle, at the base of subduction zones near the transition zone, and trigger an avalanche in the lower mantle

(Weinstein, 1993; Steinbach et al., 1994; Brunet and Machetel, 1998). Such an avalanche starting some 130 Ma ago could have set Earth on the episode of TPW which lasted until  $\sim$ 40–50 Ma ago. An alternate interpretation would be the disappearance of a major subduction zone system, after which both heat flow and mean temperature would have been rapidly and significantly altered (S. Labrosse and L.-E. Ricou, personal communication, 2002). The more recent halting of TPW at 40-50 Ma could also be related to the closure of the huge Tethys subduction zone, following the generalization of Indian collision, as has been suggested for a long time in order to interpret the Hawaii-Emperor bend (Patriat and Achache, 1984). Episodes of TPW could be the result of such (rare) events, with alternate episodes of quiescence lasting tens of millions of years. And primary hotspots would be our main source of information on their time history, if they can be considered as tracers of readjustments in the two-cell geometry of the lowermantle reservoirs.

# Modeling of true polar wander

Modeling of TPW has made significant progress in the last decade. In an early attempt, Ricard et al. (1993b) derived a model of mantle density heterogeneities based on plate motions recorded by the ocean floor, including slabs crossing the upper/lower mantle transition zone slowing down by a factor between 2 and 5. Based on this, they computed a synthetic geoid, which agreed rather well with observations, provided viscosity increased by a factor 40 going from the upper to the lower mantle. Changes in the degree two geoid should reflect the history of the inertia tensor and therefore TPW as revealed by paleomagnetism. Ricard et al. (1993a) predicted TPW velocities on the order of 300 km myr<sup>-1</sup> in the direction 130°W, much larger than observed rates. Their three-layer model could not account simultaneously for the present-day geoid and observed TPW. Slowing TPW, i.e., stabilizing the Earth, can be accomplished in two ways. Either by increasing viscosity at depth and slowing motion of the bulge (Spada et al., 1992): increasing lower mantle viscosity by a factor 100 rather than 40 slows TPW to a more reasonable 40 km myr<sup>-1</sup> but worsens the fit to the geoid. Or by slowing down time changes in the nonhydrostatic tensor: Richards et al. (1997) explain the observed long-term stability of the rotation axis by the slow rate of change in large-scale plate tectonic motions in the last 100 myr. Subducted lithosphere is for them the main component of mantle density heterogeneity and invoking readjustment of the rotational bulge is not necessary (see also early work by Chase, e.g., 1979). They find that the degree 2 geoid coefficient changes little in the last 60 myr, and that a lower/upper mantle viscosity ratio of 30 leads to TPW velocity estimates less than 50 km  $myr^{-1}$ . The computed synthetic TPW path they obtain for a model with layered viscosity has some features which qualitatively resemble observations (Figure T19).

In more recent studies, seismic tomography is used to infer 3D maps of density heterogeneities that drive flow in the viscous mantle. Steinberger and O'Connell (2002; see also Steinberger, 1996) have developed an algorithm to calculate changes in the Earth's rotation axis for rather general viscoelastic Earth models. They combine hotspot motion, polar wander and plate motions in a single dynamically consistent model (though plate velocities are imposed on the model, not derived from it), allowing all effects to be simultaneously determined and their relative effects sorted out. Changes in rotation are due to advection of "realistic" density anomaly distributions inferred from a number of seismic tomography models in a "realistic" flow field constrained by observed plate kinematics at the surface. The axis of maximum hydrostatic moment of inertia is by definition parallel to the rotation axis, and one of the principal axes of the "total" nonhydrostatic inertia tensor (see section "Definitions and early views") always follows the rotation axis closely, as originally pointed out by Spada et al. (1996a,b). This alignment does not imply an alignment with the axis of maximum "total" (Ricard et al., 1993a) or "imposed" nonhydrostatic moment of inertia; because of delayed adjustment of the

Figure T19 (a) A comparison of TPW observations and models over the past 100myr. Open circles are for observation derived determinations by Besse and Courtillot (2002; see Figures T12 and T16); gray circles are a model calculation with 2-layer mantle viscosity structure-viscosity ratio of 30-by Richards et al. (1997); the solid line with tick marks is from a model calculation by Steinberger and O'Connell (2002), with an 8-layer mantle viscosity structure and driving density heterogeneities calculated from a tomographic model of Grand (2001 personal communication to the authors of that paper). Note that this is a corrected curve (see text). (b) A comparison of the TPW curve of Besse and Courtillot (2002) for the past 80Ma and a "mean mantle" apparent polar wander path derived by B. Steinberger (personal communication, 2004) from the BC02 synthetic apparent polar wander path for South Africa (Table 4, with correction given in Besse and Courtillot, 2003) and finite African plate rotation in the mean mantle reference frame for the "preferred" model of Steinberger et al. (2004).

bulge, a misalignment may result (Steinberger and O'Connell, 2002). But this is negligible unless the viscosity of the lower mantle is much larger than  $10^{23}$  Pas (and except in the hypothetical case of inertial interchange, see section "Inertial interchange and true polar

966

wander"). Steinberger and O'Connell (2002) also find that the maximum speed of polar wander driven by mantle convection is about 100 km  $myr^{-1}$  (and incidentally that a fast rising plume head cannot cause more than a few degrees of TPW during the few myr of its ascent). A recent study by Greff-Lefftz (2004) investigates the influence of mantle plumes varying at different spatial wavelengths on the time variations of TPW. In a first model, she shows that an upwelling plume analytically represented as a sphere whose radius varies as a function of the flux of material in the conduit and which traverses the mantle at the Stokes velocity, produces very little wander of the rotational axis. Greff-Lefftz then studies the effects of two superswells which mimic the ones observed with seismic tomography, and concludes that a doming regime within the mantle involves significant polar wander. Some of the features of this TPW which are directly linked to the periodicity of doming are reminiscent of observed phases of slow and fast TPW, with similar peak velocities.

In all cases, isoviscous mantle models predict TPW rates much larger than observed, and a significant viscosity increase in the lower mantle is required to stabilize the large scale pattern of convection and bring TPW rates closer to observed values. This is also what is needed for hotspot stability as well as matching the geoid. Steinberger and O'Connell (2002) compare their model results for a number of tomographic models and discuss the effects of compressibility, deep mantle viscosity, thickness of a high viscosity layer in the deep mantle, and chemical boundaries on rates of TPW. Their TPW estimates, one of which going back to 100 Ma is shown in Figure T19a, are in qualitative agreement with observations (note that Figures 9 and 10 in Steinberger and O'Connell (2002) are incorrect, corrections being available at http://www.geodynamics.no/STEINBERGER/papers/gia vol\_fig9.pdf and http://www.geodynamics.no/STEINBERGER/papers/ giavol\_fig10.pdf; B. Steinberger, personal communication, 2004).

### Inertial interchange and true polar wander

If the principal directions of the nonhydrostatic imposed inertia tensor remain unchanged, but the eigenvalues change and the maximum nonhydrostatic imposed moment of inertia decreases whereas the intermediate one increases, until the latter becomes larger than the former, then a quasidiscontinuous 90° rotation becomes possible so that the rotation axis will align with the new axis of maximum nonhydrostatic moment of inertia (Fisher, 1974). More precisely, the preferred axis of rotation moves instantaneously by up to 90° and the rotation axis will move to its new stable position at a rate limited by adjustment of the bulge. The rate also depends on the driving force, linked to the difference in maximum and intermediate eigenvalues. In such an inertial interchange event, only the nonhydrostatic part is interchanged and there is propagation of the equatorial bulge, which must always remain equatorial. Such an occurrence is referred to as an inertial interchange true polar wander (IITPW) event. Actually, the amplitude of an IITPW event may not reach 90°. At the time when the former maximum and intermediate nonhydrostatic imposed moments of inertia become equal, the nonhydrostatic moment of inertia becomes equal along a whole great circle (the tensor is prolate or flattened with cylindrical symmetry) and the new axis of maximum imposed moment of inertia can grow anywhere on this great circle. The fact that the Earth may in the past have catastrophically exchanged two of its principal axes of inertia in that way, i.e., that the whole lithosphere (and mantle) may have rotated by up to 90° in only a few million years, bringing for instance parts of the Earth which were close to the poles at the equator, has become a new area of questioning in the geosciences. It is clear from the available TPW curves going back to the early Mesozoic that such an event has not occurred in the past 250 myr. For certain parameter values (such as lower mantle viscosity) IITPW is encountered in some numerical model runs. This was almost seen in Goldreich and Toomre's earliest calculations. Richards et al. (1999) find occasional though infrequent inertial interchanges of polar axes with duration of 20 myr, due to "avalanching" (discontinuous rearrangements in

geometry of subducting slabs) in the lower mantle (only one such event occurs in a 600 myr numerical run).

A recent review of evidence for IITPW has been given by Evans (2003). A series of paleomagnetic poles spanning an IITPW event from any continent should fall on a great circle with the pole to that great circles approximating the minimum nonhydrostatic imposed moment of inertia (Evans, 1998). Paleomagnetic indications which would support rather fast TPW in pre-Mesozoic time have been put forward by Van der Voo (1994) and for very fast TPW by Kirschvink et al. (1997). For pre-Jurassic time, ocean floor has been destroyed (together with evidence of plate kinematics and many hotspot traces) and TPW cannot be estimated in the way indicated above. Evans proposes to obtain a crude estimate of TPW in the case (to be tested) when TPW velocity would have been much faster than between-plate motions (as in Figure T13b). This requires matching APW paths from a majority of continental fragments, and extracting a large common component of latitudinal drift (if it exists). Geological evidence of subduction and collision and fossil hotspot traces can help in interpreting the common APW record. Kirschvink et al. (1997) proposed in this way that 90° of TPW had occurred in a brief interval of Early Cambrian time (possibly 15 myr or less, i.e., TPW velocities in excess of 600 km myr<sup>-1</sup>!), coinciding with the famous biological Cambrian explosion. Recall that numerical models place an upper limit of about 100 km myr<sup>-1</sup> on TPW velocity; a full 90° IITPW event would take 3-20 myr for a modern Earth viscosity structure (Steinberger and O'Connell, 2002). To this day, the issue remains contentious because of the dearth of paleomagnetic records and possibility of problems with unremoved overprints, dating uncertainties, etc. (see Evans, 2003). Various authors tend to make different data selections, and each new datum published can still throw the balance in the opposite way. For one school of thought, the terminal Proterozoic to late Paleozoic APW for Gondwanaland (Figure T20) displays up to five large angular swings, some of which reach 90° in amplitude. This oscillatory polar wander is attributed to TPW about a common, long-lived minimum inertial axis near eastern Australia, which would be the prolate axis of Earth figure, inherited from the previous super-continent of Rodinia. In this way, Evans (2003) links TPW episodes to supercontinental cycles (Wilson-like but with durations on the order of 500 myr).

**Figure T20** Terminal Proterozoic to late Paleozoic apparent polar wander path for Gondwanaland. Oscillatory APW rotations are interpreted as inertial interchange (IITPW) about a common, long-lived, minimum inertial axis (*I*<sub>min</sub>) near eastern Australia (after Evans, 2003).

This is an exciting if controversial chapter of Precambrian paleomagnetism that will require much more data than is currently available, hence a concerted effort of the paleomagnetic community.

### Most recent developments and conclusion

For the time being, the hypothesis that TPW is a go-stop-go phenomenon, with long standstills in the tens of millions of years, and periods of faster, rather uniform polar wander at velocities often not exceeding 30 km myr<sup>-1</sup>, cannot be discounted. Evidence for super fast events at any time in the past remains to be demonstrated. Much recent modeling still failed to some extent to account for the slow values of typical TPW velocity (0–30, and rarely up to 100 km myr<sup>-1</sup>), and even more so to account for the prolonged (~50 myr) periods with almost no TPW (standstills). Steinberger and O'Connell (2002) gave reasonable velocities but predicted smooth evolutions, rather than the alternating episodes, which some paleomagnetists feel they uncover from the data (Figure T19a).

The similarity between TPW estimates for the Pacific plate and the rest of the world (Besse and Courtillot, 2002), which are based on completely different and independent data sets, may be taken as supporting the idea that small yet significant TPW, on the order of 10°, occurred since the Cretaceous, though it still requires careful verification. Relatively fast rates before 50 Ma could be due to the variable difference between the largest and intermediate nonhydrostatic principal moments of inertia and to combinations of peculiar configurations of downgoing slabs and super-upwellings (Greff-Lefftz, 2004; B. Steinberger, personal communication, 2004). As seen since the time of Goldreich and Toomre, small differences may lead to faster rates. If the two superswells remain more or less in the same locations, the pole may move on the great circle perpendicular to the axis they form. Figures T12 and T16 may indicate such a tendency for the segment from 130 to 50 Ma, though as stated above the pre-80 Ma data have increasing uncertainties as one goes back into the past. The importance of the Pacific plate and severe limitations on presently available data from that plate, the fact that the global paleomagnetic database still is guite scant for certain continents and time windows, the fact that many hotspot traces are not yet sufficiently constrained in terms of age and paleolatitude, all point to the need for many more direct (paleomagnetic) measurements as opposed to indirect/remote sensing determinations of magnetization direction (i.e., "skewness" or "seamount" data).

In a very recent paper, Steinberger et al. (2004) combine hotspot motion in the large scale flow field of the mantle and intraplate deformation to account for most of the post-65 Ma misfits between computed and observed hotspot tracks. Motion of initially vertical plume conduits is dominated by advection in the high viscosity lower mantle and buoyant rising in the low viscosity upper mantle. Given the mantle flow field and a preferred viscosity distribution, Steinberger et al. (2004) find that computed hotspot motion fits observed tracks well for the last 50 myr, i.e., since the time of the Hawaii-Emperor bend. But the change in track direction at the bend is explained only when an alternative plate circuit through East Antarctica, Australia, and the Lord Howe rise is used rather than the traditional circuit through West Antarctica. This leads to East versus West Antarctic motion with a rotation pole close to the boundary and deformations which the authors believe are compatible with geologic evidence. Remaining pre-65 Ma misfits are attributed to unquantified motion internal to New Zealand. Only a combination of the two effects (hotspot motion and intraplate deformation) successfully predicts the geometry of the four selected seamount chains in the Pacific and Indo-Atlantic hemispheres. If correct, their analysis at the same time invalidates the notion of a hotspot-mantle reference frame or of separate hemispheres (for Steinberger and colleagues plumes indicate local flow and not motion of hemispheric cells) and replaces it with limited, predictable inter-hotpot motion. But TPW can still be calculated, i.e., a "mean mantle" reference frame can still be evaluated. The Hawaiian hotspot

would have moved faster between 80 and 50 Ma, and at the same time TPW would have been faster prior to 50 Ma. TPW would account alone for paleolatitudinal changes of the Reunion hotspot, whereas the two effects would be required for the Hawaiian hotspot.

Combining Steinberger *et al.* (2004) preferred model for the finite rotation of the African plate in the "mean mantle" reference frame with the synthetic apparent polar wander path for South Africa (Besse and Courtillot, 2002, Table 5, with correction given in Besse and Courtillot, 2003), one can derive a TPW curve in the "mean mantle" reference frame (or if one prefers, the "apparent polar wander path of the mean mantle") that takes hotspot motions into account. This is shown in Figure T19b (B. Steinberger, personal communication, 2004). The curve captures most of the features of the original BC02 observed TPW (standstill between 10 and 50 Ma, faster TPW in the correct direction prior to that back to 80 Ma) though with somewhat larger amplitudes.

We have seen that a number of scientists suggest possible links between (1) TPW episodes, or major changes between TPW episodes, or IITPW events if indeed they have occurred in the past, (2) reorganizations in the geometry of subduction zones or plume and superplume generation (or any other major geodynamical events occurring in the mantle), and (3) major biotic changes. These tantalizing hypotheses will likely keep analyses of polar wander very much alive in the coming decade, despite the somewhat bothering feeling that TPW still remains an elusive geophysical phenomenon.

# Acknowledgments

I am thankful to Emilio Herrero-Bervera and David Gubbins for inviting this contribution. I am particularly thankful to J. Besse, A. Cazenave, R. Gordon, M. Greff-Lefftz, K. Lambeck, J. Laskar, J.L. Le Mouël, M. McElhinny, R. O'Connell, J.P. Poirier, Y. Ricard, J. Tarduno and R. Van der Voo for very useful comments on an earlier version of this paper. Special thanks to B. Steinberger for particularly detailed and helpful comments and help with several parts of Figure T19. IPGP Contribution NS 2094.

# U

# ULVZ, ULTRA-LOW VELOCITY ZONE

Nearly half way to Earth's center, the boundary between the solid silicate rock mantle and the liquid iron-alloy outer core was long thought to be a sharp discontinuity between the two vastly different regimes. Recently, detailed seismological analyses have depicted the core-mantle boundary (CMB) as being far from simple, and in fact shows evidence for an additional thin veneer of anomalous properties in certain geographical regions. Imaged as thin as a couple of km, and up to 50-km thick, these unique zones are characterized by strong reductions in the speeds of seismic waves relative to the overlying mantle. These areas have thus been dubbed "ultra-low velocity zones" (ULVZs).

# Seismic probes

Seismology remains the most direct remote sensing tool for deciphering the subtleties of Earth's inaccessible deep interior. This is most commonly accomplished through the use of elastic energy that propagates away from earthquakes, traveling through the entire interior of the planet; some energy propagates continuously through the Earth, some reflects from local or global boundaries between contrastingly different materials, and some of it, in special cases, diffracts along boundaries between strongly contrasting media. Each of these types has provided evidence for extremely sluggish patches at the CMB.

Four of the most commonly utilized seismic probes (or "phases") to date are *SPdKS* referenced to *SKS*, and precursors (seismic energy that just slightly precedes a later more dominant phase) to the waves *PcP*, *ScP*, or *PKP* (Figure U1). Over the past decade a variety of research groups have documented anomalies in these arrivals and attributed them to CMB structure (see, e.g., Garnero *et al.*, 1998). *ScP* is a seismic phase that departs from the earthquake as an *S* wave, and upon reflection at the CMB, converts to a *P* wave (Figure U1a). If a low velocity boundary layer is present at the CMB, several additional arrivals are possible (Figure U1a, second panel). The relative timing and amplitude of these arrivals is apparent in a computer generated "synthetic" seismogram  $60^{\circ}$  in arc away from a 500-km deep hypothetical earthquake (third panel). If the top of the layer is diffuse, then these arrivals diminish in amplitude, which remains an active direction for current research.

Figure U1b shows *PcP*, which also contains pre- and postcursors, analogously to *ScP*, as well as some of the additional arrival geometries, and a synthetic seismogram showing the additional arrivals.

One challenge in data analyses is to identify the later arrivals, since they are commonly obscured by the coda of the main PcP phase, i.e., additional arrivals due to (for example) reverberations in Earth's crust due to the PcP wave.

Waves that travel into the Earth's core can contain important information about anomalous properties at the CMB, which they traverse at least twice. The phase *PKP* has been used to detect CMB structures that scatter energy resulting in precursory arrivals to *PKP*. Figure U1c shows *PKP* paths, along with an associated reference arrival *PKiKP* that reflects from the inner core boundary. Anomalous topography to the ULVZ or inclusions of low velocity material can give rise to precursory arrivals, as shown in the theoretical predictions in the bottom panel.

Another important probe of the CMB is an *S* wave that encounters the CMB at a critical angle to produce a *P* wave that diffracts along the CMB (*Pd*), then continues into the core as a *P* wave, then back through the mantle as an *S* wave (Figure U1d). This phase, *SPdKS*, has short segments of *P* wave diffraction at the core entry and exit locations. Additional internal reflections within the layer are also emerging as important (e.g., *SPuPKS*). Certainly other possible seismic probes of ULVZ structure are possible, as long as seismic energy either refracts, diffracts, or reflects at the CMB.

An important next step in ULVZ research will be to find geographical regions that permit analysis of more than one particular seismic phase, since different waves are sensitive to different ULVZ structural components. For example, the precursor analyses (Figure Ula-c) utilize short period energy, which is particularly sensitive to sharp contrasts in properties, and not able to well-resolve gradational changes in properties. *SPdKS*, on the other hand, is less sensitive to such contrasts, but very sensitive to the velocity structure within the layer, particularly at distances where the *Pd* segment in *SPdKS* is short.

## Ultra-low velocity boundary layer possibilities

The seismic phases introduced in Figure U1 have played a critical role in revealing several possibilities for transitional structure between the core and mantle. Three main possibilities are highlighted here: a layer on the mantle side of the CMB (which is most commonly referred to as ULVZ), a layer on the core-side of the CMB (essentially a corerigidity zone, CRZ), and some thickness over which the mantle changes into the core (hereafter denoted as a core-mantle transition zone, CMTZ) (Figure U2). It is important to recognize these as endmember models, and that any combination of these is equally possible.

Figure U1 Ray paths, seismic arrivals due to a ULVZ, and synthetic seismograms for (a) ScP, (b) PcP, (c) PKP, and (d) SPdKS. Synthetic seismogram predictions of (a) and (c) are from Garnero and Vidale (1999) and Wen and Helmberger (1998), respectively.

**Figure U2** P-wave ( $\alpha$ ) and S-wave ( $\beta$ ) velocity and density ( $\rho$ ) versus depth for ultra-low velocity boundary layering (shaded regions) on (a) the mantle-side of the core-mantle boundary (CMB) (a ULVZ) (b) the core-side of the CMB (a CRZ), and (c) a finite thickness transition between the mantle and core (CMTZ).

# Mantle ultra-low velocity zone

ULVZ thickness has been imaged between 5 and 50km, with strong lateral variations. The most commonly explored model parameters are those compatible with partial melt of the lowermost mantle, which results in a three times larger reduction in shear velocity (e.g., 30%) than that for compressional waves. Density increases are also possible (Figure U2a).

# Core-rigidity zone

If large density increases and shear velocity decreases are considered in ULVZ modeling, one must allow for the possibility of the layer residing on the core-side of the CMB (Figure U2b). The liquid outer core of the Earth is predominantly iron, along with a minor constituency of some lighter element(s). As the Earth cools, the solid inner core of the Earth grows, releasing the lighter elements into the outer core, which may result in "underplating" of the CMB in a sedimentation process (see Buffett *et al.*, 2000). Thus, isolated regions of nonzero rigidity may exist beneath positive topography, or, "hills" on the CMB, where such sediments can accumulate and concentrate (up to a couple km thick; Rost and Revenaugh, 2001). If electrically conductive, the CRZ may affect Earth's magnetic field, nutations, and possibly even magnetic field reversal paths.

### Core-mantle transition zone

Finally, we consider the possibility of a transitional zone between the mantle and core over some finite thickness (Figure U2c). Chemical reactions between the silicate rock mantle and liquid iron-alloy outer core (see Knittle and Jeanloz, 1989) can result in a thin mixing zone—an effective blurring of the CMB. The CMTZ can appropriately cause precursors to the short period waves (Figure U1a-c) as well as delay the SPdKS relative to SKS (Figure U1d; Garnero and Jeanloz, 2000).

### ULVZ geographic distribution

To gain insight into the possible origin of ultra-low velocity layering at the CMB, it is instructive to compare results to other phenomena, such as gross properties of the deep mantle as revealed by shear wave tomography. Figure U3 compares the strongest variations in shear wave velocity with ULVZ distributions. There is suggestion of a connection between ULVZ and low seismic wave speeds (Figure U3a,b). This ULVZ distribution also correlates strongly with hot spot volcanism at Earth's surface (Williams et al., 1998). However, an examination of a larger data set of higher quality broadband data reveals shorter scale variations, with some CMB patches showing evidence for both support and lack of an anomalous layer. Figure U3c summarizes ULVZ likelihood using broadband digital SPdKS data. The correlation with largescale lower mantle shear velocity is more difficult to assess. Greater geographical coverage in future studies will allow more confidence in such comparisons. A main limitation in achieving greater spatial coverage is uneven earthquake and seismometer distribution on the globe, limiting where the deep interior can be probed.

### Discussion and summary

While confident correlations between ULVZ layering and bulk mantle properties may be premature at present, the existence of the layer is clear, from a variety of studies and methods. While not constrained, it is instructive to briefly consider possible scenarios relating CMB structure to the thermal, chemical, and dynamical environment. Figure U4 displays a multitude of possibilities beneath upwelling and downwelling mantle regimes. The point here is to recognize the variety of structures and their scale lengths that are possible, yet unresolved at present, and hence future work should seek to sharpen our focusing ability for such possibilities.

Beneath upwelling regions, possibilities include (but certainly are not limited to) (a) a combination of ULVZ, CMTZ, and CRZ structures in the hottest lowermost mantle regions; (b) convection within a partially molten ULVZ which can sweep chemical heterogeneity into localized piles within the ULVZ; (c) large- and fine scale CMB (as well as ULVZ) topography, resulting in (d) multiple scale CRZs of variable strength; (e) some ULVZ melt entrainment into overlying convection currents, which may result in (f) mantle plume genesis, and (g) aligned melt pockets from strong boundary layer shear flow, yielding seismic anisotropy; and (h) chemical mixing between the ULVZ and outer core (or CRZ) material, giving rise to local (or widespread) CMB blurring, including chemical coupling (or interactions).

Beneath downwelling regions, similar phenomena exist, but perhaps suppressed in the vertical dimension (a) spatially organized ULVZ to the front of downwelling motions, where plume instabilities (thus local warmer zones) have been shown to exist (Tan et al., 2002); (b) a thin (undetectable?) ULVZ throughout region; (c) small- and large-scale CMB topography, which may provide localized basins or wells for material with density intermediate to that of the mantle and core; (d) possible chemical contamination from melt from either CMB chemical reaction product entrainment or ponding of former oceanic crust; and (e) anisotropy due to high strains resulting from overlying subduction stresses (McNamara et al., 2002). While provocative, Figure U4 depicts the likely scenario of CMB topography that is intimately coupled to ULVZ, CMTZ, and CRZ chemistry and dynamics. Furthermore, these structures probably play an important role with electromagnetic, gravitational, thermal, and topographic coupling between the mantle and core.

Future analyses should incorporate more realistic 3D wave propagation tools for predictions to compare to data (see, e.g., Helmberger *et al.*, 1998). Analyses that utilize more that one of the wave types presented in Figure U1 for the same patch of the CMB will also greatly reduce uncertainties.

Lastly, it is clear that ULVZ structure is an intimate part of the coremantle transition, and likely reflects core processes that may be related to the geodynamo. For example, if the ULVZ is enriched in iron from the core, it may affect geomagnetic reversal path geometries, which to

(a) High (dark) and low (light) D" shear velocity

(b) ULVZ distribution from LP WWSSN SPdKS Fresnel zones (light shading: ULVZ detected, dark shading: no ULVZ)

(c) Probablistic ULVZ distribution from broadband SPdKS

**Figure U3** (a) Shear velocity distribution in the lowermost 250km of the mantle from the model of Grand (2002). Light shaded areas have velocities equal to or lower than -1% relative to the global average, dark areas are at or great than +1%. (b) Fresnel zones of *SPdKS* sampling at the CMB from long period analog data. Light shading is for suggested ULVZ presence; dark shading for ULVZ absence, and no shading represents no data sampling. (c) Same as (b), except using modern broadband digital data, and shading represents the likelihood of ULVZ presence. For each  $1^{\circ} \times 1^{\circ}$  section of the CMB with data coverage, the following ratio is constructed and plotted: (# of records requiring an ultra-low velocity layer)/(total # of records for that cell). Thus, a value of 1 indicates all data that traversed that cell are anomalous; a value of 0 represents the case where no data sampling a particular region are anomalous (after Thorne and Garnero, 2004).

**Figure U4** Possible CMB scenarios beneath regions of (a) upwelling, and (b) downwelling (see text for details). Significant (or total) uncertainty exists for many wavelengths of interest, which include: scale-length over which ULVZ phenomena affects the lowermost mantle ( $\lambda_m$ ), scale lengths of roughness of the top of the ULVZ ( $\lambda_{ru}$ ), ULVZ thickness distribution ( $\lambda_u$ ), dimension of isolated core-rigidity zones ( $\lambda_{\mu}$ ), scale of roughness of the CMB, including the thickness of transition from pure core-to-mantle ( $\lambda_{rc}$ ), lateral and vertical scale of long wavelength CMB topography, and hence possible anomalous zones contained within the topographic depressions/elevations ( $\lambda_t$ ), and isolated thermochemical domes, scatterers, or anomalous shapes within the ULVZ ( $\lambda_d$ ).

the first order appear anticorrelated with ULVZ distributions (Garnero *et al.*, 1998). Certainly, uneven geographic distribution of patches of partially molten and/or chemically unique ULVZ material can result in variability in core heat flow that may affect core fluid motions, possibly relating to Earth's magnetic field generation and variability.

# UNITS

Scientific units were standardized to the current Système Internationale d'unités (SI) in about 1970. For the most part conversion involves applying simple factors of 10 to convert centimeters and grams to meters and kilograms, but in magnetism conversion is more complicated and confusing because the old cgs system had, for historical reasons, two sets of units for electricity and magnetism: electrostatic and electromagnetic units. The latter, abbreviated to emu, concern us here. Understanding of emu is necessary to understand the old, and some not so old, literature. The paleomagnetic community has been particularly slow to convert to SI, and even today some papers give results in emu.

SI achieved the worthy goal of unifying the system of units for both electricity and magnetism; it also removed some factors of  $4\pi$  from the basic equations (Table U1). The critical difference between the two systems arises from the distinction between magnetic induction or flux density *B* and magnetic field intensity *H*. The dimensions of *H* differ in the two systems of units, as does the magnetic moment per unit

Table U1 Relevant equations in SI and emu systems of units

SI	Emu
$B = \mu_0 H + M$ $P = \mu_0 M$ $M = \chi_{SI} H$	$B = H + 4\pi M$ $P = M$ $M = \chi_{emu} H / 4\pi$

Further discussion is given in the appendix of Jackson's (1999), 3rd edition. Butler (1992) and Blakely (1996) also have appendices on systems of units.

LMTQ denote length, mass, time, and charge. The conversion factor in the right column should be used to multiply a value in emu to yield the SI value. Note the difference in definition for H, M, and  $\chi$  between the two systems. The siemen is sometimes called the mho.

volume of a material M. Furthermore, the definition of M differs by a numerical factor of  $4\pi$  between the two systems, which has the undesirable effect that the dimensionless susceptibility  $\chi$  differs. The magnetic polarization P (usually denoted as J in paleomagnetism but this is used in *MHD* (*q.v.*) exclusively for electric current density), has the same dimensions as B in both systems. Confusion propagates because of sloppy terminology: it is standard practice in geomagnetism and paleomagnetism to refer to B as the magnetic field rather than magnetic induction, and magnetization is used to mean either M or P(Table U2).

# UPWARD AND DOWNWARD CONTINUATION

Potential fields known at a set of points can be expressed at neighboring higher or lower spatial locations in a source free region using the continuation integral that results from one of Green's theorems (see, e.g., Blakely, 1995). The principal uses of this concept are to adjust altitude of observations to a datum as an aid to the interpretation of a survey (see Crustal magnetic field), reduce short-wavelength data noise by continuing the field upward, and increasing the horizontal resolution of anomalies and their sources by continuing the field downward. It is possible to continue the field upward or downward in a number of different ways depending on the application at hand; for example, designing continuation operators in spatial or wavenumber space (Henderson and Zietz, 1949; Dean, 1958), using harmonic functions (Courtillot *et al.*, 1978; Shure *et al.*, 1982; Fedi *et al.*, 1999), and deriving physical property variations of sources causing the fields (Dampney, 1969; Emilia, 1973; Langel and Hinze, 1998). Applications also vary widely: from environmental and exploration applications involving short-wavelength anomaly fields over small height differences (a few meters to kilometers) to global distribution of anomalies measured by satellites in which anomalies are downward continued from satellite altitudes (300–700km) to Earth's surface and also downward continuing the core part of the Earth's field all the way to the top of the core to decipher features of core circulation over time.

The effect of upward/downward continuation process on the fields can be understood by examining the continuation operator in the wavenumber domain. The operator has the form  $e^{\pm |k|\hat{z}}$ , where |k| is the wavenumber ( $|k| = 2\pi\lambda$  where  $\lambda$  is the full wavelength) and z is the continuation level (Dean, 1958). The negative sign in the exponent indicates upward continuation (away from the sources of the field) and the positive sign implies the downward continuation (toward the sources of the field). The response of the continuation operator with respect to wavelength is illustrated in Figure U5, which shows that shorter wavelengths are attenuated and smoothed in the process of upward continuation, whereas in downward continuation the shorter wavelengths are amplified and sharpened. Both operations are susceptible to errors in the data and their results can be rendered invalid or at least severely compromised due to the quality of data. For example, if measurement errors are primarily short-wavelength, then the nature of downward continuation operator which amplifies primarily the shortwavelength components of the data can severely distort the downward continued result. On the other hand, if the long-wavelength portion of the field is contaminated, for example, by inaccurate compilation of different surveys having different base levels, then the retention of the corrupt long wavelengths in the process of upward continuation can render the result unusable (Ravat et al., 2002).

The most straightforward upward/downward continuation of a field is performed from one level surface to another level surface (Henderson

**Figure U5** Amplitude response of upward and downward continuation operators with respect to wavelength for certain heights (*z*) of continuation.

and Zietz, 1949; Henderson, 1970). This is often useful for interpretation and joining two adjacent surveys carried out at different altitudes. As aid in interpretation, upward continuation allows one to assess the effect of deeper sources because in this process the effect of shallower, short-wavelength features is attenuated. Preferential upward and downward continuation operators have been designed that can help attenuate only the shallow, short-wavelength part of the spectrum, leaving the deeper, long-wavelength part unaltered or, alternatively, preferentially amplify only the deeper part of the spectrum without the deleterious effects of amplifying short-wavelength noise (Pawlowski, 1995). Thus, under certain situations, it is possible to isolate a magnetic anomaly signal from different depth layers of the crust. Downward continuation into the region of sources leads the continuation integral to diverge even in the case of noise-free data; in the case of high data density noise-free data the depths at which the continuation integral blows up (data begin to vary wildly) can be used to infer the depth to the top of the shallow magnetic sources in the region.

When airborne magnetic surveys (see Aeromagnetic surveying) are conducted in rugged terrain made up of magnetic formations, it is not advisable to view the data at constant altitude because effects of topographic variations can lead to anomaly artifacts. In such situations, one might prefer to "continue" level survey data at some constant distance away from topography (on a constant terrain clearance or "draped" surface). Challenges of maintaining the constant terrain clearance of aircrafts in a rugged topography may require one to adjust the data further until the survey is accurately draping. Conversely, flying conditions can lead to unintentional altitude variations in surveys originally intended to be flown at constant barometric altitude (level survey), and such surveys need datum corrections as well. Two types of procedures have been commonly used in accomplishing datum transformations from level-to-drape and drape-to-level surfaces: Taylor's series approximation and equivalent source concept. Taylor's series allows extrapolation of a function to nearby points and, given vertical derivatives of the field and certain approximations regarding behavior of the field, the series yields adequate values of level-to-drape transformation. Similarly, an iterative Taylor's series can be used for drape-to-level transformation (Cordell and Grauch, 1985). The equivalent source method (Dampney, 1969) employs Green's equivalent layer concept and uses a set of sources with arbitrary magnetization (often induced dipoles because of their simplicity; Emilia, 1973) to approximate the field. This process is equivalent to finding the potential that satisfies the observed field. The inverted magnetization of the sources is then used to predict the field in the neighborhood of observations. Use of local harmonic functions (Fedi *et al.*, 1999) can also be useful for these purposes.

Aeromagnetic Surveying Crustal Magnetic Field

# VARIABLE FIELD TRANSLATION BALANCE

The variable field translation balance (VFTB) is an instrument for measuring isothermal magnetizations in variable fields (e.g., hysteresis loops) as well as the temperature dependence of the associated magnetic parameters. It is specifically designed to measure the weak magnetizations commonly encountered in rock magnetism.

# Measurement principles and main instrument components

The VFTB is a modification of the horizontal magnetic translation balance (e.g., Collinson, 1983). In contrast to the normal horizontal translation balance, the magnetic gradient in the VFTB is not produced by a special shape of the pole pieces of the electromagnet, but by a separate set of four gradient coils (AC; Figure V1). This separation of inducing field and gradient field was for the first time proposed by McKeehan (1934). The gradient field of the VFTB is not kept constant, but is oscillating with a certain frequency (2-4Hz). The VFTB can thus be considered a one-dimensional harmonic oscillator with damping (D), operated in forced oscillation mode. The oscillating part of the instrument is a pendulum with bifilar suspension (BS) with the specimen (S) fixed to it in a nonmagnetic quartz glass sample holder (Q). The motion of the system is excited by a periodic force acting on the sample and generated by the set of gradient coils. The system is normally operated at resonance frequency to obtain highest sensitivity, but can also be operated in a nonresonance mode for the measurement of very strong magnetic samples. The motion of the sample is monitored by a linear variable differential transformer (LVDT). This signal-after processing in the PC-is then proportional to the magnetic moment of the sample.

The temperature is controlled by a heating/cooling unit (H/C) surrounding the sample chamber, thus making possible measurements at variable temperatures. During measurement the specimen is located in the center of either an electromagnet (EM, with pole pieces) or an iron-free solenoid generating a homogeneous inducing magnetic field. In case of the pole piece configuration, two compensation coils (CCs) are attached to compensate the residual field generated by the remanent magnetization of the pole pieces in the case of zero field measurements. All instrument functions like inducing field strength, gradient field amplitude, and temperature are computer controlled.

As the sample is moving back and forth inside the gradient field its motion is detected by the LVDT vibration sensor (Figure V2). The LVDT generates a voltage proportional to the position of the sample holder inside the sensor. This voltage is amplified and read by the A/D converter. The VFTB control software records the digitized voltages from the converter board. The gradient field actuating the sample movement varies sinusoidally. The response movement of the sample is also shaped like a sine wave with the same frequency as the original signal but with differing phase and amplitude. These indicate the actual magnetization of the sample. To compute amplitude and phase of the signal the recorded voltages are analyzed via fast Fourier transformation to find the spectral amplitude at the measurement frequency. The phase is used to compute the sign of the gained amplitude thus yielding the desired magnetization value. This value is normalized by the input gain of the A/D converter and the strength of the actuating field.

# Types of measurements

VFTB measurements can be subdivided into field-dependent, temperature-dependent, and time-dependent magnetization measurements. The first group consists of isothermal magnetization measurements, i.e., IRM acquisition curves, hysteresis loops, and backfield curves. The number and spacing of field steps for these measurements can be freely chosen depending on the sample material and the desired measurement speed. It takes about 15 min to measure a hysteresis loop defined by 80 data points. Examples are shown in Figure V3.

The main purpose of temperature-dependent experiments is the determination of crystallographical or physical phase transitions, e.g., Verwey transition and Curie temperatures. The temperature can be varied between  $-190^{\circ}$ C and room temperature with liquid nitrogen as furnace coolant and between room temperature and  $800^{\circ}$ C with

**Figure V1** Schematic drawing of the main instrument components. Drawing shows the configuration with an electromagnet with pole pieces (see text for explanation of acronyms).

Figure V2 Simplified connection scheme of the VFTB.

Figure V3 Example data of a basaltic specimen measured with a VFTB.

water cooling. IRM acquisition curves as well as hysteresis loops and backfield curves can also be measured in the whole temperature range between -190 and  $800^{\circ}$ C. The VFTB can also measure the time dependence of magnetization at given temperatures, useful, e.g., for determining the decay of isothermal remanent magnetization or for observing alteration processes at elevated temperatures.

Magnetic moment sensitivity of the VFTB amounts to  $5 \times 10^{-8}$  A m<sup>2</sup>. Sample holders can accommodate samples with a diameter of either 5 or 10 mm and a length of 9mm. It is thus possible to measure fairly large samples with a maximum weight of  $\approx 1.5$  g which yields a sensitivity of  $\approx 5 \times 10^{-5}$  A m<sup>2</sup> kg<sup>-1</sup> in terms of specific magnetization. Depending on the electromagnet a maximum magnetic field of 1.0 T can be attained and the residual field during zero field measurements does not exceed 50  $\mu$ T.

# VERHOOGEN, JOHN (1912–1993)

John Verhoogen (Figure V4) was an engineer, geologist, geophysicist, and a pioneering advocate of the role of the solid inner core in the geodynamo. He was also an inspirational mentor to a generation of students, including the Earth Scientists who first established the timescale for magnetic polarity reversals.

Verhoogen was born in Brussels in 1912 in an educated, professional family. He became afflicted with poliomyelitis while in high school. Although this disease would progressively limit his physical mobility, it did not deter him from pursuing a career in the geological sciences. He earned degrees in mining engineering at the University of Brussels in 1933, engineering geology at the University of Liege in 1934, and a Ph.D. in geology at Stanford University in 1936. This was his first introduction to the United States, where he would later make his scientific mark. After a decade of fieldwork in equatorial Africa, he joined the faculty of the University of California, Berkeley in 1947 and taught there until his retirement in 1976.

Verhoogen's first major research accomplishment was to measure the gas composition of the active volcano Nyamuragira in Zaire (then the Belgian Congo). This experience convinced him that igneous processes and volcanism were indisputable evidence for large-scale flow deep in Earth's interior. One outcome of these studies proposed an explanation for the thermal evolution of the Earth in terms of heat transfer by fluid motions in the deep interior. Although the significance of this idea was not widely appreciated by his contemporaries at the time, it guided his own research for the ensuing three decades and, ultimately, it has to be accepted throughout the geoscience community.

In the late 1950s and early 1960s, Verhoogen played a seminal role in the development of paleomagnetism, particularly the paleomagnetic reversal time scale. At that time there were many reports of rocks with ferromagnetic directions reversed to the present-day geomagnetic field direction. Two competing explanations were offered to explain this puzzling phenomenon: either these rocks were magnetized during epochs when the main geomagnetic field was reversed, or their original magnetic directions had been reversed by local remagnetization effects.

Figure V4 John Verhoogen (courtesy of Margaret Gennaro, University of California Archives).

The existing techniques in geochronology were inadequate to distinguish between the two competing explanations. Verhoogen initially favored remagnetization, but several of his own graduate students, including Allan Cox and Richard Doell, were measuring the paleomagnetic directions in lavas from Hawaii and other volcanic hotspots and convinced him that the global reversal explanation was far more likely. Within a few years, new developments in mass spectrometer technology provided accurate radiometric dating methods, confirming that the main geomagnetic field had indeed reversed its polarity many times in the past. The resulting geomagnetic polarity time scale is now a cornerstone in geophysics; for example, it provides the interpretation of magnetic stripes in the ocean crust in terms of sea-floor spreading (see Glen 1982 for a description of Verhoogen's role in these developments).

As post-polio injuries curtailed his field and laboratory work, Verhoogen progressively turned his attention toward the energy balance of the Earth as a whole, and in particular, the energy needed to maintain the geodynamo. One of his major contributions to igneous geology had been a quantitative thermodynamic treatment of igneous petrogenesis, which combined the energetics of crystallization with the thermal environment of the deep crust and upper mantle where the magmas originate. He recognized that the core was like a giant magma chamber, in the sense that physical and chemical processes similar to those in magmatic systems must be operating inside the core. This represented a new perspective; previously, only thermal convection had been considered important in core energetics. Verhoogen reasoned that, because the Earth as a whole is cooling, the solid inner core must be growing by crystallization at the expense of the fluid outer core. He realized that crystallization at the inner core boundary would provide a source of energy for the geodynamo, through latent heat release and other effects associated with the solidification. In 1961, he estimated the energy release by this process, and found it adequate to maintain the geodynamo if the rate of inner core solidification is sufficiently high, about 25 m<sup>3</sup> s<sup>-1</sup> or more. Subsequent investigations by Braginsky (1963), Gubbins (1977), Buffett et al. (1992), and others have developed these concepts further, adding an important ingredient to the model, the gravitational potential energy supplied by chemical differentiation at the crystallizing inner-outer core boundary. This model has come to be called the "gravitational dynamo" and is now the favored mechanism for powering the geodynamo.

In his 1980 monograph *Energetics of the Earth*, Verhoogen systematically analyzed the various energy sources available to drive the geodynamo, including inner core solidification, heat loss to the mantle, and possible radioactive heat sources in the outer core. He concluded that, although the gravitational dynamo mechanism evidently provides enough energy, the uncertainties in the rate of heat loss to the mantle, combined with the uncertainties in radioactive abundance and important physical properties of the core, preclude us from making a definitive model of the geodynamo. Researchers today would, no doubt, come to a similar conclusion. However, in an address to the US National Academy of Science, Verhoogen expressed his scientific optimism in the following way:

Perhaps the greatest step forward since the discovery of radioactivity has been the recognition of convection as the dominant mode of heat and mass transfer in most of the mantle and core. Here at long last is something to hang onto.

This statement is as applicable today as it was two decades ago, and remains the paradigm for understanding the deep Earth.

Peter Olson

# VINE-MATTHEWS-MORLEY HYPOTHESIS

### Definition

The Vine-Matthews-Morley (VMM) hypothesis states that, when ocean crust forms at a midocean ridge (i.e., a spreading center), the cooling crust becomes magnetized in the direction of Earth's prevailing magnetic field as it cools below the Curie temperature of the magnetic minerals (Morley and Larochelle, 1964; Vine and Matthews, 1963). Typically this Curie temperature is between 150 and 300°C for titanomagnetite, the primary magnetic mineral in the upper oceanic crust, and ~580°C for pure magnetite found in the lower ocean crust. The ocean crust moves away from the spreading center through the process of "seafloor spreading" and in this way the magnetic signal recorded in the newly formed crust is preserved (Figure V5). A good analogy is that of a tape recorder where the ocean crust is the magnetic

tape and Earth's magnetic field is the signal, which is recorded onto the moving tape. In this way, changes in Earth's magnetic field polarity through time are preserved in the crustal rocks. The alternating bands of magnetic polarity give rise to magnetic anomalies when measured at the sea surface, the so-called "magnetic stripes" (Figure V6) (see Magnetic surveys, marine; Magnetic anomalies, marine).

The VMM hypothesis elegantly explains the striped patterns of magnetic anomalies measured at the sea surface without the need to call upon petrological, thermal, or some other process to be aligned parallel to the spreading axis. It also links many of the other observations about midocean ridges such as their apparent youth and thin crust. It also explains why the ocean basins are relatively young (<200 My) compared to continents. The magnetic anomalies document the progression in age of the ocean basins from young crust at midocean ridges to the oldest and deepest crust near subduction zones and in doing so strongly supports the global concept of continental drift that ocean basins have opened and closed in the past. The VMM hypothesis forms one of the cornerstones of plate tectonic theory and began a revolution in thinking about how the Earth works and how it has evolved through geologic time.

# **Historical context**

Fred Vine and Drummond Matthews were part of the geophysics group at Cambridge University in England at the time of their discoveries under the leadership of Teddy Bullard and they were very receptive to the ideas of American scientists Harry Hess and Robert Dietz (Dietz, 1961; Hess, 1962) about continental drift and the possibility of seafloor spreading in contrast to the mainstream US science community at that time (Glen, 1982). Vine began his work as a graduate student working for Drummond Matthews and their ideas grew out of work by Vine on magnetic profiles collected by Matthews over the Carlsberg Ridge in the Indian Ocean. Vine found that there were reversely magnetized seamounts indicating that the ocean crust could record both normal and reverse polarity periods in Earth's magnetic field history. A similar conclusion had been reached earlier by Girdler and Peter (1960) who suggested the possibility of reversely magnetized crust in the Gulf of Aden. Vine and Matthews (1963) suggested that this process may be more pervasive that previously thought. The Carlsberg Ridge profiles showed positive and negative magnetic anomalies ~20 km in wavelength, and Vine and Matthews suggested that these anomalies could be easily explained by polarity changes in the crustal magnetization rather than petrological or thermal differences. It was this observation that allowed Vine and Matthews to make the daring statement that perhaps 50% of the ocean floor was reversely magnetized. They borrowed on the ideas of Dietz (1961) and Hess (1962) that seafloor spreading was occurring at midocean ridges and made the key observation that ocean crust could record Earth's magnetic field as it formed and that this record would then be preserved as the crust moved away from the spreading center.

The paper initially received little fanfare, comment, or recognition. Most scientists dismissed the paper as being too speculative. What was not immediately appreciated was the prediction of symmetrical anomalies about a midocean ridge crest and the fact that seafloor spreading rates could be obtained from such magnetic records. Lawrence Morley recognized these key ideas but his initial attempts at publishing were declined. One editor reputedly commented that the paper was more suitable as a subject for discussion at a cocktail party rather than a serious scientific idea (Glen, 1982). Morley was an administrator for the Geological Survey of Canada at the time and had little time to vigorously pursue these ideas. Morley was eventually able to publish his article in an obscure journal in Canada (Morley and Larochelle, 1964). None of the significance of the VMM ideas permeated the scientific community at the time of the publications. It was not until Vine and Wilson (1965) looked at the newly published maps of Raff and Mason (1961) (Figure V6) that they recognized the location of the Juan de Fuca midocean ridge spreading center and its position at the center of symmetry

**Figure V5** Cartoon of the Vine-Matthews-Morley (VMM) hypothesis showing the process of seafloor spreading at a midocean ridge and the recording Earth's magnetic field to create the magnetic stripes. Reproduced by permission of Woods Hole Oceanographic Institution (Tivey, 2004).

**Figure V6** Magnetic anomaly "stripe" map of northeast Pacific Ocean, where positive anomalies are shaded black and reverse polarity is shown in white. It was the symmetrical pattern of anomalies about the newly discovered Juan de Fuca Ridge spreading center that began the acceptance of the VMM hypothesis. Figure modified from Raff and Mason (1961). in the northeast Pacific magnetic anomalies that the idea began to gain ground and become seriously debated in academic circles. Vine and Wilson (1965) also matched the magnetic profiles with the newly compiled geomagnetic polarity reversal timescale of Cox *et al.* (1963) based on precisely age dated terrestrial lavas.

A subsequent paper by Vine (1966) eventually put all the ideas together using a long magnetic profile over the East Pacific Rise (Eltanin Leg-19) collected by Walter Pitman of Lamont-Doherty Geological Observatory (Pitman and Heirtzler, 1966) (Figure V7). Vine showed that there was universal symmetry and correlation between magnetic profiles from several midocean ridges and that these could be modeled with the geomagnetic polarity reversal timescale of Cox *et al.* (1963). This essentially sealed the case that magnetic anomalies recorded in ocean crust preserved the history of Earth's magnetic field and that this reversal pattern could be correlated with dated reversals on land.

### Discoveries stemming from VMM hypothesis

Heirtzler and colleagues (1968) took the observations of Vine and Matthews (Glen, 1982) and Vine (1966) to the logical conclusion by producing a geomagnetic polarity timescale (GPTS) based on the marine magnetic anomaly patterns found over the ocean basins and extended the timescale to 80 My. Larson and Pitman (1972) and Larson and Chase (1972) extended the GPTS with studies of Pacific magnetic anomalies and eventually these were reconciled with anomalies of a similar age in the Atlantic (Vogt et al., 1971) into the Mesozoic or M-series anomalies. The present incarnation of the GPTS was published by Cande and Kent (1995) with extension to the Mesozoic anomalies by Channell et al. (1995). The marine magnetic record allows for a detailed history of ocean basin formation and continental drift to be documented in terms of plate tectonics. A detailed history of plate motion and spreading rates has been compiled by various researchers primarily based on the marine magnetic anomaly patterns (DeMets et al., 1990; Minster and Jordan, 1978; Scotese, 1997). A compilation of ship-based mapping of the marine magnetic anomaly patterns has allowed a digital database of seafloor age to be produced (Mueller et al., 1996).

**Figure V7** Eltanin-19 magnetic anomaly profile from Pitman and Heirtzler (1966) shown in the middle with the profile reversed shown at top and a computed model profile shown below. The geomagnetic polarity timescale is shown at the bottom with the normal polarity shown in black and the reverse polarity in white.

The shape of magnetic anomalies (i.e., their phase) contains information about their latitude of formation which can be used to determine the paleolatitude when the crust formed (Acton and Gordon, 1991; Petronotis *et al.*, 1994). Magnetic anomaly patterns have also led to the discovery of new types of seafloor spreading in the form of propagating rifts (Hey, 1977; Hey *et al.*, 1980) and rotating microplates (Courtillot, 1980; Hey, 1985; Schouten *et al.*, 1993).

Marine magnetic surveys using deep-towed sensors and autonomous underwater vehicles are now providing increased resolution in mapping magnetic anomalies, which has allowed for short-wavelength magnetic anomalies (<10 km wavelength) to be recognized (Tivey et al., 1997). It now is apparent that the ocean crust not only records the polarity of Earth's magnetic field, but also provides a record of Earth's field intensity through time (Bowers et al., 2001; Pouliquen et al., 2001). Magnetic profiles over ridge crests and show a good correlation of short-wavelength magnetic anomalies (<10 km wavelength) with terrestrial and sediment core derived paleointensity records (Gee et al., 2000; Guyodo and Valet, 1999). It may, therefore, be possible to use the paleointensity record as a fine-scale signal with which to date the seafloor in addition to the polarity reversal signal. Earth's magnetic field intensity apparently undergoes relatively rapid changes compared to the polarity reversal signal and thus the crustal accretion process will ultimately control the resolution of the recorded signal (Schouten et al., 1999).

# Some outstanding issues

One of the outstanding and unsolved issues of the VMM hypothesis is the source of the magnetic anomaly stripes. What part of the ocean crust is responsible for the generating the magnetic anomalies? Vine and Matthews (1963) made only vague stipulations as to the possible source of the magnetic anomalies. For a crustal unit to be considered as a viable source of the magnetic anomalies, it must satisfy a number of criteria (Harrison, 1981; Johnson, 1979). First, the crust has to be sufficiently magnetic in order to create the anomalies. Second, the magnetization has to be stable and robust enough to withstand millions of years of alteration without degrading. Third, the crust has to cool quickly in order to capture magnetic reversals, which occur at an average frequency of 350000 years. Finally, the geometry of the reversal boundaries must be sufficiently vertical in order to create magnetic anomalies.

Ocean crust can be crudely thought of being composed of three layers (Figure V8). The upper extrusive lava layer consists of lava that has erupted onto the seafloor and thus has cooled rapidly. This layer is highly magnetic although relatively thin, typically <1 km thick. This layer overlies the intrusive dike layer, which are the subsurface volcanic conduits that feed the overlying lava flows. The dikes cool much more slowly than the lavas and are markedly less magnetic because of their intrinsically larger and less magnetic grains and high temperature alteration associated with their emplacement. The dike layer is on the order of 1–2 km thick. The third crustal layer is the plutonic gabbro section, which can be thought of as the cooling magma chamber that is the magmatic source of the overlying dikes and lavas. Gabbros cool relatively slowly and have large crystals and would therefore be intrinsically less magnetic. Nevertheless, some gabbros can be quite magnetic with microscopic grains of pure magnetite found within plagioclase crystals. The gabbros as a layer are quite thick, up to 2-4 km thick and thus while perhaps less magnetic than the extrusive lavas could be of sufficient volume to generate a magnetic anomaly. Finally, underlying the ocean crust is the mantle, which is composed of peridotite and may also be magnetic, especially if it has undergone alteration to serpentinite through the introduction of water. The contribution of these crustal layers and mantle to the overlying magnetic anomalies is difficult to quantify, especially with in situ measurements. Early magnetic surveys determined that the upper extrusive lavas were the primary source layer based on topographic arguments (Atwater and

**Figure V8** Diagram showing a cross-section through ocean crust with the primary crustal units and thicknesses. Superimposed on the lithology is the presumed geometry of a magnetic polarity reversal boundary (thick black line). The boundary dips toward the spreading axis in the extrusive lavas, but is thought to dip away from the axis in the deeper gabbro layer following a cooling isotherm. This portion of the geometry is hypothetical. Drawing based on Macdonald *et al.* (1983) and Kidd (1977).

Mudie, 1973; Talwani *et al.*, 1971). Oceanic crustal drilling provided ambiguous results showing that the magnetization of the extrusive lavas was on average not enough to generate the anomalies and that deeper layers must be contributing as well (Harrison, 1981). While some gabbros have been drilled and are magnetic (Pariso and Johnson, 1993), ocean crustal drilling to date has not penetrated a complete section of crust from extrusive lava to gabbro so that a complete answer to this question remains.

The dip of a polarity boundary can also reveal useful information about the source and contribution of the crustal layers to the magnetic anomaly. A conceptual model of the polarity boundary (Kidd, 1977) suggests that within the extrusive lava layer the progressive overlap of lavas, as they are formed and are rafted away from the spreading center, generates a boundary that dips toward the spreading center. In the dike layer the boundary is likely to be near vertical and relatively sharp, while in the gabbro section a polarity boundary is likely to be a cooling isotherm, which would dip away from the spreading center (Figure V8). A couple of detailed near-bottom magnetic surveys showed the importance of the dip of the polarity boundary within the extrusive layer. Macdonald et al. (1983) used the submersible ALVIN to measure the magnetic polarity of seafloor outcrops of lava at a reversal boundary and found a sharply defined polarity boundary between normal and reversal magnetized lavas. This boundary location was compared to that obtained from a towed near-bottom magnetic survey that is an average of the entire layer contribution. The deeptow boundary was a kilometer closer to the spreading axis than the surficial boundary, indicating that the polarity boundary dips toward the spreading center. A submarine magnetic survey carried out at a

fracture zone wall (Tivey, 1996; Tivey et al., 1998) mapped the magnetic boundaries within the extrusive layer in cross-section and also found that the polarity boundaries dipped toward the spreading center. In this case, the authors also were able to calculate the contribution of the layer to the overlying anomaly and determined that the extrusive lavas produced about 75% of the observed anomaly, indicating that additional contribution was needed from deeper layers such as the dikes and gabbros (Tivey et al., 1998). Only one survey has unambiguously determined the dip of polarity boundaries in the gabbros to date (Allerton and Tivey, 2001). In this survey, seafloor drilling determined the surficial polarity boundary location while a nearbottom survey determined the average boundary position and found that the polarity boundary dips away from the spreading center consistent with the idea of cooling isotherms within the gabbro section (Allerton and Tivey, 2001). The contribution and geometry of the polarity boundaries within the lower ocean crust remain poorly documented and continue to be a topic of research.

# VOLCANO-ELECTROMAGNETIC EFFECTS

Volcano-electromagnetic effects—electromagnetic (EM) signals generated by volcanic activity—derive from a variety of physical processes. These include piezomagnetic effects, electrokinetic effects, fluid vaporization, thermal demagnetization/remagnetization, resistivity changes, thermochemical effects, magnetohydrodynamic effects, and blast-excited traveling ionospheric disturbances (TIDs). Identification of different physical processes and their interdependence is often possible with multiparameter monitoring, now common on volcanoes, since many of these processes occur with different timescales and some are simultaneously identified in other geophysical data (deformation, seismic, gas, ionospheric disturbances, etc.). EM monitoring plays an important part in understanding these processes.

#### **Brief history**

The identification of electromagnetic field disturbances associated with volcanic activity has a relatively young history. Initial measurements in the 1950s on Mihara volcano in Japan focused on monitoring the inclination and declination of the magnetic field while on Kilauea in Hawaii static electric fields (self-potential, SP) were shown to reflect the intrusion activity. More robust magnetic and electric field observations since the 1960s show changes of several tens of nanotesla and more than a hundred mV km<sup>-1</sup> accompany eruptions from volcanoes (Johnston, 1997; Zlotnicki, 1995). Following eruptions, much larger changes result from remagnetization processes.

#### Physical mechanisms involved

Short-term magnetic and electric field changes during volcanic eruptions result primarily from stress changes in volcanic rocks and injection of hydrothermal/magmatic fluids and gasses. Of particular importance for research in eruption prediction are changes generated in the early stages of eruptions by deformation and/or fluid/gas flow. Detection of these fields provides an independent window into the eruption process.

The dominant physical processes in play during the final stages before eruptions are stress-induced modification of magnetization (piezomagnetism), electric currents produced by fluid flow (electrokinetic effects), and thermal demagnetization and remagnetization of volcanic rocks. Other EM signals result from charge generation during fluid vaporization and the creation of ash. Changes in EM response also result from modification of the electrical conductivity structure. During and following eruptions, dramatic EM signals can result from electric charge generation from rock disintegration, lightning within the eruption ash cloud, magnetohydrodynamic effects, thermal remagnetization, stress driven magnetization changes, and coupled TIDs.

It has become increasingly clear, because of the complexity and interdependence of volcanic processes, that simultaneous multiparameter monitoring (e.g., strain, fluid pressure, tilt, ground displacement, electric fields, magnetic fields, gas emissions, etc.) on volcanoes is necessary to identify and separate contributions from the different physical processes. Interpretation of electric and magnetic fields can thus be best done within the constraints placed by other geophysical data and vise versa.

### **Piezomagnetic effects**

The magnetic properties of rocks have been shown under laboratory conditions to depend on the state of applied stress, and theoretical models for this phenomenon have been developed in terms of single domain, pseudosingle domain rotation and multidomain wall translation. The stress sensitivity of magnetization K, defined as the change in magnetization per unit magnetization per unit stress, can be expressed in the form

$$\Delta \mathbf{I} \approx K \boldsymbol{\sigma} \cdot \mathbf{I},\tag{Eq. 1}$$

where  $\Delta \mathbf{I}$  is the change in magnetization in a body with net magnetization  $\mathbf{I}$  due to a deviatoric stress  $\sigma$ , K the stress sensitivity, typically has values of about  $3 \times 10^{-3}$  MPa<sup>-1</sup>. The stress sensitivity of induced and remanent magnetization from theoretical and experimental studies has been combined with stress estimates from dislocation models of fault rupture and elastic pressure loading in active volcanoes to calculate magnetic field changes expected to accompany volcanic activity. These volcanomagnetic models show that moderate scale magnetic anomalies of several nanoteslas (nT) should accompany moderate to large volcanic eruptions for rock magnetizations and stress sensitivities of 1 Amperemeter<sup>-1</sup> (A m<sup>-1</sup>) and  $10^{-3}$  MPa<sup>-1</sup>, respectively (Johnston, 1997).

### **Electrokinetic effects**

Electrokinetic electric and magnetic fields result from fluid flow through layered volcanic rocks as ions anchored to solid material induce equivalent ionic charge of opposite sign in the fluids. The fluid flow itself is thermally and gravitationally driven. Fluid flow in this system transports the ions in the fluid in the direction of flow, producing electric potential of several tens of mV km<sup>-1</sup> and magnetic fields of a few nanoteslas.

The current density  $\mathbf{j}$  and fluid flow rate  $\mathbf{v}$  in porous media are found from the coupled equations

$$\mathbf{j} = -s\nabla E - \frac{\xi\zeta \nabla P}{\eta},\tag{Eq. 2}$$

$$\mathbf{v} = \frac{\phi \xi \zeta \nabla E}{\eta} - \frac{\kappa \nabla P}{\eta}, \qquad (Eq. 3)$$

where *E* is streaming potential, *s* is the electrical conductivity of the fluid,  $\xi$  is the dielectric constant of water,  $\eta$  is fluid viscosity,  $\zeta$  is the zeta potential,  $\phi$  is the porosity,  $\kappa$  is the hydraulic permeability, and *P* is pore pressure. Unfortunately, many of these parameters are poorly known within volcanoes.

Electrokinetic models combined with estimates of electrical conductivity structure within volcanoes have been proposed to explain the curious "W" form of electric potential commonly observed on active volcanoes (Ishido, 2004).

#### Electrical resistivity

Changes in electrical resistivity of volcanic rocks result from changes in strain, temperature, chemistry, and fluid content. While little theoretical research has been done on the details of resistivity changes within volcanoes and methods to separate the different contributions, there is no question that resistivity changes occur and are observed during eruptions (e.g., Yukutake *et al.*, 1990; Zlotnicki *et al.*, 2003). Measurement methods include magnetotellurics (MT) and Schlumberger, Wenner, DC/DC, and dipole/dipole systems.

**Figure V9** Total magnetic field differences between stations SHW, on Mount St. Helens, and remote reference station, PTM, at Portland Oregon, for the several hours preceding and following the 18 May 1980 catastrophic eruption. Time in UTC (from Johnston *et al.*, 1981).

#### Thermal remagnetization and demagnetization

Rocks lose their magnetization when temperatures exceed the Curie Point ( $\approx$ 580°C for magnetite) and become remagnetized again as the temperature drops below this value. At shallow depths in volcanic regions, particularly in recently emplaced extrusions and intrusions, cracking from thermal expansion allows gas and fluid movement to rapidly transport heat. Large local anomalies of hundreds of nanoteslas from remagnetization of the upper few tens of meters can be generated quickly (Dzurisin *et al.*, 1990). At greater depth these effects occur on very long timescales because of the small thermal conductivity of crustal rocks.

#### Observations

#### Volcanomagnetic effects

Unambiguous observations of magnetic field changes have been obtained on many active volcanoes. The best examples clearly related to volcanic activity were obtained during (1) the 18 May 1980, eruption from Mount St. Helens, (2) the 1987 eruption sequence from Piton de la Fournaise, Reunion Island, (3) the 16-22 November 1986, eruption of Izu-Oshima volcano, Japan, (4) the 1980-1990 intrusion episode in Long Valley caldera, California, (5) the 2000 eruption of Miyake-Jima, and (6) the 2003 eruption of Mt. Etna, Italy. Figure V9 shows an example of data from Mount St. Helens during the first stage of the eruption on 18 May 1980. A final magnetic field offset of  $9 \pm 2$  nT was permanent and consistent with pressure decrease within the mountain at the time of the eruption. The net positive signal contrasts with the negative change expected from the removal of magnetic material from the mountain (Johnston, 1997). The oscillatory signals are magneto-gas dynamic effects that couple into the ionosphere and propagate many thousands of kilometers round the world. Figure V10 shows this signal propagating across a 20-station magnetometer array between 1000 and 1500 km from the volcano. These TIDs are commonly generated by explosive volcanic eruptions and earthquakes.

#### Volcanoelectric effects

A number of important new electric field experiments have focused on obtaining measurements on, or near, active volcanoes. In particular, impressive self-potential observations have been made that delineate the changing electric potentials around erupting volcanoes. SP anomalies show apparent correlation with episodes of intrusive activity, active venting, and eruptions. The pertinent physical mechanisms in this case are electrokinetic effects, fluid vaporization and thermoelectric effects. These are all generated by the injection of hot magma, gas, and hydrothermal fluids into the volcano.

The best documented examples are recorded on:

1. Unzen, Japan, during 1990–1992 where large positive self-potential anomalies were identified in the vicinity of the new lava dome. Potentials generated by fluid flow in the hydrothermal system beneath the array is suggested as the most likely cause for this anomaly.

**Figure V10** Magnetic field as a function of time and great circle distance following the 18 May 1980 eruption of Mount St. Helens (from Mueller and Johnston, 1989).

Figure V11 Self-potential profile across Miyake-Jima volcano Japan (from Sasai *et al.*, 1997). The solid line in the upper plot shows the data corrected for elevation effects.

986

- 2. Piton de la Fournaise volcano on Reunion Island, where similar positive self-potential anomalies have been observed above the active magma chamber.
- 3. Oshima Eruption, Japan, in 1986, where continuous measurements of vertical electric fields in the frequency range 0–3 KHz before, during and after a minor eruption from Mt. Mihara show a series of rapidly rising slow-decaying pulses. These effects are attributed to electrokinetic phenomena in the hydrothermal system.
- 4. Miyake-Jima, Japan, in 2000, where resistivity on scales of 0.5–1.5 km show up to a 300% change before eruptions. Immediately before the onset of caldera formation on 8 July 2000, self-potential near the summit reversed sign from positive to as much as –225 mV. Figure V11 shows the SP record from Miyake-Jima about 3 years before the eruption from Sasai *et al.* (1997). Zlotnicki *et al.* (2003) suggest the preeruption observations resulted from electrokinetic effects in a changing hydrothermal system. Remeasurements in 2003 indicate the SP anomalies are much reduced in amplitude and are localized to the edges of the new crater.

# VOYAGES MAKING GEOMAGNETIC MEASUREMENTS

#### Introduction

The magnetic *compass* (q.v.) has been used in Western Europe since the early or middle 12th century (see History of Geomagnetism). By 1187 a form with pivoted needle was described by Alexander Neckam, a monk at St. Albans, in his *De naturis rerum*. At this time, however, and for the next two and a half centuries, it was believed that the compass pointed toward true north. As long as this was the case, there was no reason to make or record any form of magnetic measurement.

Even when (probably sometime about the middle of the 15th century) it was realized that the magnetic needle did not, in general, point true north the situation with regard to making measurements did not change. The discrepancy in pointing was regarded more as a fault of the needle itself or of the method of magnetizing it rather than as being caused by some external agency.

And yet, some glimmering of the truth seems to have begun to dawn. Instrument makers in different parts of Europe began to compensate for the difference between true north and magnetic north (the magnetic variation or declination) by offsetting the needle from the true north point of the compass card by the appropriate angle for the place of manufacture. This worked pretty well near where the instrument had been made but caused problems when used further away. On his second voyage to the New World Christopher Columbus took compasses manufactured in Genoa and in Flanders. Flemish compasses had their needles aligned approximately 11.5° east of true north, this being the approximate value of declination at the time in Flanders; Genoese instruments had theirs aligned with true north since the declination was close to zero in the Mediterranean.

Columbus has been credited with the discovery of magnetic declination. Mitchell (1937) made a very detailed study of the surviving versions of the journals of Columbus's four transatlantic voyages and concluded that (a) Columbus was aware of the existence of declination before setting out on his first voyage, and (b) he may have discovered that it varies with position on the Earth's surface. The journals are so vague and have been edited so extensively that these conclusions are by no means certain. It would perhaps be stretching a point to say that Columbus's journals contain geomagnetic measurements; they do however contain comments and some rather obscure discussion of the behavior of his compasses.

As it became obvious that, for accurate navigation, declination had to be allowed for, so the practice developed of measuring and recording values of declination during a voyage. These measurements were useful at the time to navigators (usually of the same nationality or trading company) following the same or similar routes. Later, such knowledge was systematized by drawing declination contour charts using the measurements as a basis. Later still measurements of declination (and, eventually, other magnetic elements such as inclination and field strength) were collected by those wishing to produce charts and/or mathematical models of the historical geomagnetic field. Among such collections are those of Hansteen (1819), *van Bemmelen (q.v.)* (1899), *Sabine (q.v.)* (1868, 1872, 1875, 1877), Veinberg (1929–1933), and Veinberg and Shibaev (1969).

The most recent, and by far the most comprehensive, data collection is described by Jonkers *et al.* (2003). It incorporates the collections mentioned above as well as others. In this database, the measurements have been derived where possible from the original sources and errors in longitude, which could be very large before the late 18th century, have been corrected. Many of the sources are logbooks and journals (published and unpublished) kept on board ship during the voyages. Others are collections of voyages of a broader nature than the data collections discussed above: collections that summarize or give edited accounts of voyages. Two important examples are Hakluyt (1598–1600) and Purchas (1625). Since the database of Jonkers *et al.* (2003) contains over 177000 measurements, of declination, inclination and field strength, from over 2000 voyages, space does not allow us to discuss every voyage that made magnetic measurements. We shall instead select a few particularly interesting voyages from each century from the 16th to the 20th, both inclusive.

#### Sixteenth century

The earliest voyage from which we have geomagnetic measurements is that of the brothers Jean and Raoul Parmentier. They sailed from Dieppe in March 1529, rounded the Cape of Good Hope and arrived in Sumatra in November, having made a brief stop in Madagascar. Soon after their arrival in Sumatra the brothers and many of their crew perished, possibly murdered, and the ships returned, with great difficulty, to France. During the outward voyage declination measurements were made in the South Atlantic and six of these were collected by van Bemmelen (1899), the earliest surviving measurements made during a sea voyage.

The earliest voyage to have scientific work as one of its planned objectives left Lisbon in the spring of 1538 bound for Goa in India. In command of one of the eleven ships that made up the fleet was Dom João de Castro who had been given the task of testing a new form of magnetic compass and its associated method of observation. Harradon (1943) describes the instrument and Harradon (1944) discusses de Castro's declination measurements, 38 made on the outward voyage and five on the return voyage. On the outward voyage de Castro noted that iron objects such as cannon in the vicinity of his measuring position adversely affected some of his measurements. Later, he was the first person to investigate the local attraction of magnetic anomaly). He was also able to cast severe doubt on the idea that different lodestones, used in the magnetization of compass needles, could result in different values of declination being measured.

The Portuguese had pioneered and, by the early 16th century, controlled the route to the Far East via the Cape of Good Hope; the Spaniards from their settlements in Central and South America controlled access across the Pacific. The seafarers of northern Europe tried to find routes around the northern fringes of North America and Eurasia, expending vast amounts of energy, and many lives, in searching for the North-West and North-East Passages. An early voyage to the north-east yielded six declination measurements. This voyage, in the years 1556 and 1557 was under the command of Stephen Borough, later Chief Pilot under Queen Elizabeth I. He had sailed with Richard Chancellor in 1553 as part of the earliest English attempt to find the North-East Passage, an attempt that failed to find the Passage but did pioneer a new route to Moscow via the White Sea.

One of the earliest voyages to search for a North-West Passage was that of Martin Frobisher in 1576. He entered Frobisher Bay and followed it inland sufficiently far to convince himself (wrongly) that this was the Passage. Because of the lateness of the season he returned home, taking with him some samples of rock that he hoped might contain gold. This voyage yielded three declination measurements. On his next two voyages, in 1577 and 1578, the collection of rocks took precedence over exploration and magnetic measurements. The ore, alas, proved to be pyrites and did not contain any gold.

The early circumnavigations led by Magellan and Drake have not, apparently, provided any magnetic measurements, but that of Thomas Cavendish (or Candish) between 1586 and 1588 did (five declination measurements). This voyage was planned as a repeat of Drake's and, like Drake's, had an element of piracy about it.

Another English voyage that furnished declination measurements was essentially a privateering expedition in 1589 commanded by the third Earl of Cumberland with the intention of capturing any Spanish, Portuguese, or French ships it might meet. The fleet of seven ships ended up in the Azores and returned with more prizes than they could really manage. Edward Wright, a mathematician and expert on navigation, wrote an account of the voyage in which he included the 30 measurements that he managed to make, presumably in the intervals between the various fights that the ships were engaged in. Wright was the first person to develop the mathematical basis of Mercator's projection. Mercator had devised this map projection, of great use in navigation because a course at a constant bearing becomes a straight line on the chart, in an empirical way in about 1569.

The Dutch also tried to find the North-East Passage. Willem Barentsz made three voyages, in 1594, 1595, and 1596. On the last, in company with Jacob van Heemskerck, he discovered Bjørnøya (Bear Island) and Svalbard. He and his crew wintered on Novaya Zemlya but Barentsz died during the voyage home. The Dutch also began to challenge the Portuguese control of the East India trade via the direct route. A Dutch fleet under the command of Cornelis de Houtman sailed in 1595 and returned, after trading successfully, in 1597. This was followed in 1598 by a second Dutch fleet under Jacob van Neck. Magnetic declination measurements were made on these two Dutch East India voyages and on the third voyage of Barentsz. They, along with the measurements made by Borough, Frobisher, Cavendish and Wright, are included in the collections of van Bemmelen (1899) and Jonkers *et al.* (2003).

#### Seventeenth century

The English had broken the Portuguese monopoly in the East Indies a little earlier than the Dutch. Sir James Lancaster sailed in 1591 and returned laden with booty in 1594. As a result of this voyage the English East India Company was formed in 1600 and Lancaster was given command of the first Company fleet that sailed in 1601 and returned in 1603. Declination measurements were presumably made on these voyages but only one value has survived, from the 1601 to 1603 voyage. A potentially beneficial discovery was made on the latter voyage. Lancaster took with him bottles of lemon juice and administered three teaspoonfuls every morning to all his crew. His ship remained relatively free of scurvy compared with the other vessels in the fleet. The antiscorbutic effect of lemon juice, due to its vitamin C content, was, however, largely forgotten until the time of James Cook almost 200 years later.

The search continued for the North-West Passage. Two English expeditions visited Hudson Bay at about the same time, believing (wrongly) that there was an exit to the west. Luke Foxe (or Fox) sailed from London at the end of April 1631 and made a thorough exploration of the shores of Hudson Bay, the islands to the north and of Foxe Basin to the south of Baffin Island. He returned safely at the beginning of November without the loss of a single member of his crew. Thomas James sailed from Bristol a month later than Foxe, met and dined with him off the southern shore of Hudson Bay at the end of August and entered and explored James Bay at its southeast extremity. There, on the mainland near Charlton Island, James and his crew were forced to spend a very difficult winter, but they managed to repair their damaged ship and returned to Bristol in October 1632. The voyages of Foxe and of James both provided declination measurements in a part of the world where few, if any, had previously been obtained.

The East India Companies of England and Holland sent out fleets annually. These have provided large numbers of declination measurements, helped by the fact that the English East India Company ordered each captain, master, mate, and purser on their vessels to submit a journal at the end of each voyage. Two Dutch voyages that provided declination measurements were those of Willem Corneliszoon Schouten and Jakob Le Maire between 1615 and 1616, the first European voyage to round Cape Horn, and of Abel Janszoon Tasman between 1642 and 1643, the first European to visit Tasmania and New Zealand.

The discovery by *Henry Gellibrand* (q.v.) in 1634 that declination at a particular place varied with time (a phenomenon known as secular variation) made the collection of geomagnetic measurements even more important. It was now crucial to record the date of observation, something that had not always been done before.

It may not have escaped the attentive reader that all the magnetic observations mentioned so far have been of declination, despite the fact that *Robert Norman* (q.v.) first measured the angle of inclination or dip (the angle a freely suspended magnetic needle makes with the horizontal plane) in 1576. One reason is that inclination is more difficult to measure accurately than declination, and this is particularly so on board a moving ship. The earliest surviving inclination measurements made at sea are seven values measured by Benjamin Harry in the Atlantic and Indian Oceans during a voyage to the East Indies in 1680. This was followed by a more extensive set of 34 measurements made by James Cunningham, a Scotsman more famous as a botanist, on a voyage to China for the English East India Company in 1700.

We cannot leave the 17th century without mentioning the voyages of Edmond Halley (q.v.). These were the first voyages planned with scientific endeavors as the main part of their program. With the backing of the Royal Society Halley persuaded the British Admiralty to build a ship in which he could survey the Atlantic Ocean making measurements of declination and, as a further aid to navigation, of the longitude of his ports of call. The ship was named the Paramore, Halley was commissioned as a Captain in the Royal Navy and was given command of the vessel. The first voyage, from October 1698 to July 1699, was cut short because of trouble with Halley's officers. A second voyage was therefore ordered. This lasted from September 1699 to September 1700 and surveyed the Atlantic as far south as latitude 52°41'S. During the two Atlantic voyages Halley made 187 measurements of declination (though, strangely, none of inclination) and used them as the basis of the first published contour chart, for the Atlantic Ocean, published in 1701. In the summer of this year Halley made a third vovage in the *Paramore*, sailing around and across the English Channel studying the tides. He also, when opportunity arose, measured declination, 13 values in all. The logbooks of Halley's three voyages have been edited by Thrower (1980).

#### **Eighteenth century**

Although by no means commonplace, voyages of circumnavigation became more numerous during the 18th century. Among those that provided geomagnetic measurements were those of Woodes Rogers between 1708 and 1711; Jacob Roggeveen (1721–1722); George Anson (1740–1744); John Byron, grandfather of the poet, (1764–1766); Samuel Wallis (1766–1768) and Philip Carteret (1766–1769); Louis de Bougainville (1766–1769); the three voyages of James Cook undertaken between 1768 and 1780; Jean-François de la Pérouse (1785–1788); Antoine d'Entrecasteaux (1791–1794); and George Vancouver (1791–1795).

The voyages of Rogers and Anson were repetitions of Drake's circumnavigation in that one of their primary purposes was the harrying of Spanish possessions in South and Central America and the disruption of their sea-borne trade. Rogers' voyage was financed by a group of Bristol merchants; Anson's was an official naval project. Both were successful financially and politically. Rogers managed, in large measure, to avoid the scourge of scurvy but the disease almost wrecked Anson's ill-equipped expedition.

The voyages of Roggeveen, Byron, Wallis and Carteret, and Bougainville all had as one of their main objectives a search for Terra Australis Incognita, the great southern continent postulated by armchair geographers. All failed to find the continent but instead added to the list of Pacific islands known to Europeans.

Cook's first and second voyages also searched for the southern continent and their failure to find it after meticulous searching proved that, if it existed, it must lie entirely south of the Antarctic Circle. During the first voyage observations of a transit of the planet Venus across the Sun's disc were made from Tahiti. Cook's third voyage included a search for the western end of the North-West Passage north of the Bering Strait. All three voyages were noted for the accuracy of their positional data (the second and third carried chronometers made by Kendall and Arnold). As well as declination measurements inclination data were also collected.

The voyage of la Pérouse ended in tragedy. He left New South Wales in February 1788 and was never seen alive again. The relief expedition of d'Entrecasteaux helped to solve the mystery of the disappearance and also made some of the earliest magnetic intensity measurements, though these were in relative rather than absolute units. Beaglehole (1934) summarizes the voyages of discovery in the Pacific from Magellan's circumnavigation to the end of the 18th century.

#### Nineteenth century

Polar exploration flourished during the 19th century, spurred on by commercial interests such as the whale fishery and seal hunting. The search for the North-West Passage also continued.

Naval voyages led by John Ross in 1818 and by William Edward Parry in 1819–1820, 1821–1823, 1824–1825, and 1827 (the latter an attempt to reach the North Pole across the ice from Svalbard) all provided geomagnetic observations, at sea and on land, inclination as well as declination. None of them achieved their major objective but greatly increased geographical knowledge of the Arctic. From magnetic observations made at Parry's winter quarters during his first three expeditions it became obvious that the North Magnetic Dip-pole (where the dip attains its maximum value of 90°) was to the south of the archipelago of islands that lie to the north of the Canadian mainland.

John Ross, having failed to persuade the Admiralty to give him command of another attempt to find the North-West Passage, found a private sponsor: the gin distiller Felix Booth. Accompanied, as second-in-command, by his nephew James Clark Ross, who had been on the elder Ross's previous expedition and on all four of Parry's, Ross established winter quarters on a peninsula that he named, in honor of his sponsor, Boothia Felix. The expedition ship, a paddle steamer named *Victory*, was beset by ice and the explorers had to spend four winters on or near Boothia Felix. During June 1831 the younger Ross led a sledging party to the North Dip-pole, which he claimed for King William IV. Other, more useful, magnetic measurements were also made.

Antarctic waters also began to attract attention, largely because they were rich in sea mammals such as seals and whales. Voyages were also sent out with more scientific aims. The Russian expedition under Baron von Bellingshausen, during his circumnavigation of Antarctica between 1819 and 1821, was the first to sight the continent. He also made geomagnetic measurements.

During the years 1837–1843 three expeditions were exploring the Antarctic: a French Expedition under Captain Dumont d'Urville between 1837 and 1840, the US Exploring Expedition under Lieutenant Charles Wilkes (1838–1842) and the British National Expedition to Antarctic Seas under James Clark Ross (1839–1843). D'Urville discovered Adélie Land and Wilkes also charted the coast of the continent in this same region. Both made geomagnetic observations but neither expedition landed on Antarctica.

Ross's expedition was largely devoted to geomagnetic studies. Three permanent and three temporary magnetic observatories were established during the voyage. Ross's personal objective was to be the first person to set foot on both North and South Magnetic Dippoles. He was thwarted in this ambition because the magnetic measurements made at sea clearly indicated that the South Dip-pole lay well inland, most probably beyond the mountains of Victoria Land. He did, however, discover the Ice Shelf that now bears his name.

Another unsuccessful attempt to find the North-West Passage was led by Sir John Franklin. It sailed in 1845 but was beset in the ice off King William Island and every member of the expedition perished. Although no results of geomagnetic measurements survived, the expedition is important to our story because of the large number of expeditions that were sent out over the next three decades to try to find news or relics of Franklin; many of these search expeditions did make geomagnetic measurements in regions where such data were scarce or nonexistent.

Two important oceanographic expeditions included geomagnetic measurements in their observational programs. Both the British *Challenger* Expedition between 1872 and 1876 and the German Expedition on board SMS *Gazelle* (1874–1876) made hundreds of measurements of declination, inclination and total intensity during their circumnavigations. And now, thanks to Gauss's pioneering work (Gauss, 1833), the intensity measurements were in absolute units (see Gauss' determination of absolute intensity).

#### **Twentieth century**

The North-West Passage was finally discovered and traversed by Roald Amundsen between 1903 and 1907. During the winters of 1903/1904 and 1904/1905 a magnetic observatory was operated at Gjöahavn on King William Island. The measurements made there served to fix the position of the North Magnetic Dip-pole for the first time since Ross's visit in 1831. A second observatory was established at King Point near the Canada-Alaska border during the winter of 1905/1906.

Interest in exploring the Antarctic continent began to increase during the final years of the 19th century, but the early years of the 20th century saw a veritable assault on the South Pole in particular and Antarctica in general. Over a dozen major expeditions visited the southern polar regions between 1900 and 1918 and the majority made geomagnetic measurements during the voyage south or on Antarctica or both. Somewhat surprisingly Amundsen's 1910–1912 expedition, which was the first to attain the South Pole, was not one of these. On Shackelton's British Antarctic Expedition of 1907–1909, David, Mawson, and Mackay became the first to visit the South Magnetic Dip-pole. Mawson retained his interest in the dip-pole and during his Australasian Antarctic Expedition of 1911–1914 detailed geomagnetic measurements by Webb enabled a revised position to be calculated, although adverse conditions prevented the party from reaching it.

Of much greater practical importance was the global magnetic survey undertaken by the Carnegie Institution of Washington under the leadership of *Louis A. Bauer* (q.v.) from 1905 onward. The oceanic part of this was begun using a converted brigantine, the *Galilee*, and was continued by the specially built nonmagnetic ship *Carnegie* (q.v.) from 1909 until her destruction by fire in 1929.

Plans by the UK Government to build a nonmagnetic ship, the RRS *Research*, to carry on the work of the *Carnegie* were delayed by World War II and were eventually abandoned after the War. Geomagnetic measurements of the complete field vector were continued, however, by the Russian nonmagnetic ship *Zarya* in a series of cruises beginning in 1956.

The development of the proton precession magnetometer revolutionized marine magnetic surveying. This type of magnetometer does not need to be accurately oriented with respect to the geomagnetic field and can be towed in a container behind a ship so that it is not affected by the intrinsic magnetic field of the ship. A disadvantage is that it is only able to measure the total intensity of the geomagnetic field rather than the complete vector. Proton magnetometer surveys have therefore been mainly used for mineral exploration and for studying magnetic anomalies associated with plate tectonics. Measurements of total intensity can be used to supplement vector measurements in producing charts and models of the main geomagnetic field and they have proved to be a valuable source of data, particularly over large areas of deep ocean were few other measurements exist.

So sparse have such measurements been in the past that routine observations made to check the reading of the magnetic compass on board merchant vessels have also been used in the production of global magnetic charts and models. These measurements, although of lower accuracy than those made on board specially designed magnetic survey vessels, have been invaluable in ensuring that the charts and models were of acceptable accuracy in remote ocean regions such as the Southern Ocean and the central Pacific Ocean.

#### Discussion

The Portuguese and Spanish were the first to venture across the major oceans in search of new trading opportunities and the conquest of newly discovered territories. It is therefore strange that very few Iberian voyages feature in the datasets of magnetic measurements that have been collected. van Bemmelen (1899) pointed out the potential riches that he thought should be available in the Spanish and Portuguese archives but was not able to confirm that this was the case.

Jonkers and his colleagues (2003) have made comprehensive searches in seven of the main Spanish archives. Apart from material relating to Malaspina's expedition in the Atlantic and Pacific between 1789 and 1794, which supplemented observations already published, they found disappointingly few logbooks. In particular, they had hoped to find a manuscript legacy of the Manila galleons that, over many decades, sailed annually across the Pacific between the Philippines and South America. No logbooks from these voyages were found in the Spanish archives. Jonkers *et al.* (2003) speculate that manuscript sources containing magnetic measurements may exist in former Spanish colonies in South America or the Philippines.

In their discussion of possible future work on collecting magnetic measurements made on board ship Jonkers *et al.* (2003) mention the Portuguese archives as one of the most promising of hitherto untapped sources "even though much Portuguese material is known to be no longer extant." The remarks made above concerning possible archives in former overseas possessions also apply here. If found such sources may provide valuable early measurements in the Indian Ocean.

Mention has already been made of the improved accuracy of the measurements made by Cook on his three voyages in the third quarter of the 18th century compared with those made on other contemporaneous voyages. The biggest improvement was in the determination of position at sea, particularly that of longitude and this was primarily due to the employment of some of the first marine chronometers. Cook's use of these was experimental, part of the tests that proved the worth of this method for finding the longitude at sea, and it was some time before their use became general. The Hydrographic Office of the British Admiralty was founded in 1795 and, together with the Royal Observatory at Greenwich, began to test and issue marine chronometers. By the end of John Pond's time as Astronomer Royal in the 1830s complaints were being made that too much of his time and that of his Observatory's staff was being taken up with chronometer testing, to the detriment of the astronomical work. By the middle of the 19th century most major navies and merchant marines were using chronometers and the accuracy of positional data approached modern values.

#### Conclusion

Since the earliest European voyages of exploration the importance of the magnetic compass as an aid to navigation has been realized along with the necessity to collect information about the behavior of the geomagnetic field that controls it. Beginning with measurements of the most obvious geomagnetic element, declination, observations of the other geomagnetic elements have gradually been added. Because about 70% of the Earth's surface is covered by oceans, measurements made at sea are of the greatest importance in making mathematical models and charts of the global geomagnetic field. This article has summarized the history of such measurements by highlighting a selection (no doubt very subjective) of the more important and interesting voyages that have made geomagnetic measurements since the beginning of the 16th century.

#### WATKINS, NORMAN DAVID (1934–1977)

Norman Watkins (Figure W1) was an innovative and dynamic paleomagnetist who in just a few years attained international recognition and high praise for his work. As a student in geophysics and paleomagnetism during the period when the polarity timescale was first being developed he experienced first hand the plate tectonics revolution in the earth sciences. He was among the first to develop a modern paleomagnetism laboratory, initially with spinner magnetometers developed during the middle-late 1960s, and then adding one of the first cryogenic magnetometers to his laboratory in 1972. In his short lifetime he published over 100 refereed publications (and hundreds of other works), received six academic degrees, rose to the rank of professor of oceanography at the Graduate School of Oceanography, University of Rhode Island, was continuously funded by NSF from 1963 until his death in 1977 (grant funding starting before he received his Ph.D.), and served as the division director of the Earth Science Division of the National Science Foundation.

Figure W1 Norman Watkins, on board the USNS Eltanin in 1970.

Born in Sunbury-on-Thames in Surrey, England, in 1934, of Welsh parents, Watkins later became a naturalized citizen of the United States. His first college degrees were from the University of London where he received a B.Sc. in mathematics, geology, and geography in 1956, and a second B.Sc. in mathematics, physics, and "geology special (Part 1 only)" in 1957. He then attended the University of Birmingham, England, where he received an M.Sc. in applied geophysics in 1958. Watkins moved to Alberta, Canada, in 1958, where he enrolled at the University of Alberta, eventually receiving another M.Sc., this time in geology with a thesis titled Studies in Paleomagnetism. During his time in Alberta, he took a job with Shell Oil Company of Canada where he worked in various areas of geophysics (gravity, magnetic, and seismic interpretation) as well as geological mapping. In 1961, he moved to California where he accepted a position at Menlo College in Menlo Park, California, as a lecturer in physics. He served in that position until 1964 when he was named the acting dean of science at the college. He enrolled as a graduate student at Stanford University in 1962, serving there as a research assistant. At Stanford he worked with Allan Cox and Richard Doell in paleomagnetism, Richard Doell nominally being his advisor. In 1963, he received an appointment upgrade at Stanford to acting assistant professor in the Department of Geophysics, and in 1964, he became a research associate there. Because of very strong personal conflicts with Doell, Watkins moved his dissertation research problem back to the University of London where he defended and was granted his Ph.D. in geophysics in 1964. The title of his dissertation was Paleomagnetism of the Miocene Lavas of Southeastern Oregon. After receiving his Ph.D. he took a position as visiting senior fellow in the Chadwick Physics Laboratory at the University of Liverpool in England. In 1965, he returned to the United States as an associate professor in the Department of Geology at Florida State University in Tallahassee, Florida, where he received tenure in 1968. In 1970, he accepted the position of professor of oceanography at the Graduate School of Oceanography, University of Rhode Island (URI). In 1972, he was granted tenure there. Later still, he received a doctor of science degree from the University of Birmingham in recognition for his contributions to geophysics. He took a leave of absence from URI in 1976 to serve as the director of the Earth Science Division of the National Science Foundation, but after 8 months, illness forced his resignation from NSF and a return to URI.

During his career, Watkins mainly taught courses in geophysics and paleomagnetism. While he was at Florida State University he supervised six students who received their MS degrees and one Ph.D. student who finished after Watkins moved to Rhode Island. While at URI he supervised three Ph.D. students, one who graduated after his death, and five MS students. He also served as chief scientist on a cruise of the USNS Eltanin to the Indian Ocean and sent students out on cruises of the RV Trident (URI), RV Chain (Woods Hole Oceanographic Institution of MIT), and other ships as his representatives during various cruises. The primary aim of this work was to collect piston cores of deep-sea sediment, to dredge for marine basalts, and for other related oceanographic studies. Sediment samples from piston cores were returned to his laboratory for paleomagnetic measurement. These samples were also shared with James Kennett (a foraminifera specialist) and his students for biostratigraphic analysis. His relationship with Kennett started when they were professors at Florida State University. Both men moved to the Graduate School of Oceanography at URI in 1970, as a "package deal."

Watkins' contributions to research in paleomagnetism began with a paper published in *Nature* in 1961, where he was a co-author with Ernest Deutsch. This work examined the direction of the geomagnetic field recorded in Triassic rocks in Siberia, and was published at that exciting time in paleomagnetism during the early development of the Plio-Pleistocene polarity timescale. Another paper in *Nature* in 1963 examined the behavior of the Miocene geomagnetic field recorded in Columbia Plateau basalts and led to his important paper on the polarity transition identified at Steens Mountain. He was very concerned with the effects of oxidation on the magnetic properties of rocks. This concern was reflected in *Nature, Science*, and other journals between 1965 and 1968.

In 1968, he published his first paper on the magnetic properties of deep-sea sediments recovered from piston cores. While he and his students continued to work actively on the magnetic properties of basaltic materials, this shift to marine sediments reflected a new direction in the overall field of paleomagnetism. It was facilitated by the availability at about this time of easy-to-use and reliable spinner magnet-ometers and adequate instruments that allowed rapid demagnetization of samples. While measurements on deep-sea sediments were important, the magnetometers were still only marginally sensitive enough for many samples. It was not until the availability of cryogenic magnetometers that many of these materials could be adequately studied. Therefore, he continued to concentrate primarily on basaltic rocks and polarity studies.

Much of his work in the 1970s involved measurements of basaltic rocks from oceanic islands and characterization of secular variation and polarity of Earth's magnetic field during the last 10-15 Ma. Watkins and his students collected samples from islands all over the world including Reunion Island, Kerguelen, and Amsterdam Island in the Indian Ocean, and the Azores Islands in the Atlantic. Much of this work was concentrated in Iceland with Leo Kristjansson (an Icelandic physicist and paleomagnetist) as well as with the late wellrecognized physical volcanologist, professor George P. L. Walker, where they had revolutionized the understanding of the growth of volcanoes in Iceland by means of volcanic and magnetic stratigraphy, and with Ian McDougal (a good friend and potassium-argon dater from Australia), where his group collected thousands of cores from stratigraphic sequences of lavas all over the island. Many of these samples and his notes are archived at the Graduate School of Oceanography, URI.

Watkins was a very aggressive scientist who enjoyed stimulating debate. For example, he would always sit in the front row during presentations at national and international meetings and ask one question of every speaker that was designed to elicit discussion. He would do this while casually resting his arm on the chair next to him and turning sideways toward the audience, as if to get their opinion. His students observed that at these meetings he would usually be dressed in a three-piece suit. That is, except when it was time for him to give a presentation. Then he would appear in his field "traveling" cloths, a light blue dungaree shirt, tan pants, and a white ship-captain's hat with a black bill. Minutes later he would be seen again wearing his threepiece suit. He was a very big man. One of his students once commented that when sitting at the back of a classroom on the first day of geophysics class he noticed there was something strange about the appearance of Prof. Watkins. The student suddenly realized that Watkins was standing with his left forearm on the top of the blackboard, bending down so that he could write on the board. "This guy is really big!" commented the student to a classmate. Watkins enjoyed impressing his students at Florida State University with the medal he earned throwing the Javelin for Wales at the 15th Commonwealth Games.

Besides being big, Watkins was also powerful. Basaltic paleomagnetic samples were collected by his group using chain saws that he had converted to rock drills. This was before such conversions were commercially available, and these drills were heavy. To impress his students and to demonstrate how the drilling method worked, he would drill several, perfectly straight, six-inch long cores, upward at a  $45^{\circ}$  angle using only one hand! On his best, in a single day he drilled and collected samples from all 55 lavas contained in a very steep, 1250 m thick stratigraphic sequence. His students were never able to keep up with him in the field.

When working in the field he was a very careful scientist and was always well prepared. He stressed back-up systems and redundant parts so that there would be no delays that might limit the number of samples returned to the laboratory. Early in his work he used a Sun compass to correct problems associated with local or anomalous magnetic field directions. To protect the collection and avoid problems he demanded that every evening the notes be recopied into a separate notebook, thus producing a redundant copy. He insisted that all samples be checked for marking errors or other problems. As a result there were very few ambiguities associated with these field collections.

In summary, Norman D. Watkins made important contributions to paleomagnetism during the early years of that developing field and helped to establish the techniques we use today. He actively stimulated thought and interaction among all who really knew him, and is missed by all of them. During his lifetime, Watkins and his wife Patricia had two sons, the oldest, Paul Watkins, currently living in the United States, became a successful teacher and author of many well-received novels. The youngest, Clive Watkins, now living in Luxembourg, received an MBA and became a successful businessman in Europe.

Brooks B. Ellwood

# WESTWARD DRIFT

The time variation (secular variation) of the magnetic field was first recognized in the late 17th century. In attempting to provide a theory to explain it, Halley (1693) (qv) noticed that a large part of the secular variation could be explained in terms of a "westward drift" of the field. If maps of declination are produced over the Earth's surface at different epochs, then there is a clear westward movement of field patterns, particularly lines of zero declination (so-called agonic lines) (e.g., Langel, 1987). Using his map of Atlantic secular variation, Halley estimated that a full revolution of the field would take about 700 years, giving a rotation rate of just over 0.5° per year. To explain the drift, he posited a model of the interior of the Earth consisting of concentric shells of magnetic material rotating at varying rates with respect to the Earth's surface. In many ways, his theory has remarkable similarities to our current understanding. The Earth does indeed consist of different layers, and it is one of these layers (the fluid core) which gives rise to the secular variation, of which a large part can indeed be represented by westward motions at the surface of the core.

As understanding of the Earth's interior improved, it became clear that Halley's theory was inadequate both observationally and 994

theoretically, not least because the thermal state of the Earth does not allow permanent magnetization at depth. With the advent of dynamo theory, and the understanding that the magnetic field originates from fluid motions in the molten iron core, the first "modern" theory of westward drift was proposed by Bullard et al. (1950). They argued that cooling of the Earth would lead to a pattern of large-scale convection in the core. As a parcel of fluid rose, it would move further from the Earth's rotation axis. Therefore, to conserve angular momentum, the angular velocity of the parcel would reduce. Similarly, a sinking fluid parcel would reduce its moment arm, and so need to increase its angular velocity. Bullard et al. suggested that this would lead to a net eastward flow with respect to the solid Earth at the base of the core near the inner core boundary, and westward flow at the core surface, which if advection by flow dominates diffusion (the frozen-flux approximation (qv)) would then carry the magnetic field in a westerly direction, giving rise to westward drift. While the basic physical ideas of this theory are very attractive, modeling of rotating convection has shown that the interaction of convection and rotation is much more complicated, and this pleasingly simple explanation for the drift does not work (although, interestingly, an eastward inner core rotation (qv) has more recently been suggested both from numerical dynamo models (qv) and seismological observations).

An alternative to Bullard's mechanism was provided by Hide (1966). While Bullard et al. had argued for an origin of westward drift in large scale flow, Hide instead suggested that it could arise as a result of wave motion. Magnetic waves called Alfvén waves (qv) were known to be supported in a fluid penetrated by a magnetic field. Adding the effect of rotation, additional families of diffusionless magnetohydrodynamic waves (qv) were shown to exist. Some have periods of order days (similar to inertial waves), but others, named magnetic Rossby waves or planetary waves, have much longer periods, for reasonable estimates of the magnetic field strength perhaps 300 years. Initial analysis based on propagation in a thin shell (similar to analysis for the atmosphere) unfortunately suggested that these waves would propagate eastward, not westward. Hide provided an intuitive argument, later confirmed by more detailed analysis, as to why in the core (a thick shell) such waves would propagate westward instead. Further examination has suggested that westward motion will dominate when the toroidal magnetic field is stronger than the poloidal magnetic field, as is thought to be the case within the core (Hide and Roberts, 1979).

However, such simple models, while attractive, can in no way explain the full complexity of secular variation. Estimates of westward drift obtained show considerable variation depending on just how it is defined-should it involve a fit to the whole field, just the equatorial dipole, the secular variation, or some combination? The value of Bullard et al. (1950) of 0.2° per year has entered the geomagnetism consciousness as a standard, but estimates have varied from 0.08° eastward per year, up to 0.733° westward (for a summary, see Langel 1987). What this range of values demonstrates is that the picture of westward drift is much too simplistic. Even in the 18th century, it was realized some features of the field drift northwards rather than westward, and once Gauss had developed a method for measuring magnetic intensity, the observed decay of the dipole could clearly not be explained by drift alone. Further, westward drift is much more clearly visible in Europe and North America than in Asia and the Pacific hemisphere. Yukutake and Tachinaka (1969) argued that other features in the field did not move at all, and proposed a division of the field into drifting and standing components. Yukutake (1969) further suggested that the equatorial dipole field could be separated into two components, drifting in opposite directions; such a process is reminiscent of wave motion, consistent with Hide's ideas. Wave theory further allows drift rate to vary with location, as the wave velocity is a function of the background field strength, which will vary over the core's surface.

However, this confused picture was largely swept away by the advent of the *Magsat satellite* (qv), and the impetus it gave to a program of high-resolution mapping of the field at the core-mantle boundary. If we want to understand the secular variation, we must really examine it at its source; upward continuation filters the field, complicating considerably the interpretation of the field at the Earth's surface. Field models constructed for different epochs, culminating in the time-dependent main field model (qv) "ufm" of Bloxham and Jackson (1992), allowed detailed features of field evolution to be examined at source. Their model from 1690 to 1990 shows apparent upwelling of field under Africa, followed by a westward motion under the Atlantic. However, such features are not observed under the Pacific, leading to the weak westward drift observed in the surface field in the Pacific hemisphere. Other features, particularly two pairs of high-latitude flux patches of opposite signs in the northern and southern hemisphere, are observed to remain stationary over historical time, contributing to Yukatake's standing field. Models of surface core motion (qv) have been generated, using the magnetic field as a tracer of fluid motion. While such models uniformly demonstrate a westward flow under the Atlantic, elsewhere the pattern is more complex, and many suggest eastward flow under the Pacific. An alternative view of drift has also recently been presented: instead of the drift of field or secular variation, the underlying flow pattern is considered steady but drifting either westward or eastward (Holme and Whaler, 2001). Such a model can explain the secular variation well with either a westward or eastward drift, again suggesting that the problem may be best posed in terms of wave motion.

In conclusion, the concept of westward drift has largely been superceded by more complex models of the secular variation, with maps of the field evolution at the core-mantle boundary allowing the secular variation to be examined at source. However, the simplicity of westward drift means that it is still used for interpretation of archeo- and paleomagnetic data. Because insufficient data have been available to enable calculation of high-resolution field models as has been done for historical time, we are limited to considering the change of the field at the Earth's surface. Therefore, interpreting changes in the field in terms of drift, and relating such drift to our understanding of the historical field, is still extremely valuable. Furthermore, the underlying controversy as to whether secular variation is dominantly generated by large scale core convection (as proposed by Bullard *et al.*) or wave motion at the surface of the core (as proposed by Hide) remains alive to this day.
